ganglion to unite with the sensory root just beyond the foramen ovale, where the nerve passes between the tensor veli palatini (medial) and the lateral pterygoid. Just beyond this junction a meningeal branch and the nerve to the medial pterygoid leave the nerve's medial side; it then divides into a small anterior and large posterior trunk. As it descends from the foramen ovale, the nerve is about 4 cm from the surface and a little anterior to the neck of the mandible.

The meningeal branch (*nervus spinosus*) re-enters the cranium through the foramen spinosum with the middle meningeal artery, dividing into anterior and posterior branches which accompany the main divisions of the artery and supply the dura mater in the middle cranial fossa and to a lesser extent in the anterior fossa and calvarium; the posterior also supplies the mucous lining of the mastoid air cells while the anterior communicates with the meningeal branch of the maxillary nerve. The nervus spinosus also contains sympathetic postganglionic fibres from the middle meningeal plexus.

The nerve to the medial pterygoid is a slender ramus entering the deep aspect of its muscle, supplying one or two filaments which pass *through* the otic ganglion (p. 1113) without interruption to supply the tensor tympani and tensor veli palatini (7.223).

The Anterior Trunk

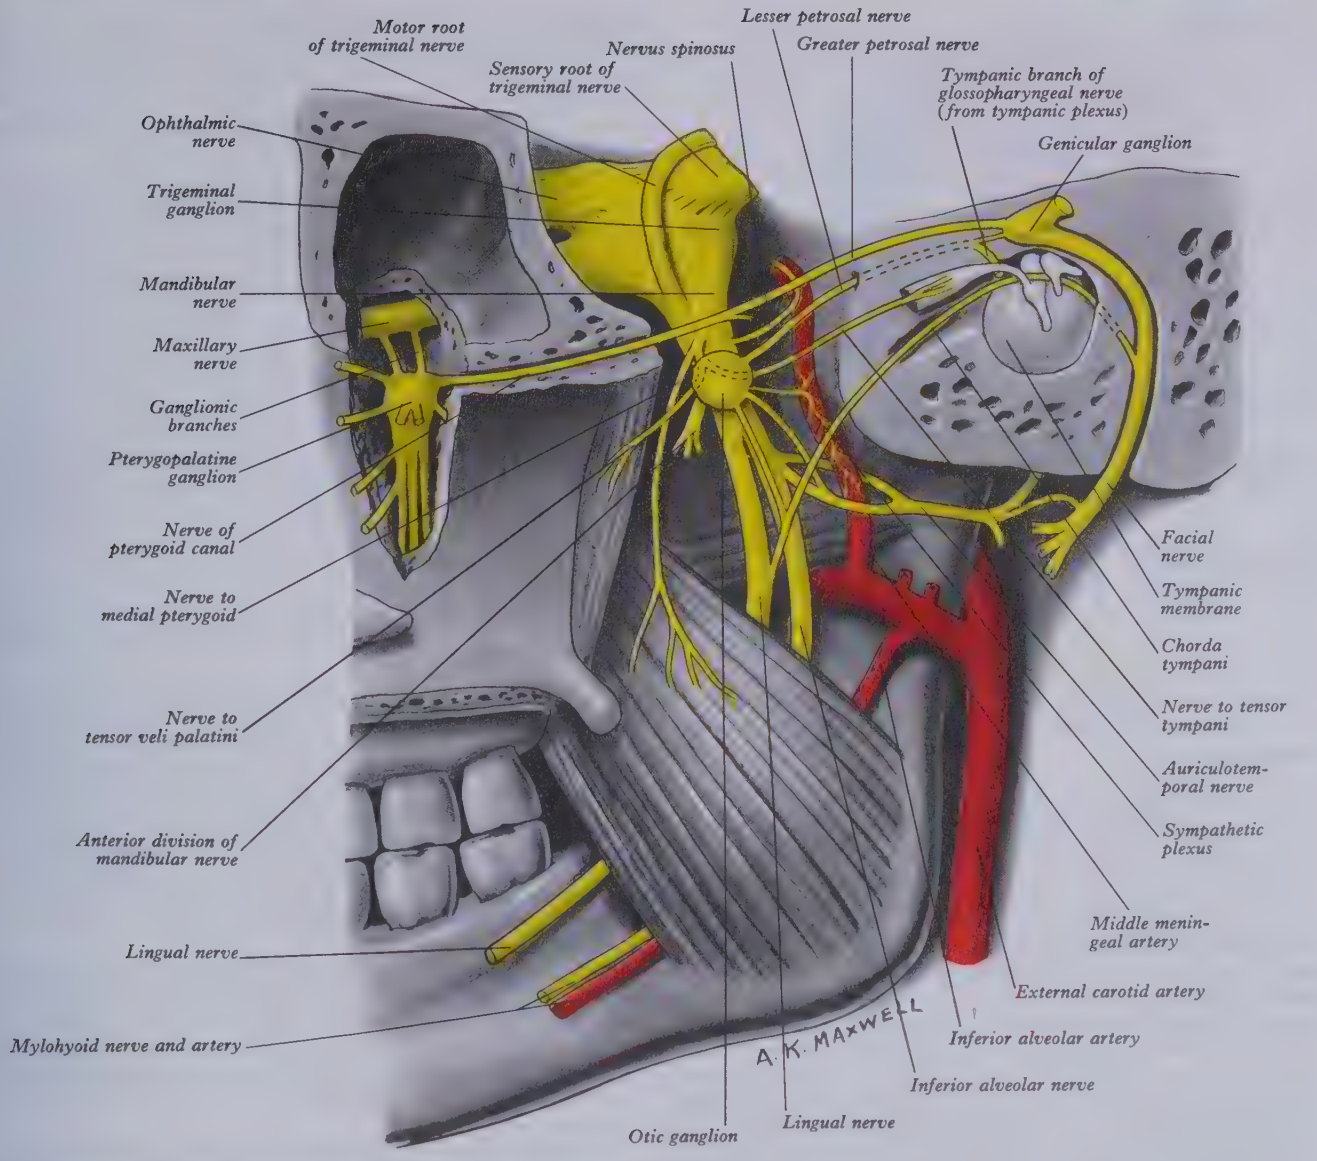
The anterior trunk of the mandibular nerve gives rise to (1) the sensory buccal nerve and (2) motor branches: masseteric, deep temporal and lateral pterygoid nerves.

The buccal nerve (7.222) proceeds between the two parts of the lateral pterygoid, descending beneath or through the lower part of the temporalis and deep to the mandible and masseter; it emerges from under the cover of the mandibular ramus and masseter anteriorly and unites with the buccal branches of the facial nerve. It supplies the lateral pterygoid while passing through it and may give off the anterior deep temporal nerve. It supplies the skin over the anterior part of the buccinator and the mucous membrane lining its inner surface, together with the posterior part of the buccal gingival surface.

The masseteric nerve (7.222) passes laterally, above the lateral pterygoid, anterior to the temporomandibular joint and posterior to the tendon of the temporalis; it crosses the posterior part of the mandibular incisure with the masseteric artery, ramifies on and enters the masseter's deep surface and also supplies the joint.

The deep temporal nerves, usually an anterior and a posterior, pass above the lateral pterygoid to enter the deep surface of the temporalis. The small *posterior nerve* is posterior in the temporal fossa, sometimes arising in common with the masseteric nerve. The *anterior nerve* is frequently a branch of the buccal nerve; it ascends over the upper head of the lateral pterygoid. A third, middle branch often occurs.

The nerve to the lateral pterygoid enters the deep surface of the muscle. It may arise separately from the anterior division of the mandibular, or with the buccal nerve.



The Posterior Trunk

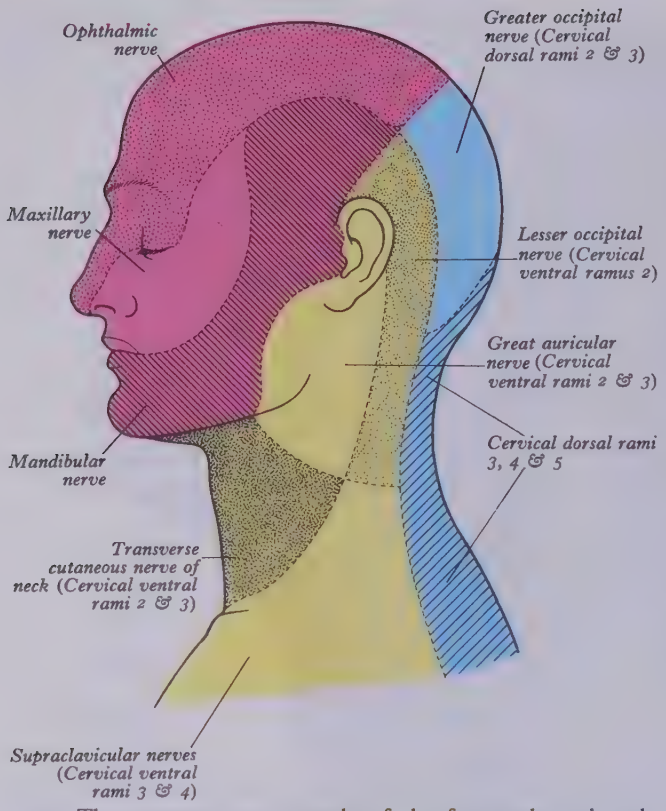
The posterior and larger, mandibular trunk is mainly sensory but receives a few filaments from the motor root. It divides into auriculotemporal, lingual and inferior alveolar (dental) nerves.

The auriculotemporal nerve usually has two roots, encircling the middle meningeal artery (7.219). It runs back under the lateral pterygoid on the surface of the tensor veli palatini to pass between the sphenomandibular ligament and the neck of the mandible and then laterally behind the temporomandibular joint in relation with the upper part of the parotid gland. Emerging from behind the joint, it ascends posterior to the superficial temporal vessels, over the posterior root of the zygoma, and divides into superficial temporal branches.

It communicates with the facial nerve and otic ganglion. The rami to the facial nerve, usually two, pass anterolaterally behind the neck of the mandible to join the facial nerve at the posterior border of the masseter. Filaments from the otic ganglion join the roots of the auriculotemporal nerve close to their origin (7.226).

The *branches* of the auriculotemporal nerve are: the anterior auricular, branches to the external acoustic meatus, articular, parotid and superficial temporal. Usually two *anterior auricular branches* supply the skin of the tragus (7.224) and sometimes a small part of the adjoining helix. Two *branches to the external acoustic meatus* pass between the osseous and cartilaginous parts of the meatus to supply the skin of the meatus; the upper sends a twig to the tympanic membrane. The *articular branches* are one or

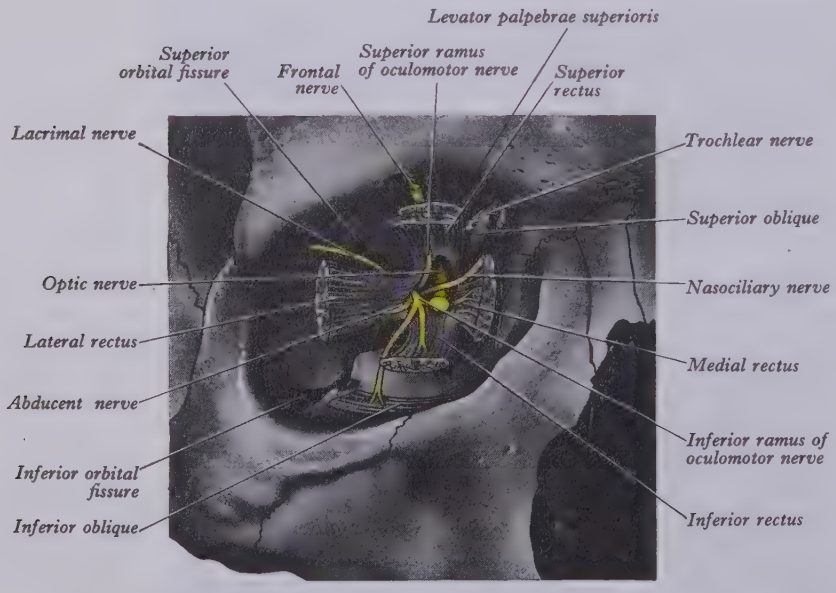
7.223 The right otic and pterygopalatine ganglia and their branches displayed from the medial side (semi-diagrammatic).



two filaments which enter the posterior part of the temporomandibular joint. The *parotid branches* convey secretomotor fibres to the gland; preganglionic fibres come from the glossopharyngeal nerve by its tympanic branch, travelling via the lesser petrosal nerve to the otic ganglion, whence postganglionic fibres pass to the auriculotemporal nerve to reach the gland (7.221). Vasomotor fibres to the blood vessels of the parotid gland are from the sympathetic root of the otic ganglion (p. 1113). The *superficial temporal branches* accompany the superficial temporal artery and its terminal branches, supplying the skin in the temporal region and connecting with the facial and zygomaticotemporal nerves.

The lingual nerve (7.219) is sensory to the mucosa of the presulcal part of the tongue, the floor of the mouth and the mandibular gingivae. It arises from the posterior trunk of the mandibular nerve and at first runs between the tensor veli palatini and the lateral pterygoid, where it is joined by the chorda tympani branch of the facial nerve and often by a branch of the inferior alveolar nerve. Emerging from the cover of the lateral pterygoid it proceeds down and forwards between the mandibular ramus and the medial pterygoid, lying anterior and slightly deep to the inferior alveolar nerve. It then passes below the mandibular attachment of the superior pharyngeal constrictor and lies against the medial surface of the mandible near the roots of the third molar tooth, where it is covered only by the gingival mucosa; here it can be pressed against the bone by a finger placed inside the mouth. It leaves the gingiva and passes on to the side of the tongue, where it crosses the styloglossus and runs on the lateral surface of the hyoglossus and deep to the mylohyoid, above the deep part of the submandibular gland and its duct. It proceeds forwards on the the side of the tongue, lateral to the hyoglossus and genioglossus; and divides into terminal branches which lie directly under the lingual mucosa. In the latter part of its course the nerve is near the submandibular duct; it passes downwards and forwards lateral to the duct, winds below it and then ascends forwards medial to it (7.219).

In addition to receiving the chorda tympani and a branch from the inferior alveolar nerve, the lingual nerve is connected to the submandibular ganglion (p. 1111) by two or three branches (7.219) and, at the anterior margin of the hyoglossus, it forms connecting loops with twigs of the hypoglossal nerve.



Branches of the lingual nerve supply the mucosa of the oral floor, lingual aspects of the gingivae and the mucosa of the presulcal part of the tongue, being overlapped slightly by lingual fibres of the glossopharyngeal nerve (p. 1113); terminal filaments join at the lingual apex with twigs of the hypoglossal nerve. It also carries postganglionic fibres from the submandibular ganglion (p. 1111) to the sublingual and anterior lingual glands.

The inferior alveolar (dental) nerve descends medial to the lateral pterygoid and then, at its lower border, passes between the sphenomandibular ligament and the mandibular ramus to enter

7.224 The cutaneous nerve supply of the face, scalp and neck. Magenta = trigeminal nerve, blue = cervical dorsal rami, yellow = cervical ventral rami.

through the mandibular foramen into the mandibular canal; in this, it runs below the teeth (which it supplies with twigs) to the mental foramen, where it emerges to divide into incisive and mental branches. Below the lateral pterygoid it is accompanied by the inferior alveolar artery. Dissection and radiography show that within most mandibles the inferior dental nerve is *plexiform* and does not occupy a single canal. It is joined directly, or through plexiform branches, by rami entering the bone as parts of neurovascular bundles derived from attached muscles such as the masseter. Such '*accessory*' *dental nerves* ramify in a plane lateral to the molar teeth; their common occurrence accounts for incomplete anaesthesia by inferior dental nerve block (Carter & Keen 1971). Variation in the inferior alveolar nerve in man has been described by Khaledpour (1984). The inferior alveolar nerve gives off the mylohyoid nerve, branches to the mandibular molar and premolar teeth and the incisive and mental nerves.

7.225 A dissection of the right orbit, viewed from in front, to show the origins of the orbital muscles and the relative positions of the nerves of the orbit.

The *mylohyoid nerve* leaves just before the inferior alveolar nerve enters the mandibular foramen. It pierces the sphenomandibular ligament, descends in a groove on the medial surface of the ramus of the mandible and, passing below the mylohyoid line, reaches the inferior surface of the mylohyoid, supplying it and the *anterior belly* of the *digastric*.

Branches to the molar and premolar teeth supply the adjoining gingiva also. Before they enter the dental roots they communicate and form an inferior dental plexus. The *incisive nerve* is often described as continuing on in the bone to supply the canine and incisor teeth. An alternative view is that the nerves supplying the incisor teeth form a plexus external to the mandible after emerging from the mental foramen and before re-entering the bone (Starkie & Stewart 1931). The canine teeth may be supplied from this incisor plexus or from the plexus innervating the premolars.

The *mental nerve*, emerging from its foramen, divides beneath the depressor anguli oris into three: a branch descending to the skin of the chin and two ascending to the skin and mucosa of the lower lip; these communicate freely with the facial nerve (mandibular branch).

Applied Anatomy. A lesion of the whole trigeminal nerve causes anaesthesia of the anterior half of the scalp, of the face (excepting a small area near the angle of the mandible supplied by the great auricular nerve), of the cornea and conjunctiva, the mucosae of the nose, mouth and presulcal part of the tongue. Paralysis and atrophy occur in the muscles supplied by the nerve; when the mouth is opened the mandible is thrust to the paralysed side. Lesions of the divisions of the nerve give a more limited sensory loss and, if the lingual nerve is involved anterior to its junction with the chorda tympani, loss of taste in half of the anterior part of the tongue occurs.

Pains referred to branches of the trigeminal nerve are frequent. Pain is at first confined to one division, though it may radiate over branches of the other divisions. The commonest example is the neuralgia often associated with dental caries. Here, though the tooth may not appear painful, most distressing referred pains may occur and these are at once relieved by treatment directed to the affected tooth.

In the area of the ophthalmic nerve, severe supraorbital pain is often associated with acute glaucoma or with frontal or ethmoidal sinusitis. Neoplasms or empyema of the maxillary sinus often cause maxillary neuralgia. Some of the most striking examples occur in the mandibular zone: earache often occurs where there is no sign of aural disease, the cause being usually a carious mandibular tooth. An ulcer or carcinoma of the tongue often first causes pain radiating to the ear and temporal fossa (the distribution of the auriculotemporal nerve).

The lingual nerve is occasionally divided in order to ease pain due to a lingual carcinoma; this is most easily done where the nerve adjoins the mandible below and behind the last molar tooth (p. 1105).

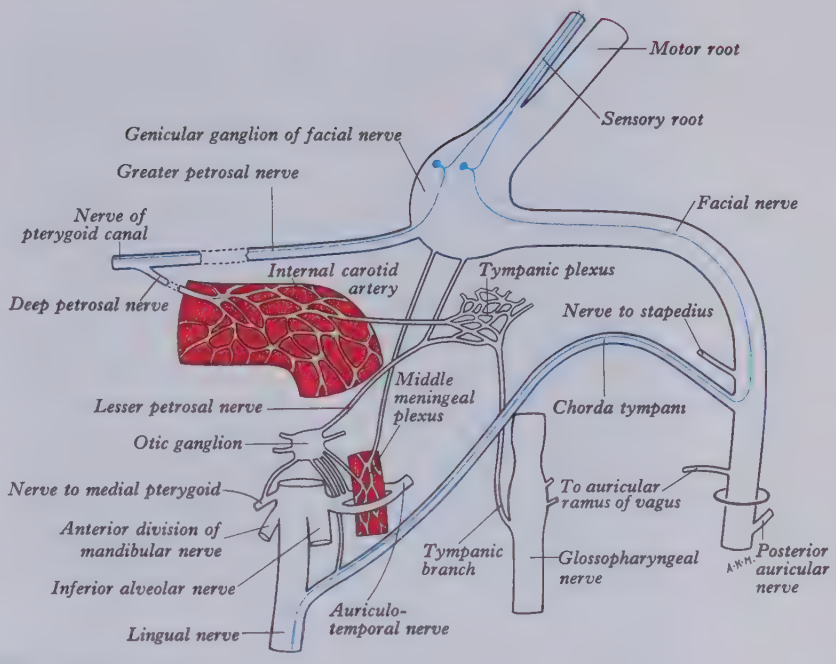
Intractable trigeminal neuralgia has promoted various surgical manoeuvres. The maxillary and mandibular nerves and trigeminal ganglion have been injected with alcohol and excision of the ganglion has frequently been performed, though this involves serious risks (laceration of the cavernous sinus, etc.) and is now rarely undertaken. The sensory root may be divided behind the ganglion and this is now the usual operation when pain is confined to the maxillary and mandibular areas (7.224). Complete division denervates the cornea, leading to neuropathic keratitis. Consequently, an endeavour is made to preserve the ophthalmic fibres, which are in the superomedial part of the root. The motor root of the nerve is left intact.

When pain is limited to the ophthalmic area or to the ophthalmic and maxillary areas, the preferred operation (Falconer 1949) is division of the spinal tract, where it is most superficial (p. 951) and sometimes forms a recognizable elevation (p. 953) between the lateral margin of the fasciculus cuneatus and the posterior

border of the lower olive. Section of the tract 4–5 mm caudal to the obex preserves most mandibular fibres. Pain can be abolished, while retaining tactile sensibility and the corneal reflex.

The Abducent Nerve

The abducent nerve (7.218) supplies the lateral rectus, its fibres arising from a small nucleus in the superior part of the floor of the fourth ventricle, near the midline and beneath the colliculus facialis (7.86, 87, 94, 95, p. 980). They descend ventrally through the pons, emerging in the sulcus between the caudal border of the pons and the superior end of the pyramid of the medullar oblongata (7.81).

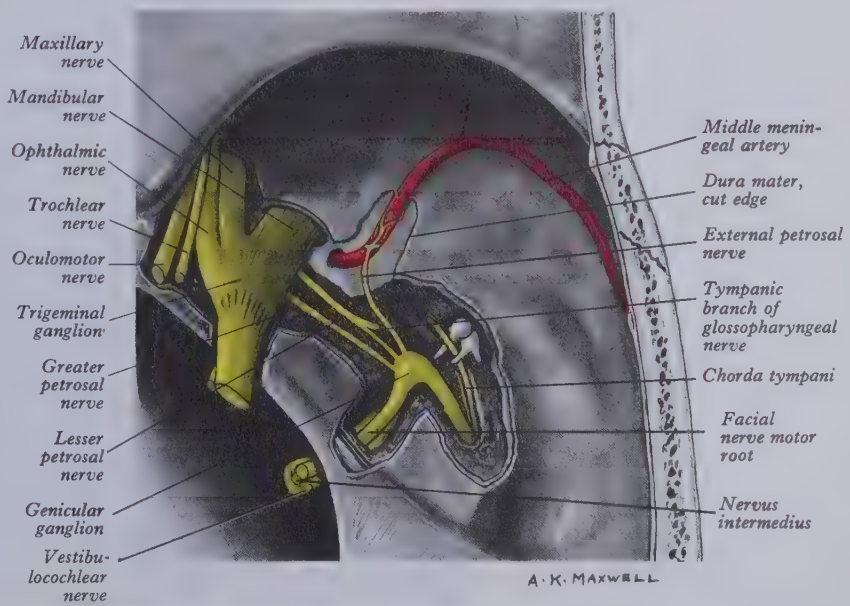


The *abducens nucleus* contains large and small multipolar neurons; the former are the sources of the abducent nerve and the latter, known collectively as the *nucleus para-abducens*, is considered to project to the oculomotor nucleus via the medial longitudinal fasciculus. The total number of neurons in the nucleus is about 22 000; only a minority can be radicular, since the nerve contains about 6600 fibres (Konigsmark et al 1969). Claims that all abducent neurons react to division (Warwick 1964 and others) are based on differing considerations of which cells should be included as 'abducent'. A study in kittens using the retrograde horseradish peroxidase technique (Gacek 1974) nevertheless indicated that 50–90% of the cells were radicular. Other studies have demonstrated that some abducent neurons project to the oculomotor and perhaps trochlear nuclei (see Steiger & Büttner-Ennever 1978, for literature). Büttner-Ennever (1977) has identified neurons in the pontine reticular formation, just rostral to the abducent nucleus, which project to regions of the oculomotor nucleus reputedly concerned with innervation of the lateral and inferior recti; and has discussed the considerable evidence for the view that these mediate horizontal and perhaps vertical integration of binocular movement.

Connections. The abducent nucleus receives afferent connections from: (1) the corticonuclear tract, principally contralateral; some of these fibres are aberrant pyramidal fibres which descend from the midbrain to this level in the medial lemniscus (p. 952) and interneurons may link them to the nucleus; (2) the medial longitudinal fasciculus, connecting it to nuclei of the third, fourth and eighth cranial nerves; (3) the tectobulbar tract, linking it with the visual cortex and other centres through the superior colliculus. (See also p. 987.)

Course. After leaving the brain stem, the abducent nerve ascends anterolaterally through the cisterna pontis, usually dorsal to the anterior inferior cerebellar artery. It pierces the dura mater lateral to the dorsum sellae and bends sharply forwards over the superior border of the petrous temporal bone, near its apex and inferior to the petrosphenoidal ligament, a fibrous band connecting the lateral margin of the dorsum sellae to the upper border of the petrous temporal bone near its median end. It next traverses the cavernous sinus, at first lying lateral and then inferolateral to the internal carotid artery (6.155, 156), and enters the orbital cavity via the medial end of the superior orbital fissure within the annular tendon and inferolateral to the oculomotor and nasociliary nerves, finally sinking into the ocular surface of the lateral rectus (7.225, 329).

In the cavernous sinus the nerve is joined by a branch from the end of the internal carotid sympathetic plexus, originally described by Monro (1746) and confirmed by Meckel (1832), but frequently omitted from subsequent textbooks and even denied (Sunderland & Hughes 1946). Its existence has been re-emphasized by Johnston & Parkinson (1974) and Parkinson et al (1978), who have also described a branch of similar calibre, leaving the abducent nerve a few millimetres distal to this sympathetic communication to join the ophthalmic nerve; they believe that sympathetic postganglionic fibres joining the abducent nerve are thus diverted into the ophthalmic division of the trigeminal. This would accord with the passage of sympathetic nerve fibres to the eye via the long ciliary branches of the nasociliary nerve, as suggested by some.

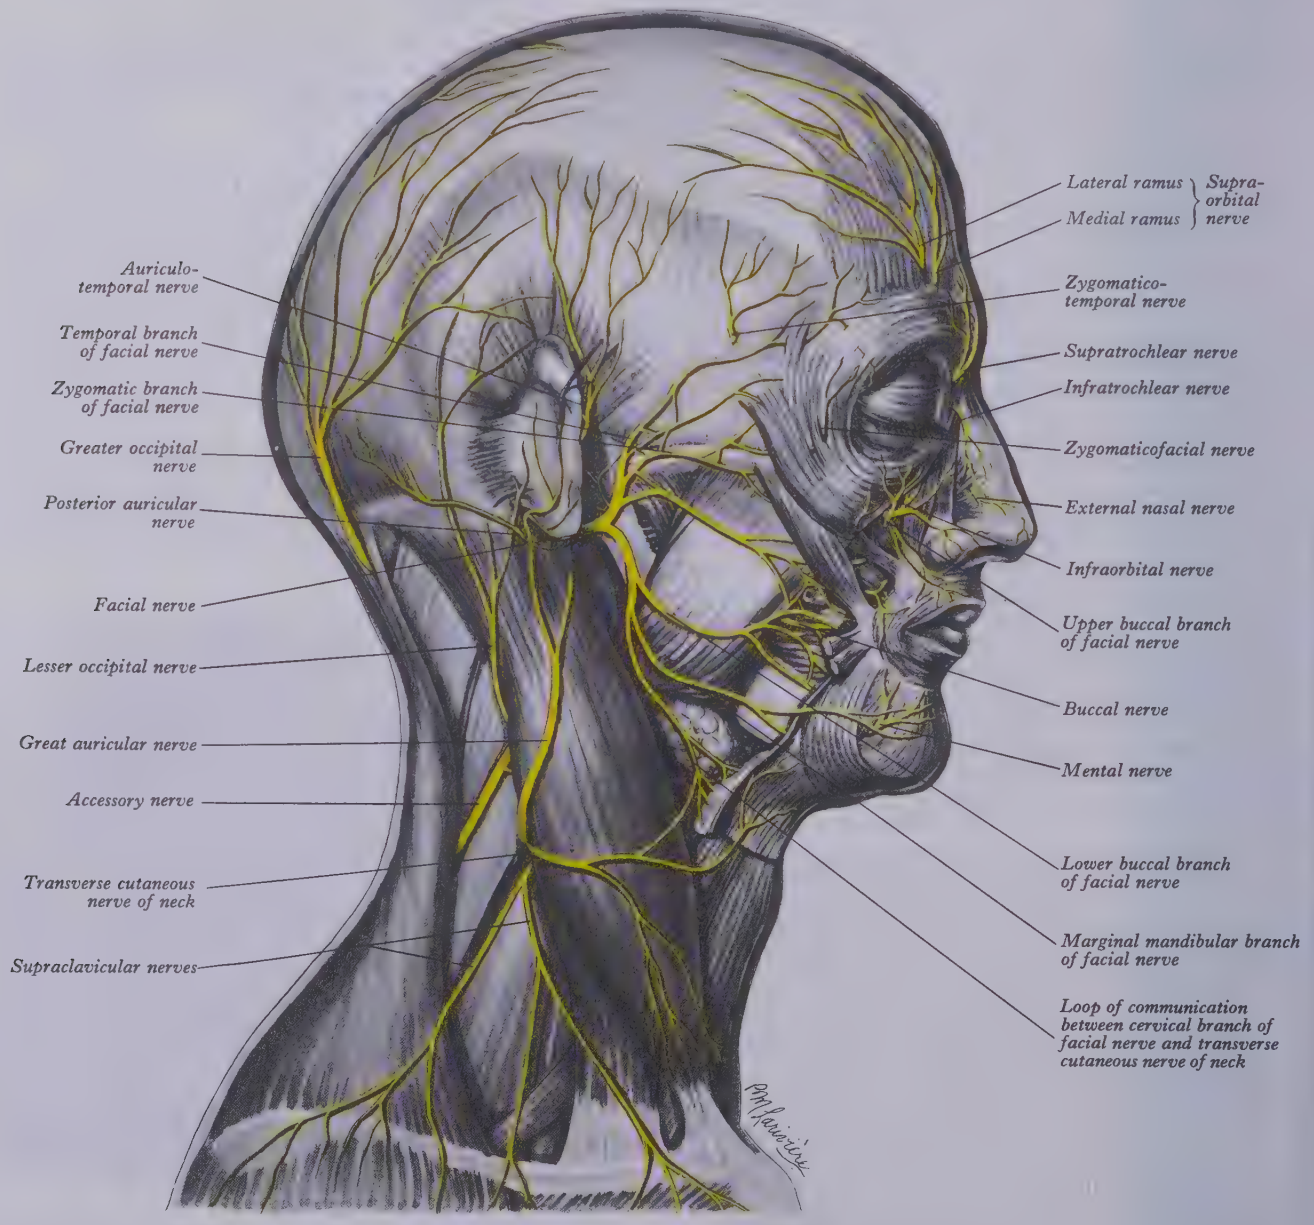


Applied Anatomy. The abducent nerve is sometimes involved in fractures of the cranial base. The resulting paralysis of the lateral rectus leads to convergent squint and diplopia. The long course of the sixth cranial nerve through the cisterna pontis and its sharp bend over the petrous temporal bone make the nerve liable to damage in conditions producing raised intracranial pressure, as a result of which the brain stem may be pushed caudally with consequent stretching of the nerve.

7.226 A plan of the intrapetrous section of the facial nerve, its branches and communications. The course of the taste fibres from the mucous membrane of the palate and from the anterior, oral or presulcal part of the tongue is represented by the blue lines.

The Facial Nerve

The facial nerve (7.226–229) has a motor and a sensory root, the latter being the *nervus intermedius* (7.227). The two roots emerge at the caudal border of the pons lateral to the recess between the inferior olive and inferior cerebellar peduncle, the motor part being medial; the vestibulocochlear nerve is lateral to the sensory



7.227 A dissection of the right middle cranial fossa, showing the course and some of the connections of the facial nerve within the temporal bone.

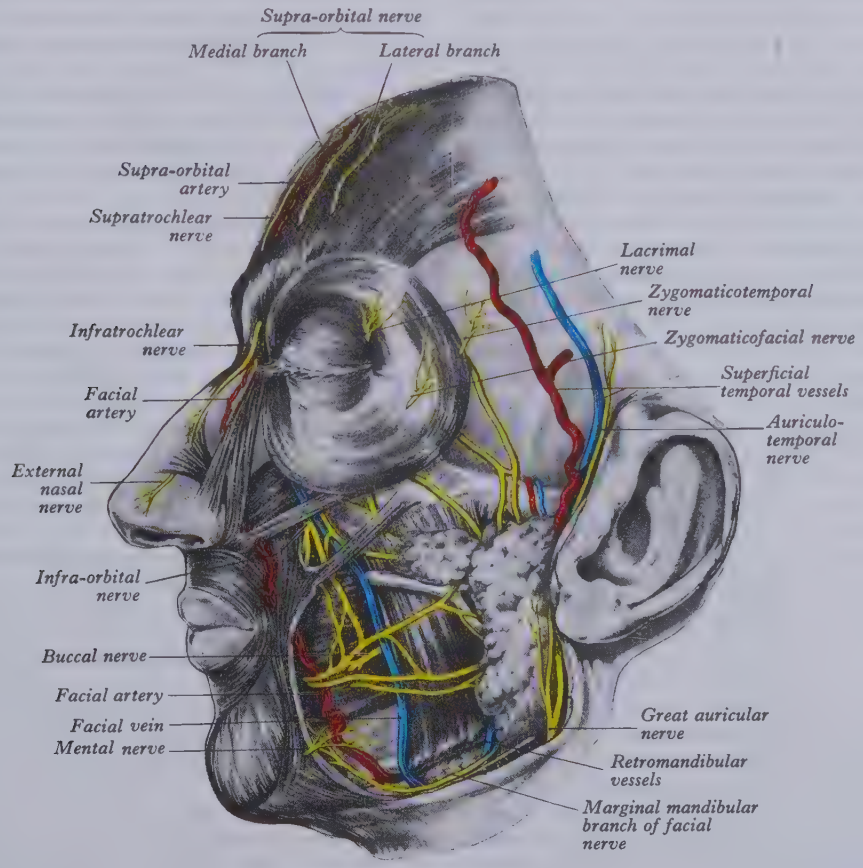
root. The nervus intermedius usually cleaves at first to the vestibulocochlear rather than the facial nerve, passing to the latter as it approaches the internal acoustic meatus, often as more than one filament. In approximately one-fifth of 73 dissections it was not a separate nerve until the meatus was reached, a point of surgical importance (Rhoton et al 1968).

The *motor root* supplies: the muscles of the face, scalp and auricle, the buccinator, platysma, stapedius, stylohyoid, and the posterior belly of the digastric. The *sensory root* conveys from the chorda tympani gustatory fibres from the presulcal area of the tongue and, from the palatine and greater petrosal nerves, taste fibres from the soft palate; it also carries the preganglionic parasympathetic (secretomotor) innervation of the submandibular and sublingual salivary glands, lacrimal gland and glands of the nasal and palatine mucosae.

The motor nucleus, from which most facial motor fibres are derived, is deep in the reticular formation of the caudal part of the pons (p. 961), posterior to the dorsal trapezoid nucleus (7.86, 87, 94) and ventromedial to the spinal tract nucleus of the trigeminal nerve. It represents the branchial efferent column but lies deeper in the pons than might be expected and its efferent fibres have a most unusual course (7.95). Both these features have been explained by invoking neurobiotaxis (p. 184). The nucleus receives fibres from both corticonuclear tracts in the lower pons and is reputedly supplied by aberrant pyramidal fibres which descend in the medial lemniscus. Contralateral corticonuclear fibres end in the part of the nucleus innervating the muscles of the lower part of the face (p. 961) while the corticonuclear projection to neurons for muscles around the eyes and forehead is bilateral. Some facial efferent fibres proceed from the *superior salivatory nucleus* (see p. 961), said to be in the reticular formation, dorsolateral to the caudal end of the motor nucleus. Neurons of the facial nucleus have been described as clustered along the intrapontine part of the nerve distal to its loop round the abducens nucleus (Crosby & Dejonge 1963); it belongs to the general visceral efferent column, sending its fibres to the sensory root, by which they ultimately, via the chorda tympani, reach the submandibular and sublingual salivary glands and perhaps also the parotid (p. 1155). Other preganglionic fibres issuing in the sensory root reach the pterygopalatine ganglion in the greater petrosal nerve and the nerve of the pterygoid canal (vide infra). From this double origin the *motor root* passes dorsomedially to the caudal end of the abducent nucleus and ascends superficial to it and deep to the facial colliculus. At the upper limit of the abducent nucleus the nerve

7.228 The nerves of the right side of the scalp, face and neck. Compare with 7.224.

swerves into a caudoventral course to its emergence between the olive and the inferior cerebellar peduncle (7.81, 95) at the cerebellopontine angle.



The facial motor nucleus is a complex consisting of lateral, intermediate and medial subnuclei (Marinesco 1899, Papex 1927). A further division of the medial nucleus into ventral, dorsal and intermediate groups has been described. (For details consult Vraa-Jensen 1942.) These subsidiary groups of neurons are arranged in columns, like those in the spinal cord or oculomotor nucleus. There is general agreement that they innervate individual muscles or correspond to branches of the nerve, but observers disagree about details. Retrograde changes following division of different branches of the nerve in dogs (Vraa-Jensen 1942, Yagita 1910) and cats (Papex 1927, Courville 1966) have provided most of the evidence; the effects on motor terminals of selective nuclear lesions have also been studied in cats. The lateral subnucleus is said to innervate the buccal musculature, the intermediate sends axons into the temporal, orbital and zygomatic facial branches and the medial group into the posterior auricular and cervical rami and probably the stapedial nerve. Nuclear lesions have produced a roughly similar but more detailed schema (Szentágothai 1948).

The sensory nucleus of the facial nerve is the rostral end of the *nucleus solitarius* in the medulla oblongata (p. 954). It receives gustatory and possibly other afferents from the sensory root and sends fibres to the contralateral ventral lateral thalamic nuclei. As they ascend in the midbrain and subthalamic regions these fibres pass near the midline (Harris 1952). From the thalamus they are relayed to the inferior part of the postcentral gyrus. For other connections, see p.1122.

The sensory root (*nervus intermedius*) contains the centripetal processes of unipolar neurons in the genicular ganglion, which leave the trunk of the facial nerve in the internal acoustic meatus in one or more slender bundles between the motor root and the vestibulocochlear nerve or adherent to the latter, and enter the brain stem at the caudal border of the pons. The peripheral branches of the ganglion cells are mainly taste fibres travelling in the chorda tympani and greater petrosal nerve and a few somatic afferent fibres from the auricular concha (p. 1219). The sensory root also contains *efferent* preganglionic parasympathetic fibres for the submandibular and sublingual salivary glands, lacrimal gland, and pharyngeal, nasal and palatine glands.

Course. From their emergence from the brain, the two roots pass anterolaterally with the vestibulocochlear nerve to the internal acoustic meatus; here the motor root is in an anterosuperior groove on the vestibulocochlear nerve, with the sensory root between them. At the lateral end of the meatus, the nerve enters the facial canal, proceeding at first laterally above the vestibule and, near the medial wall of the epitympanic recess, bending sharply back above the promontory and arching down in the medial wall of the aditus of the mastoid antrum. It then descends to the stylomastoid foramen. Its sharp bend backwards is the *geniculum*; here the nerve presents a reddish asymmetrical swelling, the *genicular ganglion* (7.226). Emerging from the stylomastoid foramen, the nerve runs forwards in the parotid gland (p. 1290), crosses the styloid process, retromandibular vein and external carotid artery and divides behind the neck of the mandible into branches which pierce the anteromedial surface of the parotid gland and diverge under cover of it. They form a network (*parotid plexus*) which distributes to the facial musculature. At the stylomastoid foramen the nerve is about 2 cm deep to the middle of the anterior border of the mastoid process. Its transparotid course is represented by a horizontal line across the upper part of the auricular lobule (**6**.70). Angular measurements of the frequent changes in direction of the facial nerve within the facial canal are of surgical importance; Kudo & Nori (1974) and Guerrier (1975) have recorded detailed metrical studies.

Arterial supply and venous drainage. The facial nerve is supplied intracranially by the anterior inferior cerebellar artery and in its canal by the superficial petrosal branch of the middle meningeal artery and the stylomastoid branch of the posterior auricular or occipital arteries; extracranially by branches from the

7.229 The terminal branches of the left trigeminal and facial nerves in the face.

stylomastoid, posterior auricular, occipital, superficial temporal and transverse facial arteries. Venous drainage is into the venae comitantes of the superficial petrosal and stylomastoid arteries (Blunt 1954).

Communicating branches are:

Intracranial:	Vestibulocochlear
Genicular ganglion:	Pterygopalatine ganglion via the greater petrosal nerve
	Otic ganglion via the lesser petrosal nerve
	Middle meningeal sympathetic plexus
Facial canal:	Auricular branch of vagus
At exit from stylomastoid foramen:	To glossopharyngeal, vagus, great auricular and auriculotemporal nerves
Post-auricular:	To the lesser occipital nerve
Facial:	With the trigeminal nerve
Cervical:	With the transverse cervical nerve

In the internal acoustic meatus some minute filaments connect the facial nerve with the vestibulocochlear nerve.

The greater petrosal nerve starts from the genicular ganglion and contains mainly taste fibres from the palatal mucosa and also preganglionic parasympathetic fibres travelling to the pterygopalatine ganglion and said to be relayed through the zygomatic and lacrimal nerves to the lacrimal gland (p. 1103) and through the nasal and palatine nerves to the nasal and palatine mucosal glands (7.221). It receives a ramus from the tympanic plexus, traverses the hiatus on the anterior surface of the petrous temporal bone and enters a groove on it, passing under the trigeminal ganglion to the foramen lacerum; here it is joined by the **deep petrosal nerve** (7.226) from the internal carotid sympathetic plexus to form the **nerve of the pterygoid canal**, which traverses the pterygoid canal to end in the pterygopalatine ganglion. Gustatory fibres pass without interruption through or over the pterygopalatine ganglion into its palatine branches.

From the facial nerve near the genicular ganglion, the ganglion itself or the root of the greater petrosal nerve (Vidić & Young 1967), a branch runs to the lesser petrosal nerve (7.226), by which it reaches the otic ganglion. However, fibres in this small communication are *not facial* but come from the vagal auricular branch. In 24 out of 25 human dissections the fibres approached the facial nerve through the stapedius, travelling in its fascial sheath almost to the genicular ganglion, before departing to join the lesser superficial petrosal nerve (Vidić 1968).

The middle meningeal sympathetic plexus is joined to the genicular ganglion by an inconstant *external petrosal nerve*.

Before leaving the stylomastoid foramen the facial nerve receives another branch from the vagal auricular nerve. After leaving the foramen, it receives a twig from the glossopharyngeal, communicating with the great auricular and auriculotemporal nerves in the parotid gland, with the lesser occipital nerve behind the ear, with terminal trigeminal branches on the face and with the transverse cutaneous cervical nerve in the neck.

The branches of distribution (7.226, 228) are:

In the facial canal:	Nerve to stapedius
	Chorda tympani
At exit from stylomastoid foramen:	Posterior auricular
	Digastric, posterior belly
	Stylohyoid
On the face:	Temporal
	Zygomatic
	Buccal
	Marginal mandibular
	Cervical

The nerve to the stapedius arises behind the pyramidal eminence of the posterior wall of the tympanic cavity, passing forwards through a small canal to reach the muscle (p. 1227).

The chorda tympani (7.223) leaves the facial nerve about 6 mm above the stylomastoid foramen, ascending forwards in a canal to perforate the posterior wall of the tympanic cavity via its posterior canaliculus near the posterior border of the tympanic membrane's medial aspect, level with the upper end of the handle of the malleus. Passing forwards between the membrane's fibrous and mucous layers, it crosses medial to the handle of the malleus to re-enter the bone via its anterior canaliculus at the medial end of the petrotympanic fissure. It now descends ventrally on the medial surface of the sphenoid spine (which it sometimes grooves) and passes deep to the lateral pterygoid. Here the nerve is posterolateral to the tensor veli palatini and is crossed medially by the middle meningeal artery, the roots of the auriculotemporal nerve and the inferior alveolar nerve. It joins the posterior aspect of the lingual nerve at an acute angle. It contains efferent preganglionic parasympathetic (secretomotor) fibres which enter the submandibular ganglion, from which postganglionic fibres are relayed to the submandibular and sublingual glands; most of its fibres are afferent from the mucosa of the anterior, presulcal part of the tongue, save the vallate papillae, constituting the nerve of taste for this lingual region. Before uniting with the lingual nerve the chorda tympani is joined by a small branch from the otic ganglion.

The posterior auricular nerve arises near the stylomastoid foramen, ascends in front of the mastoid process to be joined by a filament from the auricular branch of the vagus, and communicates with a posterior branch of the great auricular and lesser occipital nerves. As it ascends between the external acoustic meatus and mastoid process it divides into auricular and occipital branches. The *auricular branch* supplies the auricularis posterior and the intrinsic muscles on the auricle's cranial aspect; the larger *occipital branch* passes back along the superior nuchal line to supply the occipital belly of occipitofrontalis.

The digastric branch also starts near the stylomastoid foramen, dividing into several filaments which supply the posterior belly of the digastric, one joining the glossopharyngeal nerve.

The stylohyoid branch, long and slender, frequently arises with the digastric branch; it enters the middle part of the stylohyoid muscle.

The temporal branches cross the zygomatic arch to the temple, supplying intrinsic muscles on the lateral surface of the auricle, the anterior and superior auricular muscles, and join with the zygomaticotemporal branch of the maxillary nerve and the auriculotemporal branch of the mandibular nerve. The more anterior branches supply the frontal belly of the occipitofrontalis, orbicularis oculi and corrugator and join the supraorbital and lacrimal branches of the ophthalmic nerve.

Zygomatic branches cross the zygomatic bone to the lateral canthus, supplying the orbicularis oculi and joining filaments of the lacrimal nerve and zygomaticofacial branch of the maxillary nerve.

Buccal branches pass horizontally to a distribution below the orbit and around the mouth. *Superficial branches* run between the skin and superficial muscles, supplying the latter; some pass to the procerus, joining with the infratrochlear and external nasal nerves. *Upper deep branches* pass under the zygomaticus major and levator labii superioris, supplying them and forming an *infraorbital plexus* with the superior labial branches of the infraorbital nerve; they also supply the levator anguli oris, zygomaticus minor, levator labii superioris alaeque nasi and the small nasal muscles. These branches are sometimes described as lower zygomatic branches. *Lower deep branches* supply the buccinator and orbicularis oris, joining filaments of the buccal branch of the mandibular nerve.

The marginal mandibular branch runs forwards below the angle of the mandible under the platysma, at first superficial to the upper part of the digastric triangle, then turning up and forwards across the body of the mandible to pass under the depressor anguli oris (7.229). It supplies the risorius and the muscles of the lower lip and chin, joining the mental nerve (p. 1106).

The cervical branch issues from the lower part of the parotid gland, runs antero-inferiorly under the platysma to the front of the neck, supplying the platysma and communicating with the transverse cutaneous cervical nerve.

The cutaneous fibres of the facial nerve accompany the auricular branch of the vagus and probably innervate the skin on both auricular aspects, in the conchal depression and over its eminence; however, details of this are uncertain, as is a supply to the external acoustic meatus and tympanic membrane.

The Submandibular Ganglion

This is a small, fusiform body which lies on the upper part of the hyoglossus; there are further ganglion cells in the hilum of the submandibular gland. Like the ciliary, pterygopalatine and otic ganglia, the submandibular is a peripheral parasympathetic ganglion. It is superior to the deep part of the submandibular gland and inferior to the lingual nerve, suspended from the latter by anterior and posterior filaments (7.219). Though related to the lingual nerve, the ganglion is connected functionally with the facial nerve and chorda tympani. Its *motor, parasympathetic root* is the posterior filament connecting it to the lingual nerve; it conveys preganglionic fibres from the superior salivatory nucleus travelling in the facial, chorda tympani and lingual nerves to the ganglion, where they synapse, the postganglionic fibres being secretomotor to the submandibular and sublingual salivary glands. (Some fibres may also reach the parotid gland, see p. 1292.) The *sympathetic root* is derived from the plexus on the facial artery; it consists of postganglionic fibres from the superior cervical ganglion, which traverse the submandibular ganglion without synapsing. They are vasomotor to the blood vessels of the submandibular and sublingual glands. Five or six branches from the ganglion supply the submandibular gland and its duct; other fibres pass through the anterior filament connecting the gland to the lingual nerve and are carried to the sublingual and anterior lingual glands.

Applied Anatomy. Facial paralysis, often unilateral, may be due to: (1) *supranuclear lesions* in the corticonuclear fibres from the frontal lobe, variably combined with numerous other descending fibres converging on the facial nucleus; (2) *nuclear* or *infranuclear lesions* involving lower motor neurons.

Supranuclear facial paralysis involving 'upper motor neuron' pathways is usually part of a hemiplegia. Movements in the *lower* part of the face are usually more severely affected, voluntary movements being weak or absent though emotional expression is little affected. Electrical reactions of affected muscles are unaltered. Occasionally supranuclear lesions may abolish or weaken emotional movements but not voluntary movements. This dissociation shows that the supranuclear control of expressive movements is separate from the corticonuclear path for voluntary movements.

Nuclear or *infranuclear lesions* vary in their effects according to the lesion's site. If the nucleus or facial pontine fibres are involved, neighbouring structures are inevitably also involved. Facial muscles are represented in cell groups within the nucleus, their degree of involvement governing the extent of paralysis, which is ipsilateral; otherwise the effects are identical with those of more peripheral lesions. Lesions due to adjacent damage include paralysis of the lateral rectus because of the involvement of the abducent nucleus (around which the facial nerve loops), paralysis of the masticatory muscles by involvement of the motor trigeminal nucleus, sensory loss on the face from involvement of the principal sensory and spinal trigeminal nuclei or spinothalamic tract and paralysis of the upper or lower limbs due to corticospinal lesions. Due to the proximity of the facial sensory root to the vestibulocochlear nerve, lesions in the posterior cranial fossa or in the internal acoustic meatus may cause loss of taste in the anterior part of the tongue with ipsilateral deafness and facial paralysis. When damage is in the temporal bone, the chorda tympani is usually also involved and in petrous temporal fractures the vestibulocochlear nerve is also usually implicated. The most common cause is inflammation of the facial nerve near the stylomastoid foramen (*Bell's palsy* or *paralysis*), with oedema of the nerve and compression of its fibres in the facial canal or stylomastoid foramen.

If the lesion is complete, the facial muscles are all equally affected; voluntary and associated movements suffer equally. There is facial asymmetry and the affected side is immobile. The eyebrow droops, wrinkles are smoothed out; the palpebral fissure is widened by the unopposed action of the levator superioris palpebrae. Tears fail to enter the lacrimal puncta because they are no longer in contact with the conjunctiva, the conjunctival reflex is absent and efforts to close the eye merely roll the cornea under the upper lid. The ala nasi does not move in respiration. The lips remain in contact and cannot be pursed; in attempting to smile the angle of the mouth is not drawn up on the affected side, the lips remaining nearly closed and the mouth typically triangular. Food accumulates in the cheek, from paralysis of the buccinator, and dribbles or is pushed out between the paralysed lips. The protruded tongue *appears* to turn to the paralysed side though its position relative to the incisor teeth demonstrates that this is not so. Platysma and the auricular muscles are paralysed. The electrical reactions of the affected muscles are typical of degeneration, the degree of which may be a guide to prognosis. Most cases of Bell's palsy recover completely.

For variations in the course of the facial nerve near the middle ear and their surgical importance, consult Durcan et al (1967). Degeneration studies (Naoris 1968) show that the nerve contains no fascicular or other pattern corresponding to its peripheral branches, a finding of significance in suturing the nerve after injury.

The Vestibulocochlear Nerve

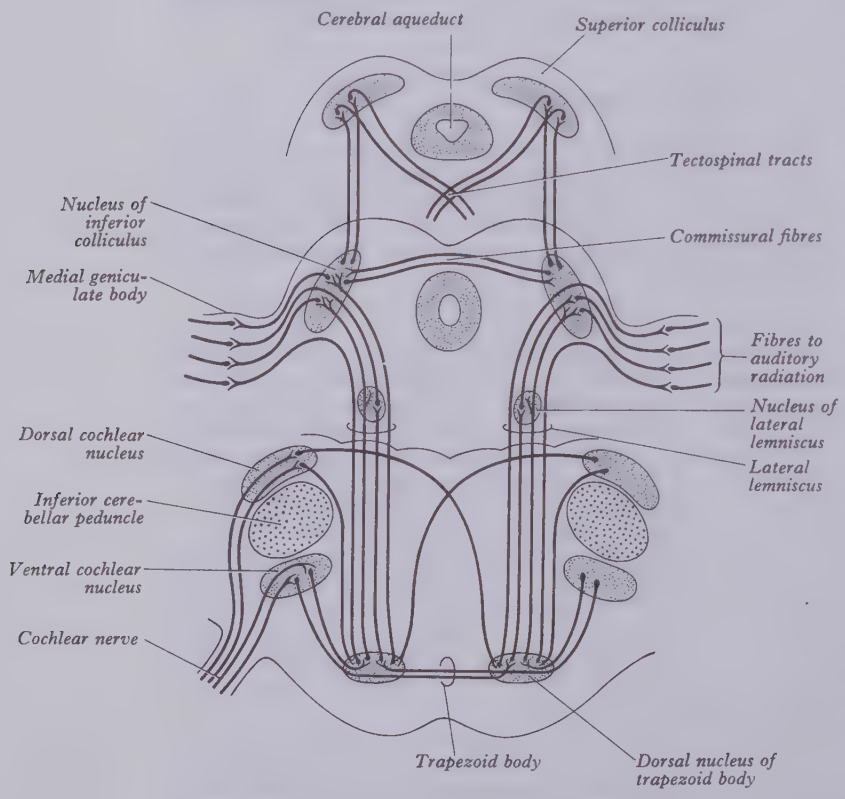
The vestibulocochlear nerve (7.86, 90, 91, 94) emerges in the groove between the pons and the medulla oblongata, behind the facial nerve and in front of the inferior cerebellar peduncle (7.81). It has two major sets of fibres, differing in their principal central connections, but both transmitting impulses from the internal ear to the brain. One set forms the vestibular nerve, concerned with equilibration and arising from neurons in the vestibular ganglion in the outer part of the internal acoustic meatus, the other forming the cochlear nerve or auditory nerve, arising from neurons in the spiral ganglion of the cochlea. Both ganglia contain bipolar neurons, each with central and peripheral fibres: the former passes to the brain and the latter to the internal ear. The nerve also contains *efferent fibres* passing from neuronal cell bodies in the brain stem to both parts of the labyrinth. The peripheral arrangement of the vestibulocochlear nerve is described on pp. 1228, 1235–1241.

THE VESTIBULAR NERVE

Vestibular fibres enter the brain superomedial to those of the cochlear nerve, pass back through the pons between the inferior cerebellar peduncle and spinal trigeminal tract to divide into ascending and descending branches ending mainly in the vestibular nuclei, although some go direct to the cerebellum through its inferior peduncle (p. 965).

The vestibular nuclear complex comprises the following: (1) The *medial vestibular nucleus* (p. 958), which lies under the vestibular area of the floor of the fourth ventricle, crossed dorsally by the striae medullares. The largest subdivision of the complex, it extends up from the medulla oblongata into the pons. (2) The *inferior vestibular nucleus* (p. 958), lateral to the medial, reaches to a lower medullary level and lies between the medial nucleus and inferior cerebellar peduncle; descending branches of afferent vestibular fibres end among its cells. (3) The *lateral nucleus* (p. 958) is ventrolateral to the upper part of the medial and it is characterized by its large neurons; its rostral end is continuous with the caudal end of (4) the *superior nucleus*, which extends higher into the pons than other subdivisions, occupying the upper part of the vestibular area. Several minor subdivisions have been described in feline vestibular nuclei (Brodal & Pompeiano 1957) and a tentative somatotopic pattern has been suggested in the lateral nucleus (Løken & Brodal 1970).

Connections. All vestibular nuclei receive *radicular fibres* from the nerve; they may receive *afferent cerebellovestibular fibres* through the inferior cerebellar peduncle, mainly derived from the flocculus and nodule (posterior lobe), together with others perhaps from the uvula, the lingula and fastigial nucleus.



From the nuclei *cerebellar fibres* enter the inferior cerebellar peduncle, most destined for the flocculus and nodule, though some may pass to the uvula, lingula or fastigial nucleus. As noted, some vestibular fibres bypass the nuclei and reach the flocculus and nodule directly via the inferior cerebellar peduncle.

As a whole, the vestibular nuclear complex is a relay station on an afferent cerebellar path and a distributing station for efferent cerebellar fibres. Fibres from vestibular nuclei also enter the medial longitudinal fasciculus (7.121), ascending and descending to motor nuclei of the ocular and nuchal muscles. This '*octavo-oculomotor system*' has attracted much attention (see pp. 958, 985) and dissension regarding the vestibular nuclei involved, routes of projections, decussation and destinations. Tarlov (1972, 1975) has described a projection from the medial and superior vestibular nuclei to specific motor pools in the feline oculomotor nucleus (p. 1097) and has also reviewed the literature; it is suggested that excitatory and inhibitory projections exist, mediating complex and subtle integration between vestibular signals and eye movements. From large neurons in the lateral vestibular nucleus efferent fibres descend to form the *vestibulospinal tract* (p. 932), and fibres from the other nuclei join the lateral lemniscus to reach the inferior colliculus and medial geniculate body and, probably, the cerebral cortex. Through its connections the vestibular system influences movements of the eyes and head and muscles of the trunk and limbs to maintain equilibrium.

THE COCHLEAR NERVE

The cochlear nerve consists chiefly of myelinated *afferent* axons of sensory ganglion cells situated in the *spiral ganglion* within the modiolus of the cochlea; peripherally, the bipolar ganglion cells have processes which receive synapses from the auditory sensory cells (hair cells) of the spiral organ. In addition, some *efferent* fibres pass in the cochlear nerve from the brain stem to the spiral organ, constituting the *olivocochlear bundle*.

As the cochlear nerve reaches the brain stem (7.86, 90, 91) it lies lateral to the vestibular nerve but they are soon separated by the inferior cerebellar peduncle. The cochlear nerve curves round the lateral aspect of the peduncle, the vestibular penetrating the brain stem on the medial side of it.

7.230 A simplified diagram to show some of the central connections of the cochlear nerve and the auditory pathway through the brain stem. Although they are shown in the figure as being of comparable size, the trapezoid body constitutes a much more important and larger commissural bundle than the fibres connecting the nuclei of the two inferior colliculi. *Efferent* fibres in the cochlear nerve and *descending* fibres in the auditory pathway have been omitted.

The cochlear nuclei are two in number and comprise a *ventral cochlear nucleus* on the ventrolateral aspect of the inferior cerebellar peduncle, receiving the larger, ascending branches of the cochlear nerve, and a *dorsal cochlear nucleus* on the dorsal aspect of the peduncle in the lateral part of the vestibular area of the floor of the fourth ventricle, forming the auditory tubercle and receiving the smaller, descending branches of the cochlear nerve. For detailed experimental analysis of the termination and distribution of primary cochlear afferents and a review, consult Osen (1970) and Kane (1974). The former demonstrated a tonotopical organization in the cochlear nuclei and connections (p. 958); both studies concern cats.

Many *ascending fibres* from the *ventral cochlear nucleus* (second neuron fibres in the auditory pathway) end in the dorsal trapezoid nucleus, either ipsilateral or contralateral. They are relayed and the tertiary fibres turn upwards as the *lateral lemniscus* (7.96, 230). Contralateral secondary fibres behave alike; decussations of contralateral fibres of both sides form the *trapezoid body* (7.230). *Efferent fibres* from the *dorsal cochlear nucleus* have similar connections (7.230), tertiary fibres ascending in both lateral lemnisci. Many cochlear efferents, mostly ipsilateral, relay in the superior olivary complex (p. 960); after relay these join both lateral lemnisci.

Each lateral lemniscus hence contains the axons of tertiary neurons from both sides; as they ascend to the midbrain some of these fibres, or their collaterals, synapse in a small group of cells, intimately related to the tract, the *nucleus of the lateral lemniscus*. Reaching the midbrain, some fibres of the lateral lemniscus end in the inferior colliculus, while others bypass it and enter the inferior brachium to reach the medial geniculate body, to be relayed to the auditory cortex (areas 41, 42 and 22). Ferraro & Minckler (1977) have estimated fibres in human lateral lemnisci at about 203 000 (right side) and 185 000 (left side), these being averages from 15 brains (newborn to 90 years).

Commissural fibres link the two auditory pathways at the inferior collicular level; auditory reflexes are mediated via the inferior colliculus to the superior colliculus and thence to the tectospinal and tectobulbar tracts and the medial longitudinal fasciculi (7.121, 230). An *efferent* component in acoustic pathways has also been noted (p. 1238); its peripheral fibres arise from neurons in or near the superior olivary complex (Rasmussen 1942, 1960), forming an *olivocochlear fasciculus* whose fibres terminate on and near hair cells of the cochlear spiral organ. The presence of sympathetic and possibly parasympathetic fibres in the vestibulocochlear nerves has received some support (Ross 1969). For further details of cochlear innervation, see p. 1238.

The vestibulocochlear nerve is soft in texture, its axons proximally ensheathed in *glial* cells. Leaving the medulla oblongata it crosses the posterior border of the middle cerebellar peduncle with the facial nerve, partially separated from the latter by the labyrinthine artery. Both nerves enter the internal acoustic meatus together. At the outer end of the meatus the vestibulocochlear nerve receives one or two filaments from the facial and splits into its *cochlear* and *vestibular* parts, the distribution of which will be described with the internal ear (pp. 1228, 1235–1241).

The Glossopharyngeal Nerve

The glossopharyngeal nerve (7.81, 86, 91, 232, 233) is both motor and sensory, supplying motor fibres to the stylopharyngeus, parasympathetic secretomotor fibres to the parotid gland and sensory fibres to the pharynx, tonsil and posterior (postsulcal) part of the tongue; it is also the gustatory nerve for this part of the tongue. It emerges as three or four rootlets from the rostral part of the medulla oblongata in a groove between the olive and the inferior cerebellar peduncle above the rootlets of the vagus nerve.

The sensory nuclei receive the central processes of unipolar neurons in the nerve's superior and inferior ganglia; fibres concerned with taste end in the *nucleus solitarius* (p. 954) and those concerned with common sensation probably terminate in the *spinal trigeminal nucleus* (Brodal 1947, and see p. 1099).

The motor nucleus, the rostral part of the *nucleus ambiguus* (pp. 956, 1114), is situated deep in the reticular formation of the medulla oblongata, connected with corticonuclear tracts of both sides both directly and through the interneurons; corticonuclear fibres leave their tract at the level of the nucleus ambiguus or in the pons to descend in the medial lemniscus (aberrant pyramidal fibres, p. 955). The glossopharyngeal part of the nucleus ambiguus sends its efferents to the stylopharyngeus.

Parasympathetic fibres join the nerve's motor part from a member of the general visceral efferent column, the *inferior salivatory nucleus* (see p. 961), located in the reticular formation below the superior salivatory nucleus; its fibres travel via the glossopharyngeal tympanic branch and the tympanic plexus (vide infra) to the lesser petrosal nerve and otic ganglion, where they relay; postganglionic fibres join the auriculotemporal nerve to reach the parotid gland (7.221) (cf. pp. 1067, 1292).

From the medulla oblongata the glossopharyngeal nerve passes anterolaterally to the triangular depression for the aqueductus cochleae, on the inferior surface of the petrous temporal bone. At first it lies under the flocculus, resting on the jugular tubercle of the occipital bone, sometimes grooving it. It then turns abruptly down, leaving the skull through the anteromedial part of the jugular foramen, anterior to the vagus and accessory nerves, in a separate dural sheath (7.231); in the foramen it is lodged in a deep groove leading from the cochlear aqueductual depression, separated by the inferior petrosal sinus from the vagus and accessory nerves; the groove is bridged by fibrous tissue, ossified in about 25% of skulls. After exit the nerve passes forwards between the internal jugular vein and internal carotid artery and then descends anterior to the latter, deep to the styloid process and its attached muscles, to reach the posterior border of the stylopharyngeus. It curves forwards on the stylopharyngeus and either pierces the lower fibres of the superior pharyngeal constrictor or passes between it and the middle constrictor (5.25) to be distributed to the tonsil, the mucosae of the pharynx and postsulcal part of the tongue, the vallate papillae, and oral mucous glands.

Two ganglia are situated on the nerve as it traverses the jugular foramen (7.231): superior and inferior.

The superior ganglion is in the upper part of the groove occupied by the nerve in the jugular foramen. It is small, has no branches and is usually regarded as a detached part of the inferior ganglion.

The inferior ganglion is larger and lies in a notch in the lower border of the petrous temporal bone (p. 379). Its cells are typical (pseudo-) unipolar neurons, whose peripheral branches convey gustatory and tactile signals from the mucosa of the tongue (posterior third including the sulcus terminalis and vallate papillae) and general sensory only from the oropharynx, soft palate and fauces.

The glossopharyngeal nerve communicates with the sympathetic trunk, vagus and facial nerves. The inferior ganglion is connected with the superior cervical sympathetic ganglion. Two filaments from the inferior ganglion pass to the vagus, one to its auricular branch and the other to its superior ganglion. A branch to the facial arises from the glossopharyngeal nerve below the inferior ganglion, perforating the posterior belly of the digastric to join the facial nerve near the stylomastoid foramen.

Branches of Distribution

These are: tympanic, carotid, pharyngeal, muscular, tonsillar and lingual.

The tympanic nerve leaves the inferior ganglion, ascends to the tympanic cavity through the inferior tympanic canaliculus (p. 379) and divides in the cavity into branches forming the **tympanic plexus**, contained in grooves on the surface of the promontory. This plexus supplies: (1) a branch to the greater petrosal nerve (p. 1110), (2) branches to the mucosa of the tympanic cavity, auditory tube and mastoid air cells, (3) a branch to the lesser petrosal nerve. For a critique of its final distribution and connections, see Winckler & Cochet (1967).

The lesser petrosal nerve contains parotid secretomotor fibres (vide infra). It enters a canal inferior to that for the tensor tympani, receives a connecting branch from the facial ganglion and reaches the anterior surface of the petrous bone through a small opening lateral to the hiatus for the greater petrosal nerve, passing thence via the foramen ovale or the canaliculus innominatus (p. 374) to join the otic ganglion.

The carotid branch, often double, arises just below the jugular foramen and descends on the internal carotid artery to the wall of the carotid sinus and to the carotid body (p. 341). It may communicate with the vagus (inferior ganglion or one of its branches) and with a sympathetic branch from the superior cervical ganglion. Another branch, either from the preceding or from the main trunk, joins a plexus which also supplies the carotid body; other branches to this plexus come from the sympathetic (superior cervical sympathetic ganglion) and vagus (p. 1116). For distribution of the carotid nerve consult Willis & Tange (1959) and p. 1473.

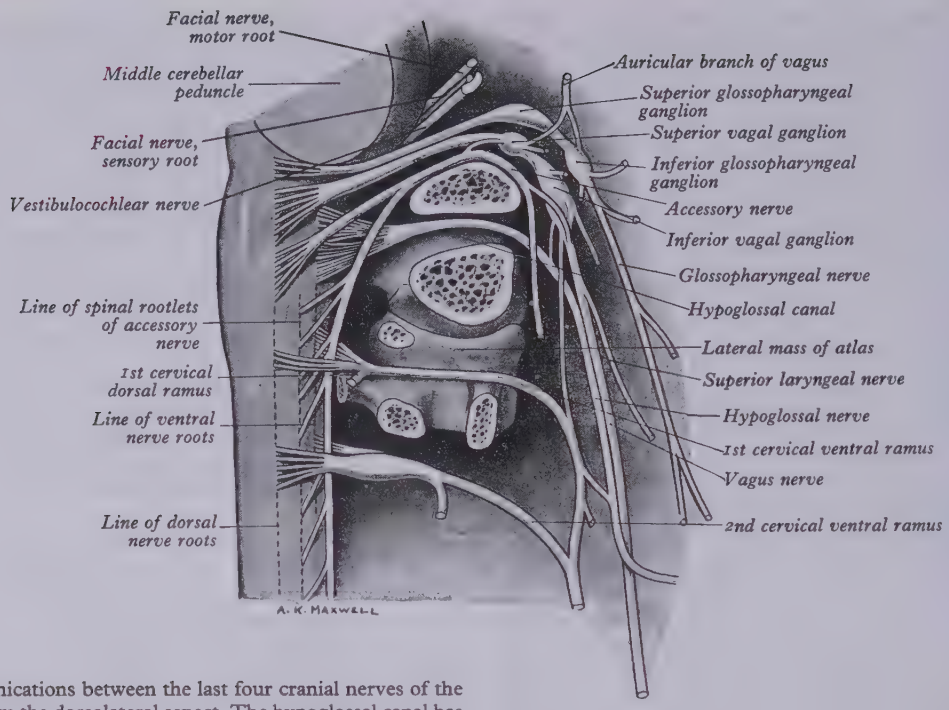
The pharyngeal branches are three or four filaments uniting, near the middle pharyngeal constrictor, with the pharyngeal branch of the vagus and the laryngopharyngeal branches of the sympathetic trunk to form a *pharyngeal plexus*, through which the glossopharyngeal nerve supplies sensory fibres to the pharyngeal mucosa.

The muscular branch supplies the stylopharyngeus.

Tonsilar branches form a plexus with branches of the middle and posterior palatine nerves around the tonsil; from this, filaments supply the tonsil, soft palate and fauces.

Of the two **lingual branches** one supplies the vallate papillae and mucosa near the sulcus terminalis (p. 1171), the other supplies the mucosa of the postsulcal (posterior) part of the tongue, communicating with the lingual nerve. It is the nerve of special sense (gustation) and general sensibility to the posterior lingual region.

The otic ganglion (7.223, 226, 184), a small, oval, flat reddish-grey ganglion, is situated just below the foramen ovale. It is a peripheral parasympathetic ganglion intimately related topographically to the mandibular nerve, but functionally connected with the glossopharyngeal. *Lateral* to it is the mandibular nerve near its junction with the trigeminal motor root, the ganglion usually surrounding the origin of the nerve to the medial pterygoid; *medial* is the tensor veli palatini, separating the ganglion from the cartilaginous auditory tube; *posterior* is the middle meningeal artery.



The *motor, parasympathetic root* of the otic ganglion is the lesser petrosal nerve, conveying preganglionic fibres from the glossopharyngeal nerve. These fibres originate from neurons in the inferior salivatory nucleus. They relay in the otic ganglion, postganglionic fibres passing by a *communicating branch* to the auriculotemporal nerve and so to the parotid gland (7.221). The *sympathetic root* is from the plexus on the middle meningeal artery; it contains postganglionic fibres, from the superior cervical sympathetic ganglion, which traverse the otic ganglion without relay; emerging with parasympathetic fibres in the connection to the auriculotemporal nerve, they supply blood vessels in the parotid gland.

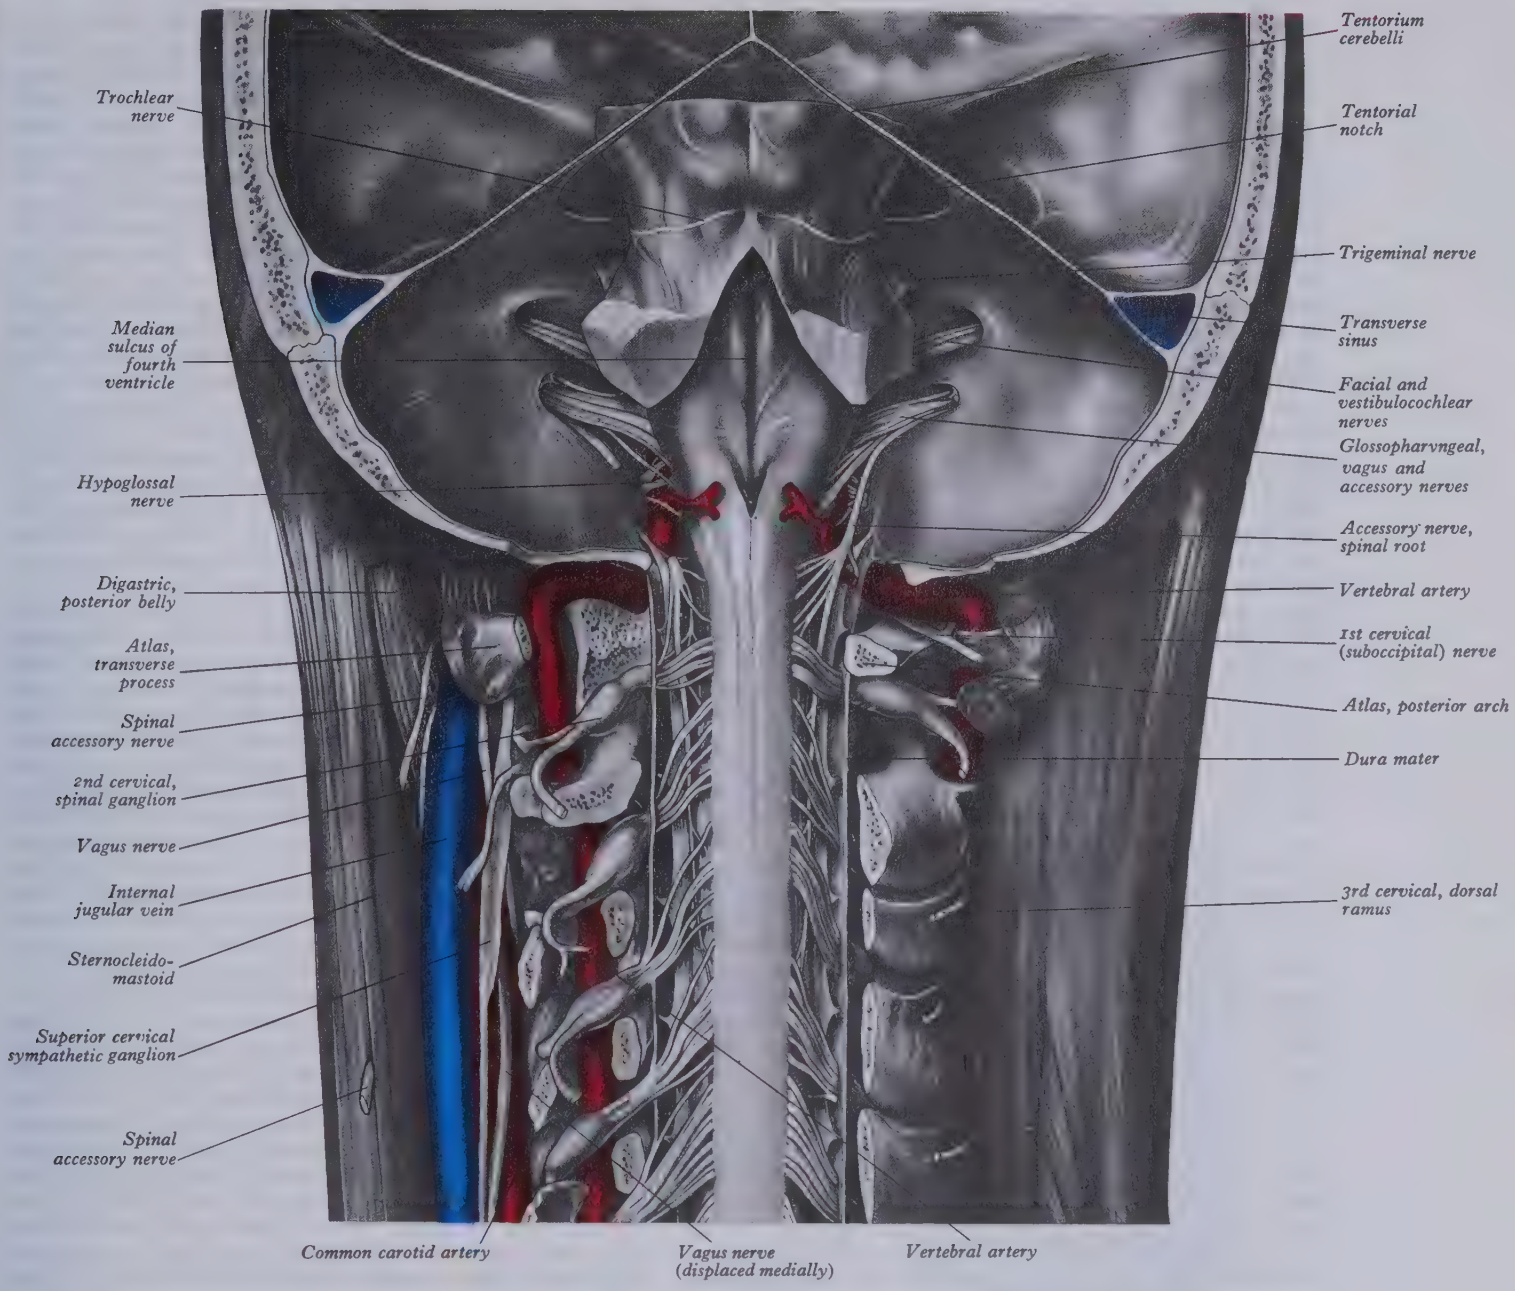
Branches. A twig connects the ganglion to the chorda tympani, another ascends to join the nerve of the pterygoid canal; these form, so some say, an additional pathway by which gustatory fibres from the presulcal area of the tongue may reach the facial ganglion without traversing the middle ear (p. 1171); they are not relayed in the otic ganglion. Motor branches (mandibular nerve) are supplied to the tensor veli palatini and tensor tympani, derived from the nerve to the medial pterygoid (p. 1104); they have no synapses in the ganglion.

The glossopharyngeal nerve is, approximately, the postrematic branch of the third branchial arch. The pretrematic branch of the second (hyoid) arch is probably the tympanic branch of the glossopharyngeal. Like the trigeminal and facial nerves, the glossopharyngeal corresponds to a dorsal nerve which has acquired special visceral efferent fibres.

The Vagus Nerve

The vagus nerve (7.81, 86, 87, 90–92, 231, 233) contains motor and sensory fibres and has a more extensive course and distribution than any other cranial nerve, traversing the neck,

7.231 The communications between the last four cranial nerves of the right side viewed from the dorsolateral aspect. The hypoglossal canal has been split in its long axis and the transverse process of the atlas has been divided close to the lateral mass. The descending branch of the hypoglossal nerve is not shown.



thorax and abdomen. It emerges as eight or ten rootlets from the medulla oblongata, below the glossopharyngeal nerve in the groove between the olive and the inferior cerebellar peduncle. It has four nuclei in the medulla oblongata. (1) **The dorsal nucleus** is usually described as a mixed nucleus, representing the fused general visceral efferent and general visceral afferent columns. It is sited in the central grey matter of the lower, closed part of the medulla oblongata and extends up into the open part, under the vagal triangle and separated from the hypoglossal nucleus by the nucleus intercalatus (p. 953). Its *motor fibres* are distributed to the non-striated muscle of the bronchi, heart, oesophagus, stomach, small intestine and part of the colon (p. 1155). Experiments, mainly based on retrograde degeneration, suggest patterns of localization in this visceral motor innervation (Szentágothai 1952, Mitchell & Warwick 1955, Lewis et al 1970, Rao & Sahu 1974) but the results are conflicting; moreover, the origin of vagal visceromotor nerve fibres is uncertain. Some observers (e.g. Kerr 1969) considered that most are derived from the nucleus ambiguus and nucleus retrofacialis (Szentágothai 1952). Sugimoto et al (1979) demonstrated that neurons innervating the heart originate in the nucleus ambiguus (and the reticular formation ventrolateral to it) by injection of horseradish peroxidase into the right cardiac vagal branches in cats. The particular *sensory fibres* which terminate in the nucleus are also uncertain. Though some regard the nucleus solitarius (p. 954) as predominantly a vagal nucleus, there is evidence that afferent fibres from the oesophagus and abdominal alimentary canal terminate in the dorsal vagal nucleus (p. 956). (2) Below the origin of the fibres joining the glossopharyngeal nerve, neurons of the **nucleus ambiguus** (p. 1113) contribute fibres to the vagus for distribution to skeletal muscle: the pharyngeal constrictors and intrinsic laryngeal muscles. It is connected to the corticonuclear tracts of both sides and to many brain stem centres (p. 1122). Detailed studies of the architecture and regional localization in the nucleus ambiguus of man and experimental animals (Szentágothai 1943, Getz & Sirnes 1949, Szabo & Dussardier 1964, Lawn 1966) have demonstrated that the nucleus ambiguus is divisible into subnuclei. Glossopharyngeal fibres arise from a rostral group; individual laryngeal muscles appear to be innervated by relatively discrete groups in more caudal zones; most caudally the ambigual neurons send axons into the cranial accessory nerve (p. 1118). (3) The caudal part of the **nucleus solitarius** (pp. 954, 1109) receives vagal fibres distributed through the internal laryngeal nerve to the taste buds of the epiglottis and vallecula. Its middle part receives visceral afferent fibres from the tongue, tonsil, palate and pharynx (glossopharyngeal nerve). The rostral part of the nucleus receives gustatory fibres from the presulcal part of the tongue and soft palate (facial nerve). (4) The vagus contains somatic afferent nerve fibres, believed to terminate in the **spinal trigeminal nucleus**.

Vagal rootlets unite to form a flat cord which passes below the flocculus to the jugular foramen, by which it leaves the cranium. As it emerges it accompanies the accessory nerve, sharing an arachnoid and dural sheath, a fibrous septum separating them from the glossopharyngeal nerve which lies anterior (7.231). Here the vagus has a well-marked enlargement, the *superior ganglion*. After exit from the jugular foramen it has a second swelling, the *inferior ganglion*.

The superior ganglion, greyish, spherical and about 4 mm in diameter, is joined by one or two delicate filaments to the cranial root of the accessory nerve, by a twig to the inferior glossopharyngeal ganglion, and to the sympathetic trunk by a filament from the superior cervical ganglion. Its auricular branch gives off an ascending twig to the facial nerve (p. 1110).

The inferior ganglion is cylindrical, reddish, about 2·5 cm long and is connected with the hypoglossal nerve, superior cervical sympathetic ganglion and a loop between the first and second cervical spinal nerves. The cranial root of the accessory nerve passes over it, attached only by fibrous tissue. Beyond the ganglion the cranial accessory blends with the vagus nerve, its fibres distributed mostly in pharyngeal and recurrent laryngeal vagal branches.

Both ganglia contain unipolar sensory neurons (Richardson & Hinsey 1933, Evans & Murray 1954), the only contrary evidence being from old and unconfirmed electrophysiological experiments and unsatisfactory histological observations, both refuted. (For discussion see Mitchell 1956, Lieberman 1968, 1969, 1974). There is no reliable evidence of any significant number of motor neurons in the ganglion, nor have synapses between pre- and postganglionic neurons been demonstrated in it. Preganglionic motor fibres from the dorsal vagal nucleus and the special visceral efferents from the nucleus ambiguus, which descend to the inferior

7.232 A dissection exposing the brain stem and the upper part of the spinal cord after removal of large portions of the occipital and parietal bones and the cerebellum, together with the roof of the fourth ventricle. On the left side the foramina transversaria of the atlas and the third, fourth and fifth cervical vertebrae have been opened to expose the vertebral artery. On the right side the posterior arch of the atlas and the laminae of the succeeding cervical vertebrae have been divided and have been removed together with the vertebral spines and the laminae of the opposite side. The tentorium cerebelli and the transverse sinuses have been divided and their posterior portions removed.

vagal ganglion, commonly form a visible band, skirting the ganglion in some mammals (Hoffman & Kuntz 1957, Mei & Dussardier 1966). It is necessary to emphasize these facts, because there is current in some textbooks an unsupported view that the vagal parasympathetic component relays in its inferior ganglion, based with questionable logic on the existence of many thinly myelinated and supposedly non-myelinated fibres in the distal parts of the nerve. Even were it valid to regard autonomic fibres as postganglionic purely on the degree of their myelination, to do so in this instance merely transgresses another tenet of peripheral autonomic morphology, for this view produces two relays: one in the inferior ganglion and one in the wall of the target organ. (See p. 1157 for alternative views.) Retrograde degeneration has been identified in the dorsal vagal nucleus by division of vagal branches as remote as the gastric nerves (Mitchell & Warwick 1955). Reliable analytical counts of nerve fibres in the human vagus nerve are not available; counts in other mammals do not favour the inferior ganglion as a relay station, a view based almost entirely on an adherence to the supposed axioms of autonomic morphology. The extensive factual information quoted above renders such a view untenable.

Both vagal ganglia are exclusively sensory, containing somatic, special visceral and general visceral afferent neurons. They are, however, traversed by parasympathetic and perhaps some sympathetic fibres. Their neurons are unipolar and bipolar (Cajal 1911, Evans & Murray 1954, Gabella 1976). The occurrence of multipolar neurons in the inferior ganglion has been suggested in the past but was strongly denied by Mitchell (1956) and Lieberman (1968); since they would almost certainly be parasympathetic postganglionic elements, their presence would imply double peripheral relay; further investigation is here required. Synapses between pre- and postganglionic neurons have not been reported. The general consensus is that all efferent fibres, special visceral (branchial) or parasympathetic preganglionic, pass uninterrupted

through both ganglia. (However, see comments on chromaffin cells below.) The disposition of somata and nerve fibres resembles that in spinal posterior root ganglia, the fibres being centrally disposed. The superior ganglion is described as grey, the inferior as pink, a difference which may reflect variation in the distribution of myelinated and non-myelinated fibres or of vessels.

The superior (jugular) ganglion is rounded and about 4 mm across in mankind. In cats (Foley & DuBois 1937) it contains about 8700 unipolar neurons, 73% of which appear to form the auricular nerve, a branch of the ganglion (p. 1117), while 15% contribute to the vagus itself. Counts are apparently not available for the human ganglion; but since the human vagus nerve contains, at mid-cervical level, about 16 500 (Rt) and 20 000 (Lt) myelinated fibres, counted in 17 paired nerves, human ganglionic neurons must be more numerous (Schnitzlein et al 1958). It is connected with the cranial root of the accessory nerve, the inferior glossopharyngeal ganglion and the superior cervical sympathetic ganglion. The significance of these connections is not clear but the first probably contains aberrant motor fibres from the nucleus ambiguus which issue in the accessory nerve, to be distributed to the palatal, pharyngeal, laryngeal and upper oesophageal musculature via the vagus; the sympathetic connection may be like the one between this sympathetic ganglion and the *inferior* vagal ganglion (vide infra). As it leaves the superior ganglion the auricular branch communicates with the facial nerve (p. 1110).

The inferior (nodose) ganglion is larger and elongate, about 25 mm in length and about 5 mm in maximum breadth. In cats (Jones 1937, Foley & DuBois 1937) it is estimated to contain about 30 000 neurons, most are unipolar or pseudo-unipolar but a few fusiform or bipolar; most are in the range of 35–40 μm in perikaryal dimensions but a few measure 20–30 μm (Mohiuddin 1953). Chromaffin cells have been observed (White 1935, Jacobs & Comroe 1951, Grillo et al 1974), which receive agranular synapses but display no efferent synapses. The ganglion is connected with the hypoglossal nerve (p. 1120), the loop between the first and second cervical spinal nerves (p. 1128) and with the superior cervical sympathetic ganglion (p. 1158); the last may be formed by the peripheral axons of sensory neurons resembling nodose ganglion cells, which have been described in this sympathetic ganglion by Terni (1922) as a group of displaced nodose ganglion neurons.

While neurons in the vagal ganglia have received less attention than those in the superior cervical sympathetic ganglion, extensive counts of fibres in the vagus and its periganglionic branches have been made (Gabella 1976). While overall counts show a general agreement, there are discrepancies in the estimated ratios between myelinated and non-myelinated fibres and between fibres of different diameters; both thinly-myelinated and non-myelinated fibres are numerous and while most are preganglionic parasympathetic, a few may be postganglionic sympathetic fibres. Though the feline superior vagal ganglion contains, according to DuBois & Foley (1937), about 8700 nerve cells, about 8800 fibres (chiefly small and non-myelinated) enter the auricular nerve and 1700–3500 continue into the vagus caudal to the superior ganglion. Many discrepancies of this kind await clarification and it would be unprofitable at present to quote further quantitative data. There is wide agreement that the superior ganglion is chiefly somatic, most of its neurons entering the auricular nerve, while neurons in the inferior ganglion are concerned with visceral sensation in the heart, larynx and lungs and the alimentary tract from the pharynx to the transverse colon. In addition, some fibres transmit impulses from taste endings in the vallecula and epiglottis.

Course

The vagus nerve descends vertically in the neck in the carotid sheath, between the internal jugular vein and the *internal* carotid artery to the thyroid cartilage's upper border and then passes between the vein and the *common* carotid artery to the root of the neck. Its further course differs on the two sides.

The *right* vagus nerve descends posterior to the internal jugular vein to cross the first part of the subclavian artery, entering the thorax and descending through the superior mediastinum, at first behind the right brachiocephalic vein, then right of the trachea and posteromedial to the right brachiocephalic vein and superior vena cava. The right pleura and lung are lateral to it above but are separated from it below by the azygos vein, which arches forwards above the right pulmonary hilum (**6**.164). The nerve then passes behind the right principal bronchus to the posterior aspect of the right hilum and divides into the posterior pulmonary (bronchial) branches, which unite with rami from the second to fifth or sixth thoracic sympathetic ganglia to form the **right posterior pulmonary plexus**. From the caudal part of this plexus two or three branches descend on the dorsal surface of the oesophagus, where, with a left vagal ramus, they form the **posterior oesophageal plexus**, from which a trunk is re-formed and continued posterior to the oesophagus to traverse the diaphragmatic oesophageal opening. This posterior vagal trunk contains fibres from both vagus nerves (p. 1118).

(Details of the **cardiac plexuses** are on pp. 1155, 1158, 1164.)

In the abdomen the **posterior vagal trunk** divides into a small gastric and a larger coeliac branch. The former supplies the postero-inferior gastric surface except the pyloric canal. The coeliac branch ends chiefly in the coeliac plexus but sends twigs to the splenic, hepatic, renal, suprarenal and superior mesenteric plexuses (p. 1165).

The *left* vagus enters the thorax between the left common carotid and subclavan arteries and behind the left brachiocephalic vein. It descends through the superior mediastinum and crosses the left side of the aortic arch to pass behind the left pulmonary hilum. Above the aortic arch it is crossed anterolaterally by the left phrenic nerve and on the arch by the left superior intercostal vein (**6**.30A). Behind the hilum it divides into the posterior pulmonary (or bronchial) branches, which unite with rami of the second to fourth thoracic sympathetic ganglia; this forms the **left posterior pulmonary plexus**, two branches of which descend anteriorly on the oesophagus forming, with a ramus from the right posterior pulmonary plexus, the **anterior oesophageal plexus**. From this a trunk containing fibres from both vagus nerves continues anterior to the oesophagus, entering the abdomen through the oesophageal diaphragmatic opening (p. 593).

In the abdomen the **anterior vagal trunk** supplies the cardiac antrum of the stomach and then divides into right and left branches. The left group follows the lesser gastric curvature to supply the stomach's anterosuperior surface. The right group has three main branches. The first, sometimes duplicated, proceeds between the layers of lesser omentum towards the porta hepatis, dividing into: (*a*) upper branches entering the porta, and (*b*) lower rami supplying chiefly the pyloric canal, pylorus, superior and descending parts of duodendum and the head of the pancreas. The second is distributed to the anterosuperior surface of the body of the stomach; the third branch follows the lesser curvature to the angular notch (see also p. 1355).

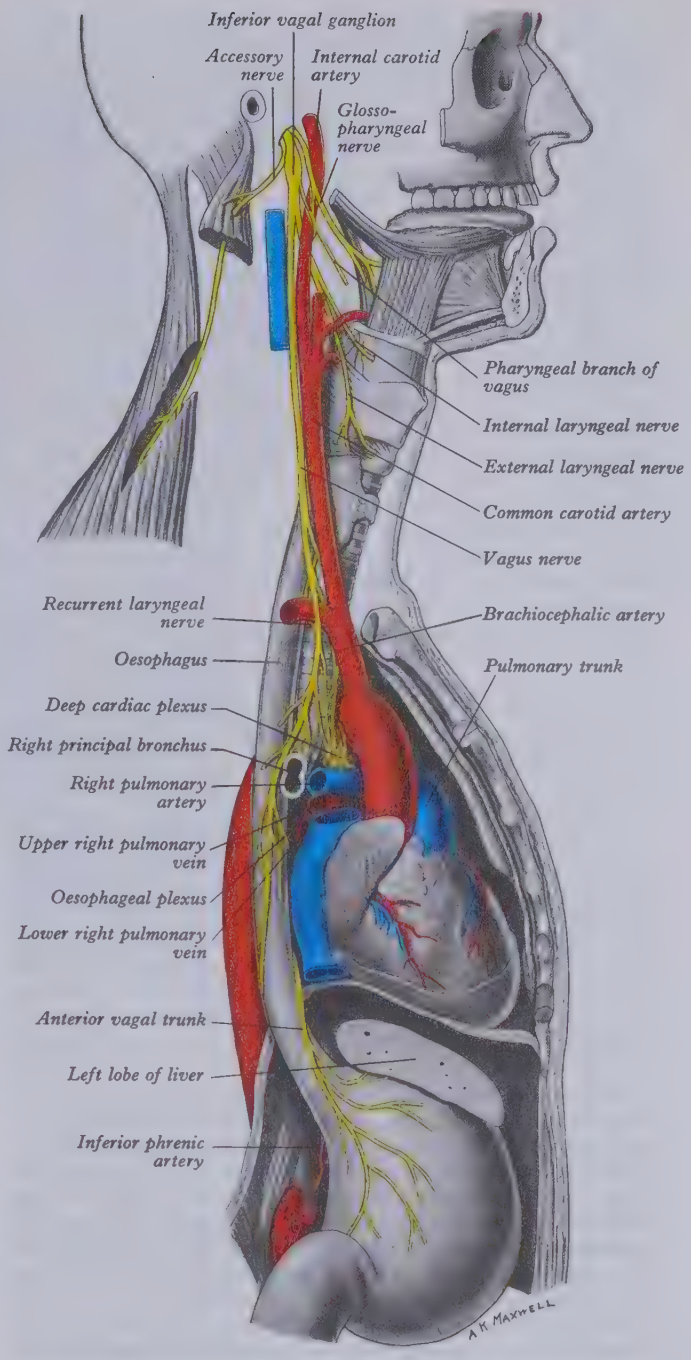
Branches of the Vagus Nerve

In the jugular fossa:	Meningeal
	Auricular
In the neck:	Pharyngeal
	Branches to carotid body
	Superior laryngeal
	Recurrent laryngeal (right)
	Cardiac
In the thorax:	Cardiac
	Recurrent laryngeal (left)
	Pulmonary
	Oesophageal
In the abdomen:	Gastric
	Coeliac
	Hepatic
	Renal

The meningeal branch or branches appear to start from the superior vagal ganglion and are distributed to the dura mater in the posterior cranial fossa. However, evidence suggests (Kimmel 1961a, b) that they are in fact recurrent sensory and sympathetic nerves from the upper cervical spinal nerves and superior cervical sympathetic ganglion, which run for a short distance in the sheath of the vagus nerve (pp. 1088, 1125).

The auricular branch also arises from the superior vagal ganglion and is joined soon after by a ramus from the inferior ganglion of the glossopharyngeal nerve. It passes behind the internal jugular vein and enters the mastoid canaliculus on the lateral wall of the jugular fossa. Traversing the temporal bone thus, it crosses the facial canal about 4 mm above the stylomastoid foramen and here supplies an ascending branch to the facial nerve. (Here fibres of the nervus intermedius may pass to the auricular branch, perhaps explaining the cutaneous vesiculation which sometimes accompanies geniculate herpes.) The auricular branch then traverses the tympanomastoid fissure, dividing into two rami: one joining the posterior auricular nerve and the other distributed to the skin of part of the cranial auricular surface and to the posterior wall and floor of the external acoustic meatus and adjoining part of the outer surface of the tympanic membrane. The vagal auricular branch thus contains *somatic afferent* nerve fibres, which probably terminate in the spinal trigeminal nucleus.

The pharyngeal branch, the main motor nerve of the pharynx, emerges from the upper part of the inferior vagal ganglion and consists chiefly of filaments from the cranial accessory nerve. It passes between the external and internal carotid arteries to the upper border of the middle pharyngeal constrictor, dividing into numerous filaments which join rami of the sympathetic trunk and glossopharyngeal and external laryngeal nerves to form a *pharyngeal plexus*, by which vagal fibres are distributed to the pharyngeal and palatal muscles, except the tensor veli palatini. A minute filament, the *ramus lingualis vagi*, joins the hypoglossal nerve as it curves round the occipital artery.



Branches to the carotid body (p. 1473), variable in number, may arise from the inferior ganglion or travel in either the pharyngeal branch or the superior laryngeal nerve, though rarely in the latter. They form a plexus with the glossopharyngeal rami and branches of the cervical sympathetic trunk (Sheehan et al 1941, also pp. 1113, 1158).

The superior laryngeal nerve, larger than the pharyngeal branch, issues from the middle of the inferior vagal ganglion and receives a branch from the superior cervical sympathetic ganglion. It descends alongside the pharynx, first posterior, then medial to the internal carotid artery, and divides into the internal and external laryngeal nerves. The human nerve contains about 15 000 fibres (Ogura & Bello 1952).

The *internal laryngeal nerve* is sensory to the laryngeal mucosa down to the level of the vocal folds. It also carries afferent fibres from the laryngeal neuromuscular spindles and other stretch receptors (Keene 1961, Schever 1964). It descends to the thyrohyoid membrane, pierces it above the superior laryngeal artery and divides into an upper and lower branch; the upper is horizontal and supplies the mucosa of pharynx, the epiglottis, vallecula and laryngeal vestibule; the lower descends in the medial wall of the piriform recess, supplying the aryepiglottic fold, the mucosa on the back of the arytenoid cartilage and one or two branches to the arytenoideus, which unite with twigs from the recurrent laryngeal to supply the same muscle (p. 1258). The internal laryngeal nerve ends by piercing the inferior constrictor muscle to unite with an ascending branch from the recurrent laryngeal. Past observers (see Latarjet 1947, for citations) have described small ganglia on the superior and internal laryngeal nerves. Ramaswamy (1974) has revived this description, describing a ganglion on the internal laryngeal nerve in more than 100 human larynges. Cells in the ganglia were described but without photographic confirmation.

The *external laryngeal nerve*, smaller than the internal, descends posterior to the sternothyroid with the superior thyroid artery but on a deeper plane; it lies at first on the inferior pharyngeal constrictor and then, piercing it, curves round the inferior thyroid tubercle to reach and supply the cricothyroid. It also supplies the pharyngeal plexus and inferior constrictor; behind the common carotid artery it connects with the superior cardiac nerve and superior cervical sympathetic ganglion (Skórnicki et al 1968).

The recurrent laryngeal nerve differs, in origin and course, on the two sides. On the *right* it arises from the vagus anterior to the first part of the subclavian artery, curving backwards below and then behind it to ascend obliquely to the side of the trachea behind the common carotid artery. Near the lower pole of the thyroid lateral lobe it is near the inferior thyroid artery, crossing *either* in front of or behind it, or between its branches. On the *left*, the nerve arises from the vagus on the left of the aortic arch, curves below it immediately behind the attachment of the ligamentum arteriosum to the arch's concavity and ascends to the side of the trachea. On both sides the recurrent laryngeal nerve ascends in or near a groove between the trachea and oesophagus and is closely related to the medial surface of the thyroid gland before passing under the lower border of the inferior constrictor to enter the larynx behind the articulation of the inferior thyroid cornu with the cricoid cartilage. It supplies all laryngeal muscles, except the cricothyroid; it communicates with the internal laryngeal nerve, supplying sensory filaments to the laryngeal mucosa below the vocal folds. It also carries afferent fibres from laryngeal stretch receptors.

7.233 The course and distribution of the glossopharyngeal, vagus and accessory nerves.

As the recurrent laryngeal nerve curves round the subclavian artery, or the aortic arch, it gives cardiac filaments to the deep cardiac plexus. As it ascends in the neck it supplies branches, more numerous on the left, to the mucosa and tunica muscularis of the oesophagus and trachea and to the inferior constrictor.

The varying relations of the recurrent laryngeal nerves near the larynx are important in thyroid surgery (Bowden 1955, Doyle et al 1967). The nerve does not always lie in a protected position in the tracheo-oesophageal groove but may be slightly anterior to it (more often on the right) and it may be markedly lateral to the trachea at the level of the lower part of the thyroid gland. On the right the nerve is as often anterior to, or posterior to, or intermingled with terminal branches of the inferior thyroid artery, while on the left the nerve is usually posterior to the artery, though occasionally anterior to it. The nerve may supply extralaryngeal branches to the larynx, arising before the nerve passes behind the inferior thyroid cornu. Outside its capsule the thyroid gland has a distinct covering of pretracheal fascia (p. 583), which splits into two layers at the posterior border of the gland. One layer covers the entire medial surface of its lobe and, at or just above the isthmus, has a conspicuous thickening, the *lateral ligament* of the *thyroid gland* (p. 1459) which attaches the gland to the trachea and the lower part of the cricoid cartilage. The other layer is posterior, passing behind the oesophagus and pharynx and attached to the prevertebral fascia. By this splitting of the fascia, a compartment is formed on each side, lateral to the trachea and oesophagus, and it is in the fat that this contains that the recurrent laryngeal nerve and terminal parts of the inferior thyroid artery lie. The nerve may be lateral or medial to the lateral ligament of the thyroid gland, or sometimes may be embedded in it.

The cardiac branches, two or three in number, arise from the vagus at superior and inferior cervical levels. The small *superior branches* join sympathetic cardiac branches and reach the deep cardiac plexus. The *inferior branches* arise in the root of the neck, the right passing in front or by the side of the brachiocephalic artery to the deep cardiac plexus, the left descending across the left side of the aortic arch to join the superficial cardiac plexus. Additional cardiac branches arise from the right vagus nerve near the trachea and from both recurrent laryngeal nerves, ending in the deep cardiac plexus. The cardiac plexuses are described on p. 1164.

The anterior pulmonary branches, two or three in number, and small, reach the anterior surface of the hilum of the lung, forming with sympathetic rami the *anterior pulmonary plexus*.

The posterior pulmonary branches, more numerous and larger, pass behind the hilum, forming with sympathetic rami from the second to fifth or sixth thoracic sympathetic ganglia the *posterior pulmonary plexus*, branches from which accompany the bronchial ramifications and supply the constrictor muscles and other tissues of the pulmonary tree (pp. 1165, 1271, 1285).

The oesophageal branches arise above and below the pulmonary, the lower being numerous and larger. They form the *oesophageal plexus*, from which filaments supply the oesophagus and the back of the pericardium (p. 1116).

The gastric branches supply the stomach's anterosuperior surface (mainly from the left vagus) and postero-inferior surface (mainly from the right) (p. 1165). Brizzi et al (1973) described separate 'cardiac' branches to the cardia; they found that both gastric branches supplied the fundus and body, while the pylorus received a complex innervation mainly from the anterior gastric nerve and vagal hepatic branches, less frequently from the posterior gastric nerve. Both anterior and posterior gastric nerves lie within the hepatogastric ligament, respectively anterior and posterior to the peri-arterial nerves that surround the left gastric artery (Mackay & Andrews 1983).

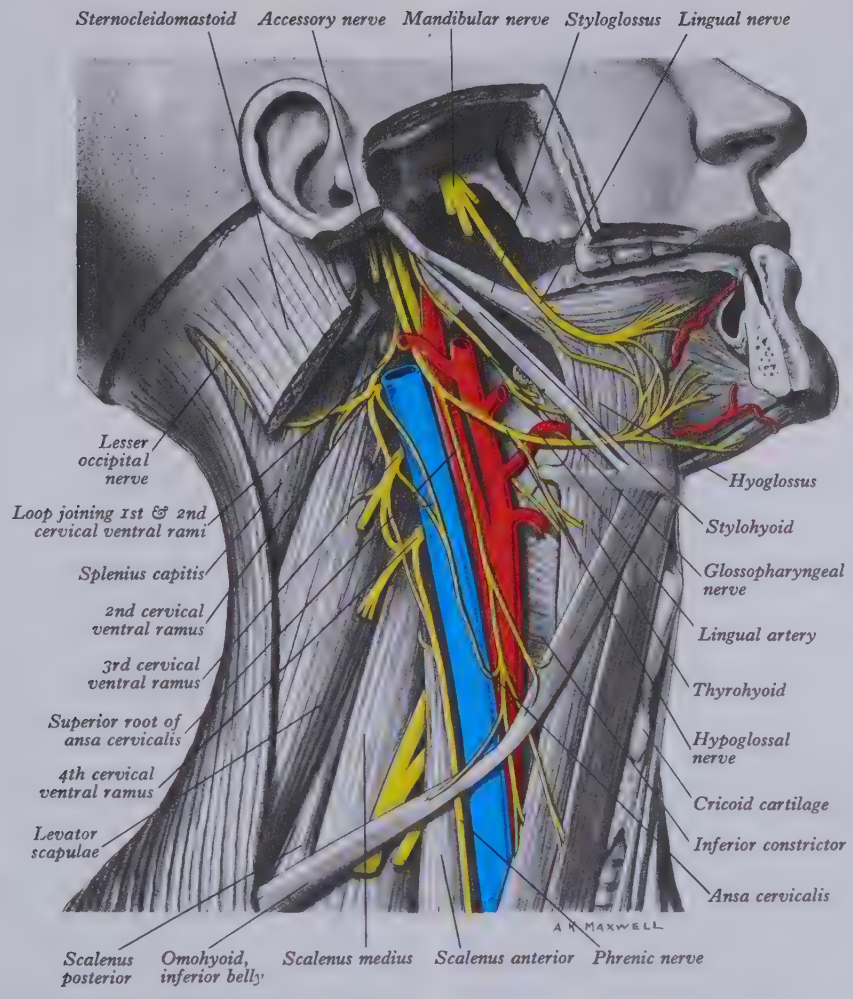
The coeliac branches of the posterior vagal trunks join the coeliac plexus.

The hepatic branches from both vagi (p. 1165) join the hepatic plexus and supply the liver.

The renal branches, also from both nerves, join the renal plexus (p. 1165).

For details of the abdominal distribution of the vagus nerves, see pp. 1156, 1165, 1166.

Applied Anatomy. The vagus is not often injured but its functions may be affected by damage to its nuclei in the medulla oblongata or in its intracranial course. The effects include palpitation, tachycardia, vomiting, slowing of respiration and a sensation of suffocation.



Abnormal 'reflexes' in connection with the vagus may occur. The 'ear cough' is perhaps the commonest, where wax in the external acoustic meatus may irritate receptors of the auricular nerve, producing a persistent cough. Syringing the meatus often excites coughing and in children vomiting may occur. Syringing the ear has occasionally caused fatal reflex cardiac inhibition. Another example is persistent cough due to enlarged bronchial lymph nodes in children, irritating the recurrent laryngeal nerve. When peripheral terminations of the superior laryngeal nerve are irritated by a foreign body, reflex spasm of the glottis results. When the nerve is out of action, anaesthesia of the upper laryngeal mucosa ensues, so that foreign bodies can easily enter the larynx; since the nerve supplies the cricothyroid, the vocal folds cannot be tensed; the voice is deep and hoarse. Irritation of the recurrent laryngeal nerves produces spasm of the laryngeal muscles. When both recurrent laryngeal nerves are interrupted, the vocal folds are motionless, and are in the so-called 'cadaveric position', i.e. neither closed as in phonation, nor widely open as in deep inspiratory efforts. When only one nerve is affected, its vocal fold is motionless, the opposite fold crossing the median plane; hence phonation is possible but the voice is weak. In progressive lesions of the recurrent laryngeal nerve abduction of the vocal folds is abolished before adduction; conversely, during recovery, adduction returns before abduction (*Semon's law*). There is no direct evidence that nerve fibres to the abductor muscles have any special grouping in the recurrent laryngeal nerve.

The Accessory Nerve

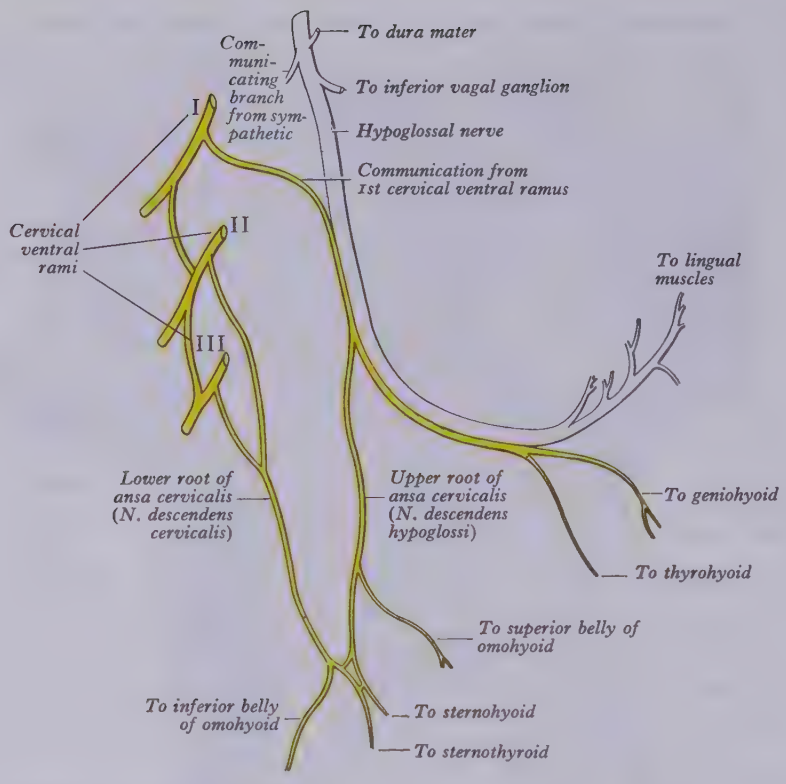
The accessory nerve (7.86, 87, 231–233) is formed by the union of its cranial and spinal roots but these are associated for a short distance only. The cranial part joins the vagus and should really be considered part of it; it is a branchial or special visceral efferent nerve. The spinal 'root' may be considered as somatic, special visceral efferent or mixed, depending on the view taken of the embryological origin of the sternocleidomastoid and trapezius, which it supplies. The custom of describing the two parts as a single cranial nerve has been followed here. The spinal part is usually assumed to be purely motor, but evidence for the presence of afferent fibres is provided by the occurrence of ganglia on the nerve in prenatal and early postnatal human material (Pearson et al 1964); the nerve may also communicate with the dorsal roots of the upper cervical spinal nerves, although such observations are unconfirmed in adult material.

The cranial root is the smaller, arising from caudal neurons of the **nucleus ambiguus** (p. 1114) and possibly also of the **dorsal vagal nucleus**. The former is connected with corticonuclear tracts of *both* sides, some fibres from this source descending from the midbrain in the medial lemniscus (aberrant pyramidal fibres, p. 955). The cranial root emerges as four of five fine rootlets from the side of the medulla oblongata below the vagal roots; it runs laterally to the jugular foramen, perhaps interchanging fibres here with the spinal root, with which it unites for a short distance; it also connects with the superior vagal ganglion. It traverses the foramen, separates from the spinal part and continues over the inferior vagal ganglion, to which it adheres. It is distributed mainly in the pharyngeal and recurrent laryngeal branches of the vagus and is probably the source of the vagal motor fibres which run in the pharyngeal branch to the palatal muscles, except the tensor veli palatini. Some filaments continue into the vagus below the ganglion, to be distributed with the recurrent laryngeal and possibly the cardiac nerves.

The spinal root arises from a column of motor neurons, *the spinal nucleus*, located lateral in the spinal anterior grey column and descending as far as the fifth cervical segment (p. 927). Traversing the lateral white columns of the spinal cord, the fibres emerge midway between the upper cervical ventral and dorsal spinal roots (7.231), forming a trunk ascending between the

7.234 A dissection to show the general distribution of the right hypoglossal and lingual nerves and the position and constitution of some parts of the cervical plexus of the right side.

ligamentum denticulatum and dorsal spinal roots to enter the skull via the foramen magnum, behind the vertebral artery (7.232). It then turns up and laterally to the jugular foramen, traversing this in a single dural sheath with the vagus but separated from it by a fold of the arachnoid mater. In the foramen it may receive one or two rami from the cranial root or join it for a short distance. At its exit from the foramen it runs posterolaterally, usually posterior to the internal jugular vein but anterior in about one-third of subjects; rarely it passes through the vein. Here the nerve crosses the transverse process of the atlas and is itself crossed by the occipital artery. It then descends obliquely, medial to the styloid process, stylohyoid and posterior belly of the digastric. With the superior sternocleidomastoid branch of the occipital artery it reaches the upper part of the sternocleidomastoid and enters its deep surface, joining branches of the second cervical spinal nerve in supplying it. Emerging a little above the midpoint of the muscle's posterior border it crosses the posterior triangle on levator scapulae (7.228), separated from it by the prevertebral layer of deep cervical fascia and adipose tissue. Here it is comparatively superficial, is related to the superficial cervical lymph nodes, and receives rami of the second and third cervical spinal nerves (Raveau 1968). About 5 cm above the clavicle it passes behind the anterior border of the trapezius, forming a plexus on its deep surface with branches of the third and fourth cervical nerves. From this plexus the trapezius is innervated. The nerve's cervical course follows a line from the lower anterior part of the tragus to the tip of the atlantal transverse process and then across the sternocleidomastoid and the posterior triangle to a point on the anterior border of the trapezius 5 cm above the clavicle. For the significance of the double innervation of the trapezius and sternocleidomastoid see McKenzie (1955) and p. 584.



The cranial and spinal roots, after separating, are also known respectively as the *internal* and *external rami* of the accessory nerve. The spinal root is accepted to be the sole motor supply to the sternocleidomastoid, the second and third cervical nerves conveying proprioceptive fibres from it. The innervation of the trapezius is less certain; some consider the third and fourth cervical spinal supply as purely proprioceptive but others consider that they supply motor fibres to the muscle's lower part.

Applied Anatomy. The functions of the accessory nerve may be affected by central changes or at its cranial exit by fractures across the jugular foramen or by cervical lymphadenitis. Acute torticollis in children is usually due to the latter; central irritation causes clonic spasm of the sternocleidomastoid and trapezius, termed spasmodic torticollis. When all palliative treatment fails, division or partial excision of the nerve may be performed. Where extensive dissection is necessary in the posterior triangle, the nerve should be isolated at the outset from diseased nodes.

The Hypoglossal Nerve

The hypoglossal nerve (7.86, 87, 234, 235) is motor to all the muscles of the tongue, except the palatoglossus (p. 1290); it lies in series with the oculomotor, trochlear and abducent nerves and the ventral nerve roots of the spinal nerves and represents the fused ventral roots of probably four precervical or spino-occipital nerves whose dorsal roots have disappeared.

The hypoglossal nucleus is in line with the spinal anterior grey column. It is about 2 cm long, its rostral part corresponding with the hypoglossal triangle in the floor of the fourth ventricle (p. 980), its caudal part extending into the closed part of the

7.235 A plan of the right hypoglossal nerve and ansa cervicalis.

medulla oblongata, where it is ventral and paramedial in the central grey matter (7.89). Its fibres pass ventrally through the medulla to emerge as a linear series of 10–15 rootlets in the anteriolateral sulcus between the pyramid and olive (7.81).

The hypoglossal nucleus is divided longitudinally into dorsal and ventral laminae, each subdivisible into a mediolateral sequence of relatively discrete subnuclei, considered to correspond to individual muscles (Kosaka & Yagita 1903, Sturman 1916, Barnard 1940). More recently, Jansen & Korneliussen (1977) have described division into four columns in Cetacea, suggesting that these correspond to four occipitocervical somites and hence, perhaps, to individual lingual muscles.

Connections and Course

The hypoglossal nucleus receives corticonuclear fibres from the precentral gyrus and adjacent areas of mainly the *contralateral* hemisphere, some fibres leaving the tract in the pons to travel in the medial lemniscus; they connect with the nucleus directly or via internuncial neurons. Evidence indicates that the most medial subnuclei receive projections from *both* hemispheres. The nucleus may connect with the cerebellum via adjacent perihypoglossal nuclei (Torvik & Brodal 1954, p. 953) and perhaps also with the medullary reticular formation, the trigeminal sensory nuclei and the solitary nucleus.

The hypoglossal rootlets run laterally behind the vertebral artery, collected into two bundles which perforated the dura mater separately opposite the hypoglossal (anterior condylar) canal in the occipital bone, uniting after traversing it; the canal is sometimes divided by a bony spicule. The separate dural sheaths confirm the nerve's composite character. It emerges from its canal in a plane medial to the internal jugular vein, internal carotid artery, ninth, tenth and eleventh cranial nerves and passes inferolaterally behind the internal carotid artery, glossopharyngeal and vagus nerves to the interval between the artery and the internal jugular vein. Here it makes a half-spiral turn round the inferior vagal ganglion, being united with it by connective tissue. It then descends almost vertically between the vessels and anterior to the vagus to a point level with the mandibular angle, becoming superficial below the posterior belly of the digastric and emerging between the internal jugular vein and internal carotid artery. It loops round the inferior sternocleidomastoid branch of the occipital artery (p. 736), crosses lateral to both internal and external carotid arteries and the loop of the lingual artery a little above the tip of the greater cornu of the hyoid (7.234) and is itself crossed by the facial vein. It inclines up and forwards on the hyoglossus, passing deep to the digastric tendon, stylohyoid and the posterior border of the mylohyoid. Between the hyoglossus and mylohyoid the nerve is inferior to the deep part of the submandibular gland, submandibular duct and lingual nerve. It then passes on to the lateral aspect of the genioglossus, continuing forwards in its substance as far as the tip of the tongue and distributing fibres to the muscle.

The hypoglossal nerve communicates with the sympathetic trunk, vagus, first and second cervical nerves and lingual nerve. Near the atlas it is joined by branches from the superior cervical sympathetic ganglion and by a filament from the loop between the first and second cervical nerves which leaves the hypoglossal as the *upper root* of the *ansa cervicalis* (7.215). The vagal connections occur close to the skull, numerous filaments passing between the hypoglossal nerve and the inferior vagal ganglion in the connective tissue uniting them. As the hypoglossal nerve curves round the occipital artery it receives from the pharyngeal plexus the *ramus lingualis vagi* (p. 1117). Near the anterior border of hyoglossus it is connected with the lingual nerve by many filaments ascending on the muscle (p. 1105).

Branches

The branches of distribution of the hypoglossal nerve are: meningeal, descending, thyrohyoid and muscular.

The meningeal branch or branches leave the hypoglossal nerve in its canal, returning through it to supply the diploë of the occipital bone, the dural walls of the occipital and inferior petrosal sinuses and much of the floor and anterior wall of the posterior cranial fossa. These meningeal rami (pp. 1088, 1158) may not contain hypoglossal fibres but ascending, mixed sensory and sympathetic fibres from the upper cervical nerves and superior cervical sympathetic ganglion (Kimmel 1961a, b).

The descending branch (descendens hypoglossi or upper root of the ansa cervicalis) leaves the hypoglossal nerve where it curves round the occipital artery and then descends anterior to or

in the carotid sheath. It contains only fibres from the first cervical spinal nerve. After giving a branch to the superior belly of the omohyoid, it is joined by the ansa's *lower root* from the second and third cervical spinal nerves. The two roots form the *ansa cervicalis* (*ansa hypoglossi*), from which branches supply the sternohyoid, sternothyroid and the inferior belly of the omohyoid; another branch is said to descend anterior to the vessels into the thorax to join the cardiac and phrenic nerves.

The nerves to the thyrohyoid and geniohyoid arise near the posterior border of the hyoglossus and cross obliquely the greater cornu of the hyoid to supply the thyrohyoid and geniohyoid; they contain fibres of the first cervical spinal nerve.

Muscular branches are distributed to the styloglossus, hyoglossus and genioglossus. Numerous slender rami ascend into the tongue to supply its intrinsic muscles; all contain true hypoglossal fibres.

Applied Anatomy. Complete hypoglossal division causes unilateral lingual paralysis and hemiatrophy; the protruded tongue deviates to the paralysed side; on retraction, the wasted and paralysed side also rises higher than the unaffected side. The larynx may deviate towards the active side in swallowing, due to unilateral paralysis of the hyoid depressors. If paralysis is bilateral, the tongue is motionless. Taste and tactile sensibility are unaffected but articulation is slow and swallowing very difficult.

MORPHOLOGY OF THE CRANIAL NERVES

It is now possible to group cranial nerves to conform with their phylogenetic history, components and functions.

Group I includes the oculomotor, trochlear, abducent and hypoglossal nerves. All arise from neurons of the somatic efferent column and are distributed to musculature derived from the *cranial myotomes*. They therefore correspond to *ventral* spinal roots and, with the exception of the trochlear, they emerge from the brain stem in line with them. The identification of the segments with which each nerve is associated presents great problems and is at present beyond experimental or any other type of proof; even the number of cephalic segments is uncertain (p. 139).

Group II includes the trigeminal, facial, glossopharyngeal, vagus and accessory nerves, which innervate the derivatives of the *branchial arches* but differ from the spinal nerves in having motor roots distributed to musculature derived from the *neural crest* (p. 136) and *lateral plate mesoderm* of the branchial region. Some (trigeminal, vagus and accessory) are compound nerves, formed by the fusion of two or more dorsal nerves (p. 1092); in this process cutaneous branches, originally connected with facial, glossopharyngeal and vagus nerves, have been absorbed into the trigeminal; hence these three cranial nerves differ much in humans from their homologues in the lower vertebrates and even more from the dorsal roots of spinal nerves.

Due to this complexity each nerve may possess more than one nucleus of origin and of termination. Neurons of the facial, inferior glossopharyngeal and inferior vagal ganglia, though derived largely from the neural crest, originate partly in *ectodermal epibranchial placodes* developed at the dorsal ends of the first three branchial clefts close to the ganglia (p. 200).

Despite some discrepancies, the homologies of nerves in Groups I and II are generally accepted; but those of the three remaining cranial nerves are entirely uncertain. In its mode of development the optic nerve is unlike other cranial nerves, except for its *special somatic afferent* function; the retinal sources of its fibres are really an outlying part of the brain, although it may be argued that they are derivatives of precursors of neural crest cells. The olfactory and vestibulocochlear nerves may be grouped together or separated, only the vestibulocochlear being considered as the homologue of a dorsal nerve. Both arise, in part at least, from ectodermal cells outside the neural tube and crest; but whereas olfactory neurons remain amongst the epithelial cells of the nasal mucous membrane, the cochlear neurons migrate away from the otic vesicle. Nevertheless, many believe that the contribution made by the neural crest is responsible for both the vestibular and spiral cochlear ganglia and hence consider the vestibulocochlear to be a modified dorsal nerve. In comparing the olfactory and vestibulocochlear nerves it must be remembered that olfactory nerves are restricted to the head, whereas the human vestibulocochlear nerve is the survivor of a series of nerves from lateral line organs, distributed in fish not merely to the head but to the whole length of the body.

For discussion of the phylogeny of vertebrate cranial nerves consult Black (1917), Herrick (1922), Bolk et al (1934), Kappers et al (1936), Kappers (1947), Young (1950), Grassé (1954), Goodrich (1958).

General Considerations of Cranial Nerves

Because of the brain stem's complex structure, changing from level to level, in which many neuronal groups and pathways exist, the difficulties of investigation of this area of the nervous system are great and the finer details of the cranial nerve nuclei are less certain than are the origins of spinal nerves. The descriptions of the site, structure and connections of many cranial nuclei in anatomical texts often convey a misleading simplicity. It may therefore be useful to summarize some of the concepts concerning their organization which are either emerging or are suspected by analogy with spinal cord organization; it must be noted, however, that much has not been established with certainty in primate brains. The olfactory, optic and vestibulocochlear nerves are considered elsewhere.

The motor nuclei of cranial nerves include somatic efferent, special visceral efferent (branchiomotor) and general visceral efferent (autonomic) groups. However, somatic and special visceral efferent nuclei of the oculomotor, trochlear, trigeminal, abducent, facial, glossopharyngeal, vagus, accessory and hypoglossal nerves may be grouped together, since all innervate *skeletal muscle*. Spinal ventral grey matter forms a series of longitudinal columns of neurons, whose significance is uncertain (p. 929), though they exhibit some somatotopic organization. They include α, β, and γ motor neurons (p. 939) innervating extrafusal and intrafusal muscle fibres; the α motor neurons to extrafusal muscle are of 'tonic' and 'phasic' types, 'static' and 'dynamic' types of fusimotor γ neurons being also recognized. Among these motor neurons are many small excitatory and inhibitory interneurons, the latter including the so-called Renshaw cells. Converging on these cell varieties are numerous fibres, completing a wide array of local control loops, both contralateral and ipsilateral, and others descending from supraspinal sources such as the vestibular nuclei, brain-stem reticular formation, red nucleus, midbrain tectum and tegmentum and the cerebral cortex. These regions, which project directly to the lower motor centres, themselves receive essential control fibres from the cerebellum, corpus striatum, thalamus and hypothalamus and many parts of the cerebral neocortex and limbic system. All are detailed elsewhere. Despite uncertainties about the central connections of cranial nerves, it is probable that comparable controls operate in all cases; in view of the precise motor integrations necessary in phonation and ocular activity, their connections may well be of a *higher* order of complexity than those at spinal levels.

The trochlear and abducent nerves each innervate a single small muscle and, reflecting this, their motor nuclei are single small groups of neurons. In contrast, the oculomotor, trigeminal, facial and hypoglossal nerves and the glossopharyngeal-vagus-

cranial accessory complex innervate musculature capable of highly precise patterns of movement and in each case their nuclei contain subnuclei perhaps related to major branches or even innervation of single muscles. Some subnuclei show a longitudinal columnar arrangement, the columns varying in their mediolateral and dorsoventral location and in their axial extent. This somatotopic localization is reminiscent of that in spinal ventral grey columns. Though precision of control may be in some way associated with such grouping (p. 929), the ontogenetic, phylogenetic and functional significance of these groups require further exploration. Also, much less is known than in the spinal cord concerning the quantitative degrees of longitudinal and transverse overlap of the *dendritic trees* of motor neurons in adjacent motor nuclei and subnuclei. Though muscle spindles were long considered to be absent or rare in facial, masticatory, lingual, laryngeal and ocular muscles, they have now been confirmed in most of these sites (facial muscles having the least); but the siting and functions of their γ efferent neurons are obscure. Similar uncertainty exists concerning smaller multipolar neurons in or near cranial nerve motor nuclei, many of which are presumably excitatory or inhibitory interneurons, including 'Renshaw' cells.

The afferent connections of cranial nerve motor nuclei include components corresponding to all those converging on spinal grey matter, but some are merely recognized in outline. The best known are: (1) the *medial longitudinal fasciculus*, interconnecting the vestibular nuclei, a longitudinal series of other cranial nerve nuclei and the cervical spinal cord (p. 985); (2) *tectotegmental*, *tectopontine* and *tectobulbar* projections from the superior and inferior colliculi (p. 986); (3) projections from the *red nucleus* (p. 983); (4) interconnections with the *brain-stem reticular formation* (p. 988); (5) *corticonuclear* projections from cerebral sensorimotor areas (p. 1049); (6) projections from *sensory nuclei* of other cranial nerves. However, little is known of how these afferents terminate: e.g. whether directly on α and/or γ motor neurons or through interneurons, and how far they mediate pre- or postsynaptic facilitatory or inhibitory effects. In cortico*spinal* tracts (p. 933) contralaterally-derived fibres predominate, with a variable ispilateral content. Similar considerations apply to cranial nerve motor nuclei. Thus, although mainly *contralateral*, cortico*nuclear* fibres reach most of the hypoglossal nucleus and the part of the facial nucleus innervating the lower face; those to the trochlear nucleus are largely *ipsilateral* and the rest, including the most medial parts of hypoglossal nucleus, receive a *bilateral* projection. The cerebellum, diencephalic centres and corpus striatum are considered to influence the cranial nerve nuclei via indirect paths like those proposed for the control of spinal motor centres.

The general visceral efferent nuclei of the oculomotor, facial, glossopharyngeal and vagus nerves have largely uncertain central connections. (Those of the accessory oculomotor nuclei related to visual reflexes are discussed elsewhere.) It is presumed that the dorsal vagal and salivatory nuclei receive terminals of ascending tracts and those from other cranial nerve nuclei (particularly the solitary nucleus), conveying both somatic and visceral information. They also probably interconnect with the brain-stem reticular formation and receive hypothalamic projections, probably polysynaptic, through which the frontal neocortex, limbic structures and thalamus exert indirect effects. These descending paths have not been satisfactorily analysed. The central connections of **general visceral afferent pathways** (p. 1155) are equally uncertain, though they influence many brain-stem centres, including particularly the brain-stem reticular formation, hypothalamus, limbic lobe and prefrontal neocortex (consult the appropriate sections on these regions). The proportions of primary general visceral afferent fibres terminating in the dorsal vagal nucleus or in the solitary nucleus are undetermined, but the latter are accompanied by **special visceral afferent** (gustatory) fibres of the facial, glossopharyngeal and vagus nerves, which end in a rostrocaudal sequence of overlapping zones in the solitary nucleus. After synaptic relays, the secondary gustatory fibres decussate, ascending to terminate in the thalamic nucleus ventralis posterior medialis and several hypothalamic nuclei. Such *solitariothalamic* and *solitario-hypothalamic* routes have not been detailed in human brains, but the former probably accompanies medial fibres in the *medial lemniscus*, whilst the latter may join the *dorsal longitudinal fasciculus* (p. 986) and *mamillary peduncle* (p. 1009). Collateral branches probably leave these ascending fibres to end in the brain-stem reticular formation and in the nuclei of other cranial nerves. From the caudal levels of the nucleus solitarius fibres descend as a *solitariospinal tract*, but this is not a simple relay on the visceral afferent pathways; other connections converge to the nucleus, including fibres from the spinal cord, vestibulocerebellum and cortex, probably interacting in the nucleus, its transmission characteristics being modified by cortical activity.

Somatic afferent nuclei of the brain stem are the spinal, principal sensory and mesencephalic nuclei of the trigeminal nerve. The unique features of the *mesencephalic trigeminal nucleus* (which consists of unipolar *primary* sensory neurons) and its probable proprioceptive role have been described (p. 1099). Electrophysiology supports this role, since rapid responses have been recorded in the nucleus following stretching of the masticatory muscles, passive jaw movement and pressure on the teeth. The peripheral processes of mesencephalic unipolar neurons are hence considered to innervate muscle spindles in the masticatory muscles, temporomandibular joint and periodontal tissues. Possibly some also innervate muscle spindles of the facial, lingual and laryngeal muscles, but this is uncertain, as is the siting of somata of proprioceptive fibres from extraocular muscles (p. 1097). Since the somata of these primary afferents are deep in the midbrain, they present experimental difficulties, the smallest lesions inevitably involving adjacent structures. Hence, the central projections of these neurons are uncertain but some may descend to the principal sensory nucleus of the trigeminal; others may project to the trigeminal motor nucleus, completing a masticatory reflex. Collateral branches are described as a *trigeminocerebellar* tract (p. 966). Other connections are conjectural.

The manner of termination of the primary sensory axons in the three trigeminal divisions, all from neurons in the trigeminal ganglion, have been described. Data from brain-stem disease or neurosurgical manoeuvres suggest that the principal sensory nucleus is a simple relay for tactile information and the spinal nucleus for thermal and nociceptive information; but this is certainly an oversimplification. Bifurcation of many sensory fibres occurs on entry into the pons, one branch reaching the principal and the other the spinal nucleus. The *spinal nucleus*, continuous below with the substantia gelatinosa of the cervical spinal cord, shows regional variation in cytoarchitecture (sometimes divided into three subnuclei termed *oralis*, *interpolaris* and *caudalis*), progressing rostrocaudally. Further, the spinal and principal nuclei not only receive terminals of somatic afferent *trigeminal* fibres but also of *facial*, *glossopharyngeal* and *vagal* axons and others ascending from the cervical spinal cord. Both nuclei interconnect with the brain-stem reticular formation and both receive numerous corticonuclear fibres from the sensorimotor cortex; many afferents thus converge on both and unit recording has confirmed a *wide range* of different cell responses in them, varying from rapidly-adapting neurons with modality-specific, small receptive fields, to those with multimodal responses and larger receptive fields. Neurons responding to light tactile stimuli, others to nociceptive stimuli, occur in *both* nuclei. Some units show an inhibitory 'surround' (p. 865), and both pre- and postsynaptic inhibition and facilitation occur in the nuclei. Their transmission characteristics are modified by stimulation or interruption of the corticonuclear tracts and areas of the brain-stem reticular formation. The clinical conceptions of these nuclei as functionally segregated relay stations are negated by experimental data, which show them to be centres of complex integration. An analogy has been drawn between the principal trigeminal sensory nucleus and the nuclei gracilis and cuneatus, and between the spinal trigeminal nucleus and the substantia gelatinosa, in structural and functional organization. (See pp. 927, 941, 942–943 for details and a theory of action of the substantia gelatinosa in modulating sensory input.)

The ascending efferent connections from the principal and spinal trigeminal nuclei (p. 961) consist of fibres crossing to the thalamus as a 'trigeminal lemniscus'. Experimentation and observations on human material both show that many multiple

trigeminothalamic pathways exist. From the principal sensory nucleus a substantial bundle of fibres crosses the midline, a minor part remaining ipsilateral, both ascending through the upper pons, midbrain and subthalamus as the *dorsal trigeminothalamic tract* (dorsal division of the trigeminal lemniscus); in the midbrain this is dorsomedial to the red nucleus and medial lemniscus, ending in the thalamic nucleus ventralis posterior medialis (VPM) (p. 1002). Other fibres from the principal sensory and spinal nucleus (in its whole length) mainly cross to ascend near the medial lemniscus as the *ventral trigeminothalamic tract* (ventral division of the trigeminal lemniscus); many also end in the VPM but others, mainly from neurons in the caudal part of the spinal nucleus, perhaps end in the medial geniculate body and intralaminar nuclei. Collaterals may leave these ascending tracts to terminate in the brain-stem reticular formation and other cranial nerve nuclei while some probably enter the cerebellum (p. 966).

THE SPINAL NERVES

Spinal nerves are united ventral and dorsal spinal roots, attached in series to the sides of the spinal cord. There are 31 pairs: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, 1 coccygeal. The abbreviations C, T, L, S and Co, with appropriate numerals, are commonly applied to individual nerves. These emerge through intervertebral foramina; C1 leaves the vertebral canal between the occipital bone and atlas and is hence often termed the *suboccipital nerve*; C8 issues between the seventh cervical and first thoracic vertebrae. Each nerve is continuous with the spinal cord by the ventral and dorsal roots, the latter each bearing a *spinal ganglion*.

Ventral (anterior) roots contain axons of neurons in the anterior and lateral spinal grey columns. Each emerges as a series of *rootlets* in two or three irregular rows in an area about 3 mm in horizontal width. In rats the rootlets of lumbar ventral roots are each ensheathed by a single fenestrated layer of cells. At the spinal cord surface the rootlets are separated by a labyrinth of interradicular spaces lined by this sheath. Between adjacent rootlets the interradicular spaces, which contain small blood vessels, taper distally. The interradicular spaces communicate with the endoneurial spaces of the rootlets and with the subpial space but are isolated from the subarachnoid space by the multilayered, unfenestrated sheath which surrounds the aggregations of rootlets which comprise each ventral root (Kaar & Fraher 1986).

Dorsal (posterior) roots contain centripetal processes of neurons sited in the spinal ganglia. Each consists of medial and lateral fascicles both diverging into *rootlets* entering along the posterolateral sulcus. In many mammals, including humans, the rootlets of adjacent dorsal roots are often connected by oblique filaments, especially in the lower cervical and lumbosacral regions (Pallie & Manuel 1968).

Each root is covered by the pia mater and is loosely invested by the arachnoid mater prolonged to where the roots pierce the dura mater. The dorsal and ventral roots do so separately, each receiving a dural sheath (7.204, 208); where the roots unite to form spinal nerves these sheaths fuse with the epineurium.

Spinal ganglia are large groups of neurons on the dorsal spinal roots. Each is oval and reddish, its size being related to that of its root; it is bifid medially where the dorsal root's two fascicles emerge to enter the cord. Ganglia are usually sited in the intervertebral foramina, immediately lateral to the perforation of the dura mater by the roots (7.61), but the first and second cervical ganglia are on the vertebral arches of the atlas and axis, the sacral inside the vertebral canal and the coccygeal ganglia usually within the dura mater.

The first cervical ganglia may be absent. Small *aberrant ganglia* sometimes occur on the upper cervical dorsal roots between the spinal ganglia and cord. (Heterotopic ganglionic neurons also occur in other sites, see p. 897.)

The internal structures of sensory ganglia, cranial and spinal, is similar (p. 896 and consult Van Gehuchten 1892, Marinesco 1909, Cajal 1911, De Castro 1932, Scharf 1958, Lieberman 1976). Each sensory ganglion has a laminar connective tissue capsule continuous with the epineurium of the spinal root. Endoneurial stroma permeates the ganglion, supporting its neuronal and axonal population; perineurial capsular trabeculae extend between groups of these elements. The stroma is intimately related to the satellite cells (amphicytes); it contains a few mast cells and a dense vascular network, denser around ganglion cells, into which capillary loops may be invaginated (Scharf 1958). These capillaries are non-fenestrated in rodents (Lieberman 1968) but commonly fenestrated in primates (Olsson 1971). Ganglionic vascular permeability varies among species, amounting to a 'blood–nerve' barrier in some, largely dependent on the junctional complexes between endothelial cells; details are not available for mankind. Ganglionic neurons vary in size (15–110 μm in man, Ohta et al 1974); most are spheroidal but smaller cells appear ellipsoidal or angular in section.

Ganglionic neurons resemble other neurons but vary much in the distribution of cytoplasmic chromatin, from fine disperal to concentration in large masses (Nissl granules); this has been the chief basis of many classifications, which remain conflicting. Melanin and lipofuchsin pigments occur in some but less than in some cranial sensory ganglia. Dense-cored vesicles are common (Lieberman 1968), despite the apparent absence of catecholamines. However, the occurrence of two extreme types is agreed: large 'light' neurons (A cells) and small 'dark' ones (B cells). In 'light' cells the granular endoplasmic reticulum is more dispersed but highly concentrated in 'dark' cells. The latter are sometimes mimicked by artefact, perhaps due to poor fixation. Both types appear in prenatal material. Functional differences remain unclarified but the axons of A cells are said to be myelinated and those of B cells non-myelinated. It has been suggested that B cells are visceral. 'Atypical' neurons have been described in dorsal root and other sensory ganglia, the most interesting being reputed to be multipolar neurons; but since synapses have not been identified in dorsal root ganglia, this is improbable and is unconfirmed. Almost all ganglionic neurons are unipolar (p. 863), many with a coiled 'stem' process close to the parent soma, forming an axonal 'glomerulus' before branching into peripheral and central parts (p. 1094). Spinal ganglionic cells have been submitted to ultrastructural studies (Duce & Keen 1977), assessment of specific intracellular substances (Hokfelt et al 1976), preferential glutamine absorption (Duce & Keen 1978) and specific reactions to neurotoxins (Jancsco et al 1977). Such data, while confirming 'light' and 'dark' cells, collectively suggest a subdivision into further types, particularly of 'dark' cells. Small dark cells may occur in at least two variants, differentiated by production of either substance P or somatostatin. Different cells respond also to different neurotoxins or differ in glutamine metabolism.

Counts of cells in the dorsal root ganglia show *specific* variation, as expected; few estimates exist for human ganglia. Maximal counts are reached about three years after birth; but the subsequent supposed loss has not been confirmed. The distribution of somata and axons is variable, the former often being peripherally concentrated; but grouping of the somata between large fascicles of axons is described as more usual in human ganglia. Such grouping may indicate somatotopic organization, sometimes described in terms of somata and axons. Burton & McFarlane (1973), by injection of labelled amino acids into ganglia, associated local groups of neurons in cats' lumbar ganglia with branches of spinal nerves and also with particular spinal radicles. Horseradish peroxidase injections near peripheral receptor endings have produced more exact results in rodent sensory ganglia; no results are available for primates.

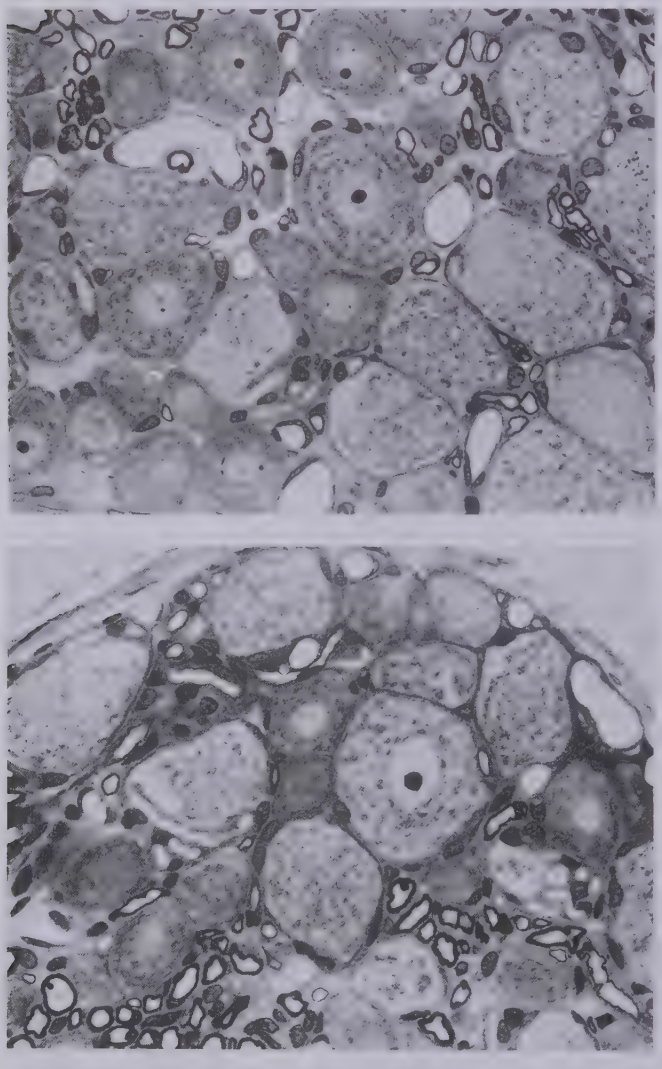
Size and direction of spinal nerve roots vary. The upper four *cervical* roots are small, the lower four large. Cervical dorsal roots have a thickness ratio to the ventral roots of three to one, greater than in other regions. The first dorsal root is an exception,

being smaller than the ventral; in about 8% it is absent. The first and second cervical roots are short, running almost horizontally to their exits from the vertebral canal. From the third to the eighth cervical they slope obliquely down, obliquity and length increasing successively; the distance between spinal attachment and vertebral exit never exceeds the height of one vertebra.

Thoracic roots, except the first, are small, the dorsal only slightly exceeding the ventral in thickness. They increase successively in length and in the lower thoracic region descend in contact with the spinal cord for at least two vertebrae before emerging from the vertebral canal (but vide infra).

Kubik & Müntener (1969) consider that the cervicothoracic part of the spinal cord grows more in length than other parts and thus explain their observations which differ from the above remarks. They state that upper cervical roots *descend*, the fifth being horizontal, and that the sixth to eighth actually *ascend*, that the first two thoracic roots are horizontal, the next three ascend, the sixth is horizontal and the rest descend.

Lower *lumbar* and upper *sacral roots* are the largest and their radicles the most numerous, while the *coccygeal* roots are the smallest. Kubik & Müntener (1969) confirm that lumbar, sacral and coccygeal roots descend with increasing obliquity to their exits; since the spinal cord ends near the lower border of the first lumbar vertebra, the lengths of successive roots rapidly increase. The consequent collection of roots is the *cauda equina* (7.60B).



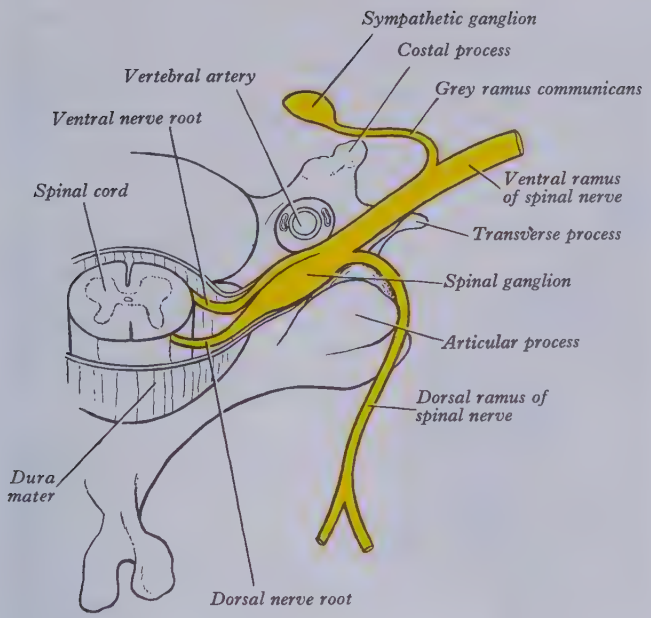
The largest roots and the hence largest spinal nerves are continuous with the spinal cervical and lumbar swellings and innervate the upper and lower limbs.

Immediately distal to the spinal ganglia, ventral and dorsal roots unite to form *spinal nerves*, which emerge through intervertebral foramina and give off recurrent meningeal branches (vide infra), dividing immediately into *dorsal* and *ventral* rami (7.250). (From limited dissections Sato (1974) has described the *trifurcation* of spinal nerves at some cervical and thoracic levels, the third branch being a *ramus intermedius*.) At or distal to its origin each ventral ramus receives a *grey ramus communicans* from the corresponding sympathetic ganglion, while the thoracic and first and second lumbar ventral rami each contribute a *white ramus communicans* to the corresponding ganglia (7.236, 238). The second, third and fourth sacral nerves also supply visceral branches, unconnected with sympathetic ganglia, which carry a parasympathetic outflow direct to the pelvic plexuses (pp. 1156, 1166).

Cervical spinal nerves enlarge from the first to the sixth, the seventh and eighth cervical and first thoracic being like the sixth cervical in size. The remaining thoracic nerves are relatively small. Lumbar nerves are large, increasing in size from the first to the fifth. The first sacral is the largest spinal nerve, thereafter they decrease to the coccygeal, the smallest.

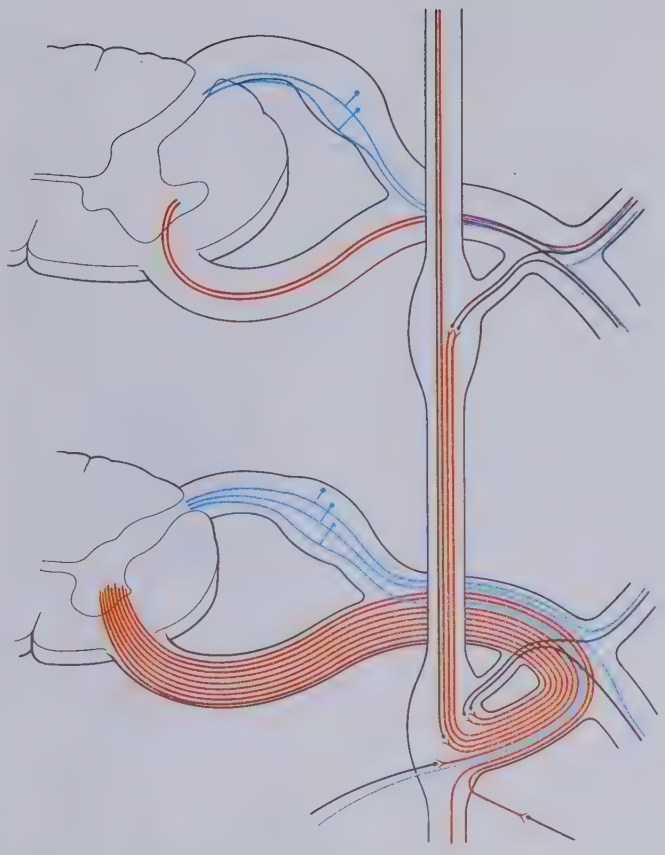
In the intervertebral foramina spinal nerves have clinically important relations. *Anterior* are the intervertebral discs and adjacent vertebral bodies. *Posterior* are the synovial zygapophysial joints. *Superior* and *inferior* are vertebral notches of the pedicles of adjoining vertebrae. Each nerve, accompanied by a spinal artery, a small venous plexus and its own meningeal branch or branches together traverse a foramen.

Applied Anatomy. Spinal roots may be compressed in their course between the spinal cord and their exit from intervertebral foramina. In the cervical region, vertebral disease, the degeneration of an intervertebral disc or disease of the intervertebral joints may affect the roots in their intervertebral foramen, causing pain, diminished cutaneous sensibility and muscular weakness in the field of supply. At the lumbar level, the posterior protrusion of an intervertebral disc or rupture of its annular fibres, with herniation of the nucleus pulposus, is common, particularly in the discs between the fourth and fifth lumbar and first sacral vertebrae. Disc lesions may compress one or both roots in their foramina, resulting in back pain ('lumbago'), with or without radiation of pain to one or both legs ('sciatica'), diminished cutaneous sensibility in the area of supply and weakness of the muscles innervated (e.g. tibialis anterior L. 4, extensor hallucis longus L. 5, flexor hallucis longus S. 1). Less commonly, tumours in the vertebral canal or spina bifida with meningomyelocoele may affect one or more roots in the cauda equina.



7.236 Two photographs of fields in normal rat cervical dorsal root ganglion to show contrasting features of light and dark neuronal somata. Note the capsules of satellite cells; the darkly stained multiple profiles between many of the nerve cells represent glomeruli in repeated transverse section. Interneuronal capillary profiles are also visible. Cresyl fast violet staining of semi-thin sections of material embedded in araldite. Photographs supplied by J M Jacobs, National Hospital for Nervous Diseases, London.

FUNCTIONAL COMPONENTS OF SPINAL NERVES



Each typical spinal nerve contains somatic and visceral fibres.

The somatic components are efferent and afferent. *Somatic efferent* fibres for the innervation of skeletal muscles are axons of α, β and γ neurons in the spinal anterior grey column. *Somatic afferent* fibres convey impulses into the central nervous system from receptors in the skin, subcutaneous tissue, muscles, fasciae, joints, etc. (pp. 909–915); they are peripheral processes of unipolar neurons in the spinal ganglia.

The visceral components, also afferent and efferent, belong to the autonomic nervous system (p. 1154). They include sympathetic or parasympathetic fibres at different spinal levels. Preganglionic *visceral efferent* sympathetic fibres are axons of neurons in the spinal lateral grey column in the thoracic and upper two or three lumbar segments; they join the sympathetic trunk along corresponding white rami communicantes to synapse with postganglionic neurons distributed to non-striated muscle or glands. The preganglionic *visceral efferent* parasympathetic fibres are axons of cells in the spinal lateral grey column of the second to fourth sacral segments; they leave the ventral rami of corresponding sacral nerves to synapse in pelvic ganglia, the

7.238 Scheme showing the constitution of a typical spinal nerve. In the upper part of the diagram the spinal nerve roots show the somatic components; in the lower part of the diagram the spinal roots show the visceral components. Red = somatic efferent and preganglionic sympathetic fibres, blue = somatic afferent and visceral afferent fibres, black = postganglionic sympathetic fibres.

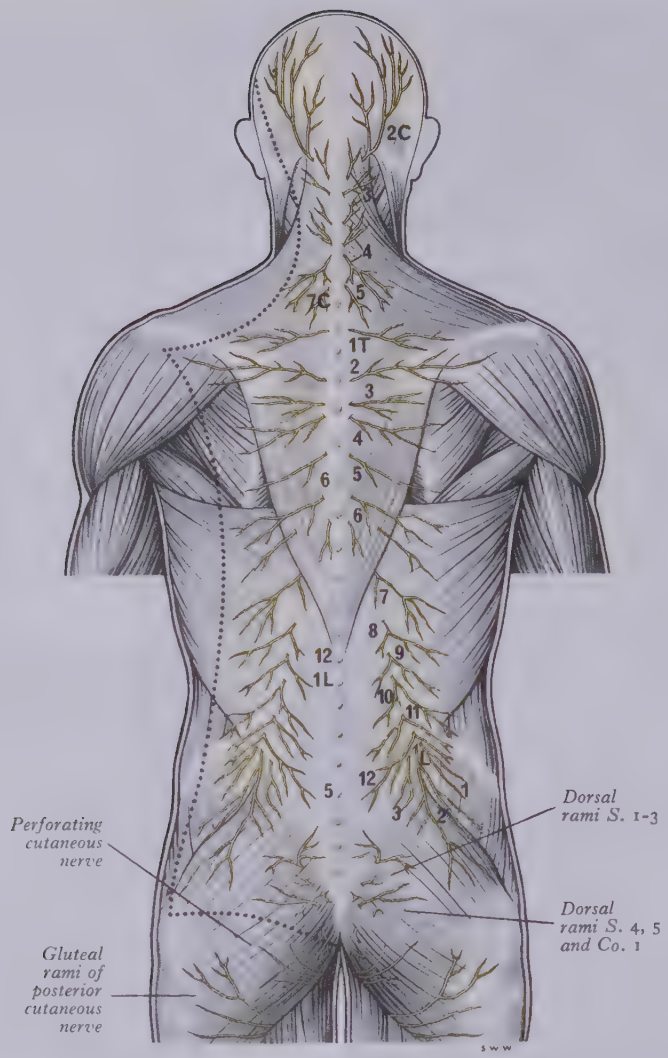
postganglionic axons being distributed mainly to muscle or glands in the walls of the pelvic viscera. *Visceral afferent* fibres are from neurons in the spinal ganglia. Their peripheral processes pass through white rami communicantes and, without synapsing, through one or more sympathetic ganglia to end in viscera. Some visceral afferent fibres may enter the spinal cord in *ventral* roots; Coggeshall et al (1973) claim that almost 30% of fibres in the feline seventh lumbar and first sacral ventral roots are non-myelinated afferents, which may project *into* the cord from neurons in the corresponding dorsal root ganglia.

Central processses of ganglionic unipolar neurons enter the spinal cord by posterior roots and connect with somatic or sympathetic efferent neurons, usually through interneurons, completing reflex paths, or they synapse with other neurons in the spinal or brain-stem grey matter which provide a variety of ascending tracts.

Little detail of the dendrites of spinal autonomic neurons is available. Schramm et al (1976) showed that sympathetic efferent neurons have largely horizontal dendritic arrays in newborn rats, re-orientated into longitudinal arrays in the next five or six postnatal weeks. No such data are available for the human spinal cord.

After emerging from its intervertebral foramen each spinal nerve supplies small *meningeal* branches and splits almost at once into *dorsal* and *ventral rami*, both receiving fibres from both roots.

The meningeal branches (*recurrent meningeal* or *sinuvertebral nerves*), numbering two to four filaments on each side, occur at all vertebral levels (Kimmel 1961a, b). Each receives one or more rami from a nearby grey ramus communicans or from a thoracic sympathetic ganglion directly; most then pursue a recurrent (often perivascular) course into the spinal canal through the intervertebral foramen ventral to the dorsal root ganglion. Here these mixed sensory and sympathetic nerves divide into transverse, ascending and descending branches distributed to the dura mater, the walls of blood vessels, the periosteum, ligaments and intervertebral discs in the ventrolateral region of the spinal canal. Fine meningeal branches occasionally pass dorsal to the spinal ganglia to the dorsal dura, periosteum and ligaments, others passing ventrally to the posterior longitudinal ligament. Ascending branches of the upper three cervical meningeal nerves are large and distributed to the dura mater in the posterior cranial fossa (p. 1088). Meningeal nerves are important in relation to the referred pain characteristic of many spinal disorders and in occipital headache.



DORSAL RAMI OF THE SPINAL NERVES

Dorsal (posterior primary) rami of spinal nerves, usually smaller than the *ventral* and directed posteriorly, divide (except for the first cervical, fourth and fifth sacral and the coccygeal) into medial and lateral branches to supply the muscles and skin (7.239) of the posterior regions of the neck and trunk.

CERVICAL DORSAL RAMI

Each cervical spinal dorsal ramus, except the first, divides into medial and lateral branches, all innervating muscles; but in general only medial branches of the second to fourth and usually the fifth supply the skin. Except for the first and second, each dorsal ramus passes back medial to a posterior intertransverse muscle, curving round the articular process into the interval between the semispinalis capitis and semispinalis cervicis.

The first cervical dorsal ramus (suboccipital nerve) (5.40), larger than the ventral, emerges superior to the posterior atlantal arch and inferior to the vertebral artery. It enters the suboccipital triangle to supply local muscles: the rectus capitis posterior major and minor, superior and inferior oblique and the semispinalis capitis. A filament from the branch to the inferior oblique joins the second dorsal ramus (5.40). The suboccipital

7.239 The cutaneous distribution of the dorsal rami of the spinal nerves. The nerves are shown lying on the superficial muscles; on the left side the limit of the skin area supplied by these nerves is indicated by the dotted line. The nerves are numbered on the right side and the spines of the seventh cervical, sixth and twelfth thoracic and first and fifth lumbar vertebrae are labelled on the left side.

nerve occasionally has a cutaneous branch which accompanies the occipital artery to the scalp, connecting with the greater and lesser occipital nerves.

The second cervical dorsal ramus, slightly larger than the ventral and all other cervical dorsal rami, emerges between the posterior atlantal arch and the lamina of the axis, below the inferior oblique which it supplies, receiving a connection from the first cervical dorsal ramus, and divides into a large medial and smaller lateral branch. Its ganglion is extradural. The *medial* branch, termed the *greater occipital nerve* (7.239, 241), ascends between the inferior oblique and semispinalis capitis, pierces the latter and the trapezius near their occipital attachments and is joined by a filament from the medial branch of the third dorsal ramus; ascending with the occipital artery, it divides into branches which connect with the lesser occipital nerve and supply the skin of the scalp as far forward as the vertex. It supplies the semispinalis capitis and occasionally the back of the auricle. The *lateral* branch supplies the splenius, longissimus capitis and semispinalis capitis and is often joined by the corresponding third cervical branch.

The third cervical dorsal ramus, between the second and fourth in size, courses back round the third cervical articular pillar, medial to the posterior intertransverse muscle, dividing into medial and lateral branches. Its *medial* branch runs between the spinalis capitis and semispinalis cervicis, piercing the splenius and trapezius to end in the skin. Deep to the trapezius it gives rise to a branch, the *third occipital nerve*, which pierces the trapezius to end in the skin of the lower occipital region (7.239), medial to the greater occipital nerve and connected to it. The *lateral* branch often joins that of the second cervical dorsal ramus.

The dorsal ramus of the suboccipital and medial branches of the dorsal rami of the second and third cervical nerves are sometimes joined by loops to form the *posterior cervical plexus*.

Dorsal rami of the lower five cervical nerves curve back round the vertebral articular pillars and divide into medial and lateral branches. *Medial* branches of the fourth and fifth run between the semispinalis cervicis and semispinalis capitis, reach the vertebral spines and pierce the splenius and trapezius to end in the skin (7.239). The fifth medial branch may not reach the skin. The medial branches of the lowest three cervical nerves are small and end in the semispinalis cervicis, semispinalis capitis, multifidus and interspinales. The *lateral* branches supply the iliocostalis cervicis, longissimus cervicis and longissimus capitis.

THORACIC DORSAL SPINAL RAMI

Thoracic dorsal rami pass backwards close to the vertebral zygapophysial joints to divide into medial and lateral branches. Each medial branch emerges between a joint and medial edges of the superior costotransverse ligament and intertransverse muscle, but each lateral branch runs in the interval between ligament and muscle before inclining posteriorly on the medial side of the levator costae.

Medial branches of the *upper six* thoracic dorsal rami pass between and supply the semispinalis thoracis and multifidus; they pierce the rhomboids and trapezius, reaching the skin near the

vertebral spines (7.239). *Medial branches* of the *lower six* thoracic dorsal rami chiefly supply the multifidus and longissimus thoracis and occasionally skin in the median region. *Lateral* branches increase inferiorly in size, running through or deep to the longissimus thoracis to the interval between it and the iliocostalis cervicis, supplying these muscles and the levatores costarum; the lower five or six also have cutaneous branches, piercing the serratus posterior inferior and latissimus dorsi in line with the costal angles (7.239). Some upper thoracic lateral branches also supply the skin. The twelfth thoracic lateral branch sends a filament medially along the iliac crest, then passes down to the anterior gluteal skin. Medial cutaneous branches of the thoracic dorsal rami descend close to the vertebral spines before reaching the skin; lateral branches descend as far as the level of four ribs before becoming superficial, the branch of the twelfth thoracic reaching the skin a little above the iliac crest.

LUMBAR DORSAL SPINAL RAMI

Lumbar dorsal rami pass back medial to the medial intertransverse muscles, dividing into medial and lateral branches.

Medial branches run near the vertebral articular processes to end in the multifidus; they are related to the bone between the accessory and mamillary processes and may groove it, traversing a distinct notch or even a foramen. *Lateral* branches supply the erector spinae (sacrospinalis). In addition, the upper three give rise to cutaneous nerves which pierce the aponeurosis of the latissimus dorsi at the lateral border of the erector spinae and cross the iliac posteriorly to reach the gluteal skin (7.239), some reaching as far as the level of the greater trochanter.

SACRAL DORSAL SPINAL RAMI

Sacral dorsal rami are small, diminishing downwards; excepting the fifth, they emerge through the dorsal sacral foramina. The *upper three* are covered at the exit by the multifidus, dividing into medial and lateral branches. Medial branches are small and end in the multifidus. *Lateral* branches join together and with lateral branches of the last lumbar and fourth sacral dorsal rami form loops dorsal to the sacrum; from these loops branches run dorsal to the sacrotuberous ligament to form a second series of loops under the gluteus maximus; from these two or three *gluteal branches* pierce the gluteus maximus (along a line from the posterior superior iliac spine to the coccygeal apex) to supply the posterior gluteal skin (7.239).

The dorsal rami of the *fourth* and *fifth* sacral nerves are small and lie below the multifidus. They unite with each other and the coccygeal dorsal ramus to form loops dorsal to the sacrum; filaments from these supply the skin over the coccyx. Berthold & Carlstedt (1977) have recorded a detailed study of the feline first sacral nerve at its junction with the spinal cord.

COCCYGEAL DORSAL SPINAL RAMUS

This does not divide into medial and lateral branches. Its connections and distribution are noted above.

VENTRAL RAMI OF THE SPINAL NERVES

The ventral rami of spinal nerves supply the limbs and the anterolateral aspects of the trunk; they are mostly larger than the dorsal rami. The *thoracic* are independent and retain, like all *dorsal* rami, a largely segmental distribution. The *cervical*, *lumbar* and *sacral* connect near their origins to form plexuses. Dorsal rami do not join these plexuses.

CERVICAL VENTRAL RAMI

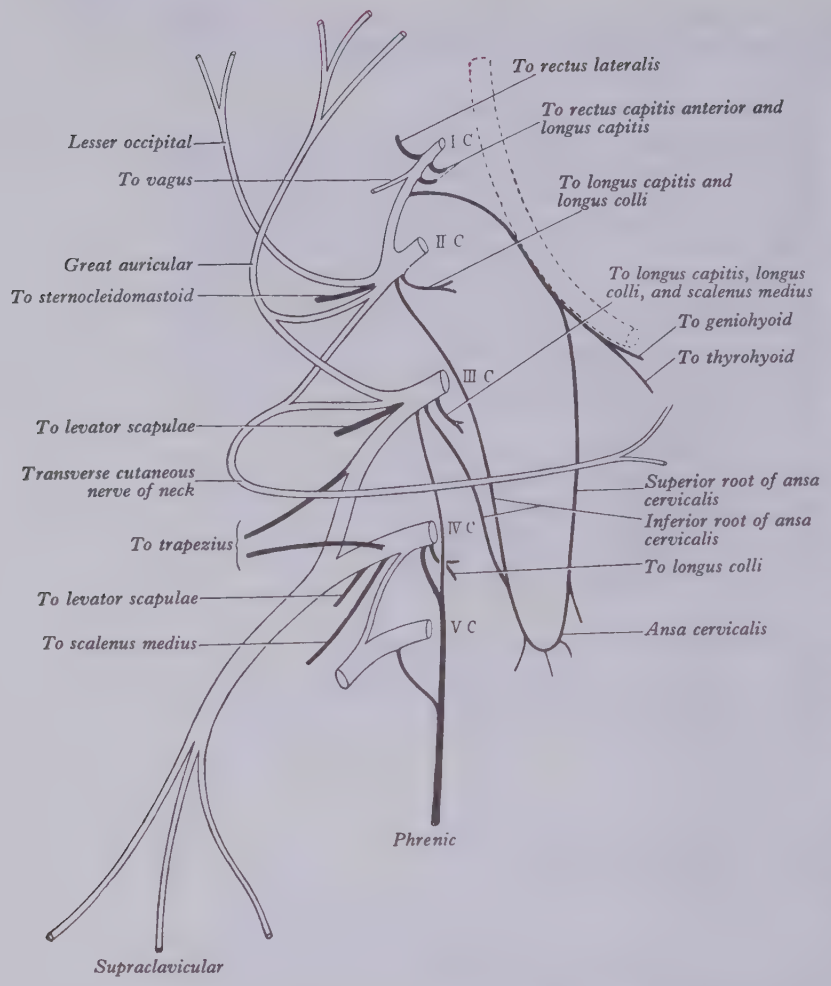
Cervical ventral rami, except the first, appear between the anterior and posterior intertransverse muscles. The *upper four* form a *cervical plexus*; the *lower four*, with most of the first thoracic ventral ramus, form a *brachial plexus*. Each receives at least one grey ramus communicans, the upper four from the superior cervical sympathetic ganglion, the fifth and sixth from the middle ganglion and the seventh and eighth from the cervicothoracic ganglion (p. 1160).

The *first cervical ventral ramus* (*suboccipital nerve*) emerges above the posterior arch of the atlas, passes forwards lateral to its lateral mass and medial to the vertebral artery. It supplies the rectus lateralis, emerges medial to it, descends anterior to the atlantal transverse process and posterior to the internal jugular vein and joins the ascending branch of the second cervical ventral ramus.

The *second cervical ventral ramus* issues between the vertebral arches of the atlas and axis, ascends between their transverse processes, passes anterior to the first posterior intertransverse muscle and emerges lateral to the vertebral artery generally between the longus capitis and levator scapulae, but when scalenus medius is attached to the atlas it intervenes between the nerve and the levator scapulae. The ramus divides into an ascending branch which joins the first cervical nerve and a descending one which joins the ascending branch of the third cervical ventral ramus.

The *third cervical ventral ramus* appears between the longus capitis and scalenus medius. The remaining ventral rami emerge between the scalenus anterior and scalenus medius.

The Cervical Plexus



The cervical plexus (7.240), formed by the upper four cervical ventral rami, supplies some nuchal muscles, the diaphragm and areas of skin in the head, neck and chest (7.224). Level with the first four vertebrae, it is deep to the internal jugular vein and sternocleidomastoid and anterior to the scalenus medius and levator scapulae. Each ramus, except the first, divides into ascending and descending parts, which unite in communicating loops. From the first loop (C2 and 3) superficial branches supply the head and neck; from the second (C3 and 4) arise cutaneous nerves of the shoulder and chest. Muscular and communicating branches arise from the same nerves. The branches are superficial or deep; the superficial perforate the cervical fascia to supply the skin while the deep branches mostly supply muscles. The superficial form ascending and descending groups and form the deep medial and lateral series.

ASCENDING SUPERFICIAL BRANCHES

These branches of the cervical plexus (7.240–242) include:

Lesser occipital	C2
Greater auricular	C2, 3
Transverse (anterior) cutaneous	C2, 3

The lesser occipital nerve (7.240, 241), from the second cervical ventral ramus and sometimes also from the third, curves

7.240 A plan of the cervical plexus. The hypoglossal nerve is shown by interrupted lines and the muscular branches by solid black lines. The roman numerals and letters I C to V C indicate the *ventral rami* of these cervical spinal nerves.

around the accessory nerve and ascends along the posterior border of the sternocleidomastoid. Near the cranium it perforates the deep fascia and ascends the scalp behind the auricle, supplying the skin and connecting with the great auricular and greater occipital nerves and the posterior auricular branch of the facial. It varies in size and is sometimes double. Its *auricular branch* supplies the skin on the upper third of the medial auricular aspect and connects with the posterior branch of the great auricular nerve. The auricular branch is occasionally derived from the greater occipital nerve.

The great auricular nerve (7.240, 241), is the largest ascending branch. It arises from the second and third cervical rami, encircles the posterior border of the sternocleidomastoid, perforates the deep fascia and ascends on the muscle beneath the platysma with the external jugular vein. It passes to the parotid gland, dividing into anterior and posterior branches. The *anterior branch* is distributed to the facial skin over the parotid gland, connecting in the gland with the facial nerve. The *posterior branch* supplies the skin over the mastoid process and on the back of the auricle (except its upper part); a filament pierces the auricle to reach its lateral surface where it is distributed to the lobule and concha. The posterior branch communicates with the lesser occipital, the auricular branch of the vagus and the posterior auricular branch of the facial nerve.

The transverse (anterior) cutaneous nerve of the neck (7.240, 241) arises from the second and third cervical rami, curves round the posterior border of the sternocleidomastoid near its midpoint and runs obliquely forwards, deep to the external jugular vein, to the muscle's anterior border. It perforates the deep cervical fascia, dividing under the platysma into ascending and descending branches distributed to the anterolateral areas of the neck. The *ascending branches* ascend to the submandibular region, forming a plexus with the facial nerve's cervical branch beneath the platysma; others pierce the platysma and are distributed to the skin of the upper anterior areas of the neck. The *descending branches* pierce the platysma and are distributed anterolaterally to the skin of the neck, as low as the sternum.

DESCENDING SUPERFICIAL BRANCHES

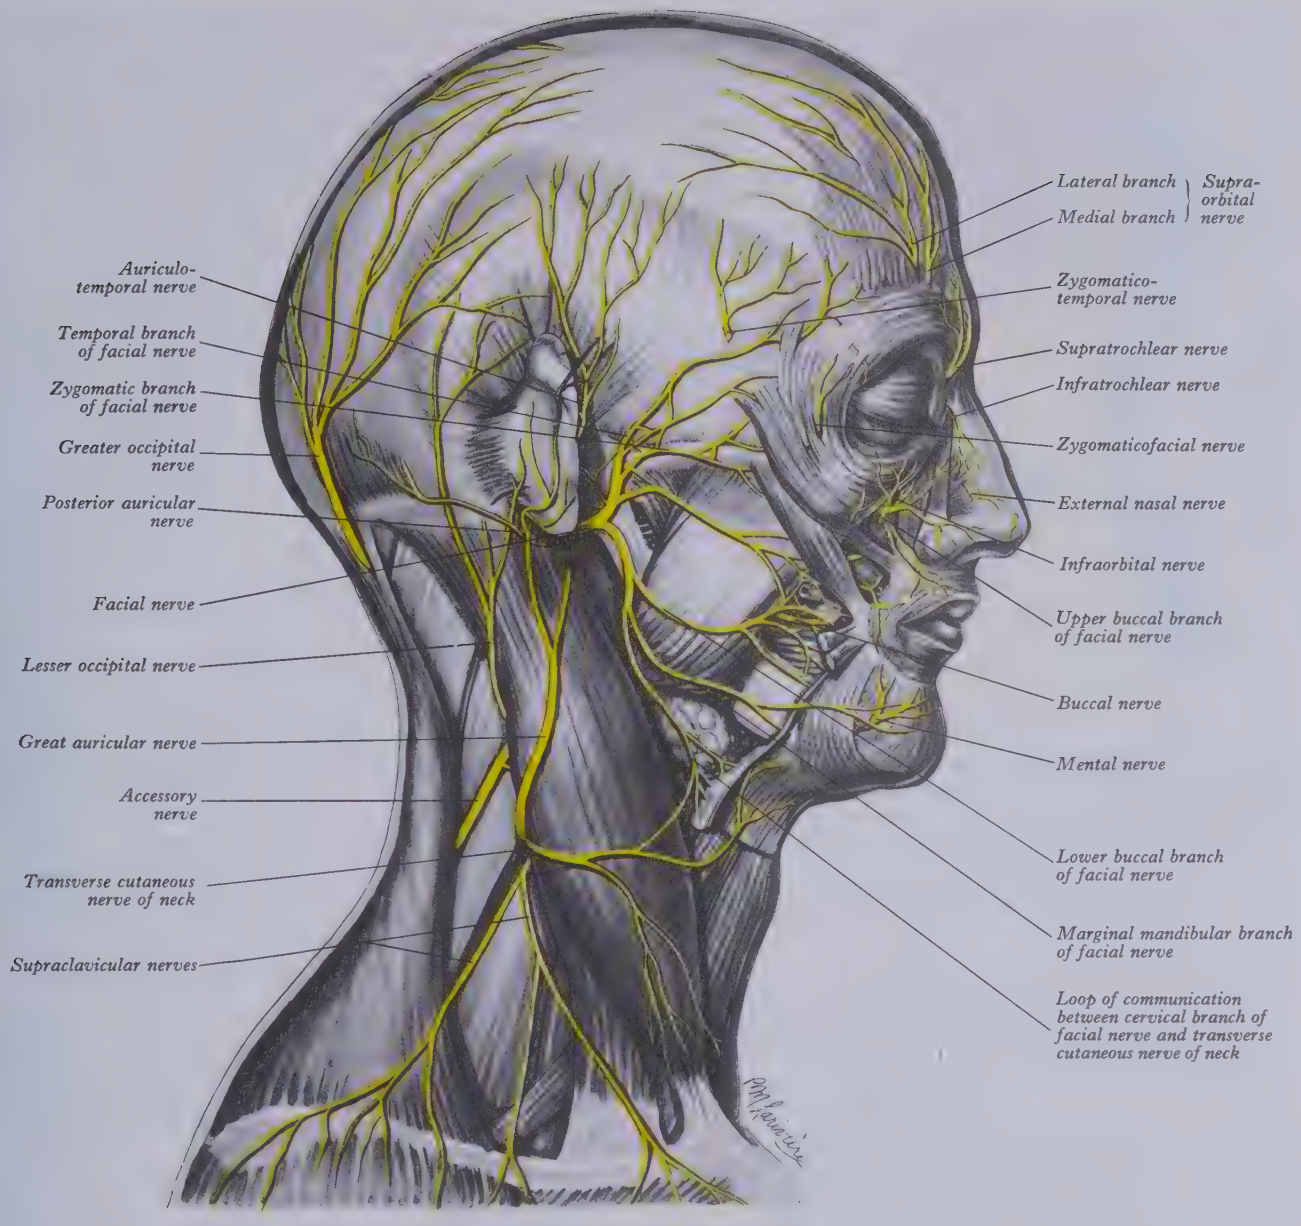
These are: supraclavicular (C3, 4): medial, intermediate and lateral.

The supraclavicular nerves (7.240, 241) arise by a common trunk from the third and fourth cervical ventral rami and emerge from the posterior border of the sternocleidomastoid, to descend under the platysma and the deep cervical fascia; they divide into medial, intermediate and lateral (posterior) branches, which diverge to pierce the deep fascia a little above the clavicle.

The *medial supraclavicular nerves* run inferomedially across the external jugular vein and the clavicular and sternal heads of the sternocleidomastoid to supply the skin as far as the midline and as low as the second rib. They supply the sternoclavicular joint. The *intermediate supraclavicular nerves* cross the clavicle to supply the skin over the pectoralis major and deltoid down to the level of the second rib, next to the area of supply of the second thoracic nerve (7.254). Overlap between these nerves is minimal. The *lateral (posterior) supraclavicular nerves* descend superficially across the trapezius and acromion, supplying the skin of the upper and posterior parts of the shoulder.

DEEP BRANCHES—MEDIAL SERIES

These include the following communicating and muscular branches:



Communicating branches with	Hypoglossal	C1, 2
	Vagus	C1, 2
	Sympathetic	C1–4
Muscular branches to	Rectus capitis lateralis	C1
	Rectus capitis anterior	C1, 2
	Longus capitis	C1–3
	Longus colli	C2–4
	Inferior root of ansa cervicalis	C2, 3
	Phrenic nerve	C3–5

Communicating branches pass from the loop between the first and second cervical rami to the vagus, hypoglossal nerve and sympathetic. The hypoglossal branch later leaves it as a series of branches, viz. the meningeal, *superior root of ansa cervicalis*, nerves to the thyrohyoid and probably to the geniohyoid (p. 585). A branch also connects the fourth and fifth cervical rami; the first four cervical ventral rami each receive a grey ramus communicans from the superior cervical sympathetic ganglion.

Muscular branches supply the rectus capitis lateralis, rectus capitis anterior, longus capitis and longus colli.

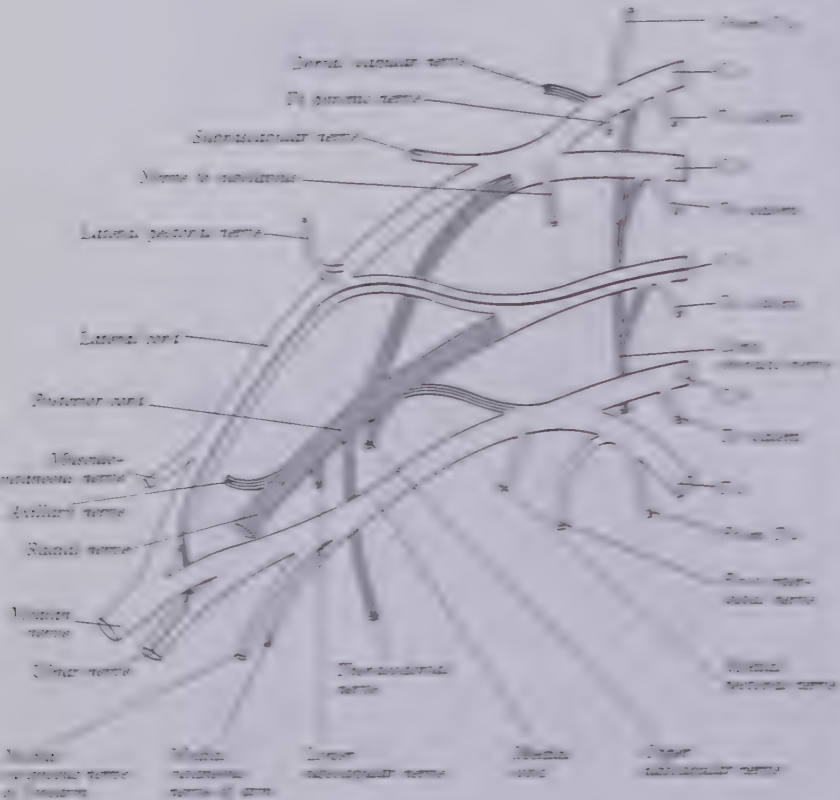
The inferior root of the ansa cervicalis (nervus descendens cervicalis) (7.240) is formed by the union of a branch from the second with another from the third cervical ramus. It descends on the lateral side of the internal jugular vein, crosses it a little below the middle of the neck, and continues forwards to join the superior root anterior to the common carotid artery, forming the *ansa cervicalis* (*ansa hypoglossi*) (**6**.69), from which all infrahyoid muscles are supplied, except the thyrohyoid. In 160 dissections, the inferior root was from the second and third cervical ventral rami in 74%, from the second to fourth in 14%, from the third alone in 5%, from the second alone in 4% and from the first to third in 2% (Poriraer & Chernikov 1965).

The phrenic nerve, sole *motor* supply to the diaphragm, also contains widespread sensory fibres. It arises chiefly from the fourth cervical ramus but also has contributions from the third and fifth (7.240). Formed at the upper part of the lateral border of the scalenus anterior, it descends almost vertically across it *behind the prevertebral fascia* on its anterior surface. It descends posterior

7.241 The nerves of the right side of the scalp, face and side of the neck.

to the sternocleidomastoid, the inferior belly of omohyoid (near its intermediate tendon), the internal jugular vein, transverse cervical and suprascapular arteries (**6**.68) and, on the left, the thoracic duct. It then runs anterior to the subclavian artery, posterior to the subclavian vein and enters the thorax by crossing medially in front of the internal thoracic artery (**6**.90), after which it descends anterior to the pulmonary hilum, between the fibrous pericardium and mediastinal pleura, to the diaphragm, accompanied by the pericardiacophrenic vessels. The right and left phrenic nerves differ in their intrathoracic relations.

The *right phrenic nerve*, shorter and more vertical, is separated at the root of the neck from the second part of the right subclavian artery by the scalenus anterior. It is then lateral to the right brachiocephalic vein, the superior vena cava and the fibrous pericardium covering the right surface of the right atrium and inferior vena cava.



The *left phrenic nerve*, at the root of the neck, is commonly stated to leave the medial edge of the scalenus anterior to pass anterior to the *first* part of the left subclavian artery and behind the thoracic duct. However, Quist (1977) claims that both right and left nerves are *symmetrical* in their cervical course and that at the thoracic inlet the left crosses anterior to the *second* part of the left subclavian artery, separated by the scalenus anterior. Thereafter the left phrenic crosses anterior to the left internal thoracic artery, descending across the medial aspect of the left lung's apex and its pleura to the first part of the subclavian artery, which it crosses obliquely to reach a groove between the left common carotid and subclavian arteries. It passes anteromedially superficial to the left vagus nerve just above the aortic arch and behind the left brachiocephalic vein. It then passes superficial to the aortic arch and the left superior intercostal vein, anterior to the left pulmonary hilum, to lie between the fibrous pericardium covering left surface of the left ventricle and the mediastinal pleura (p. 750).

In the neck each nerve receives variable filaments from the cervical sympathetic ganglia or their branches and may also connect with internal thoracic sympathetic plexuses (Pearson & Sauter 1971); these connections may represent a devious course of sympathetic fibres to these plexuses (p. 1161). In its thoracic course each nerve supplies sensory branches to the mediastinal pleura, fibrous pericardium and parietal serous pericardium.

Diaphragmatic relations (Merendino et al 1956, Perera & Edwards 1957). The right phrenic nerve traverses the diaphragm's central tendon, either by the caval orifice or just lateral to it. The

7.143 A plan of the brachial plexus. The posterior division of the trunks and their derivatives are shaded and the fibres from C_8 which enter the ulnar nerve are shown as a heavy black line. Letters and numbers C_4–C_8 and T_1–T_2 indicate the ventral rami of these cervical and thoracic spinal nerves.

DEEP BRANCHES—LATERAL TERMINAL BRANCHES

These include:

Communicating	Ansa	C_5, C_6, C_7
Muscular branches	Sternothyroid and sternohyoid	C_5, C_6, C_7
	Diaphragm	C_4, C_5
	Longus colli and scalenus anterior	C_5, C_6
	Subclavius muscle	C_5, C_6

Communicating branches. Lateral and medial branches of the brachial plexus connect with the spinal accessory nerve in the sternocleidomastoid, posterior triangle and under the trapezius.

Muscular branches are distributed to sternothyroid, sternohyoid and to the diaphragm, anterior scalenus and scalenus medius. Trapezial branches cross the posterior triangle immediately below the spinal accessory nerve.

The Brachial Plexus

The brachial plexus (C5–T1) is a union of the lower four cervical ventral rami and the greater part of the first thoracic ventral ramus (p. 1127). The fourth ramus usually gives a branch to the fifth and the first thoracic frequently receives one from the second. Contributions to the plexus by C_4 and T_2 vary when the branch from C_4 is large, that from T_2 is frequently absent and the branch from T_2 is reduced, forming a *prefixed* type of plexus. If the branch from C_4 is small or absent, the contribution of C_5 is

reduced but that of T1 is larger and one from T2 is always present. In arrangement it combines a prefixed type of plexus. The ventral rami are the roots of the plexus, almost equal in size but variable in their mode of junction. The commonest arrangement is as follows: the fifth and sixth rami unite at the lateral border of the scalenus medius as the *upper trunk*; the eighth cervical and first thoracic rami run behind the scalenus anterior as the *lower trunk*; the seventh cervical becomes the *middle trunk*. These three trunks incline laterally, first above or behind the clavicle and bifurcates into *anterior* and *posterior divisions*. The anterior divisions of the upper and middle trunks form a *lateral cord*, lateral to the axillary artery. The anterior division of the lower trunk descends at first behind, then medial to the axillary artery, forming the *medial cord* which often receives a branch from the seventh cervical ramus. Posterior divisions of all three form the *posterior cord*, at first above and then behind the axillary artery. The lower trunk's posterior division is much smaller than the others, containing few T1 fibers, from the first thoracic ramus. It is frequently derived from the eighth cervical before the trunk is formed.

Despite the extensive developmental changes in upper-limb innervation, the human brachial plexus reflects the original flexor–extensor organization of a primitive limb. The posterior cord supplies the extensor muscles, the medial and lateral cords the flexor muscles. Muscles of mixed nerve supply (e.g. pectoralis major) have undergone this pattern: e.g. the sternal part of the pectoralis major is supplied by the lateral pectoral nerve (flexor), whereas the clavicular part is supplied by the upper subscapular nerve (extensor). For a comparative comparison of the plexus in other species, see Plexus (topic).

Relations of the Brachial Plexus

In the neck, the plexus is in the posterior triangle, in the angle between the clavicle and lower posterior border of the sternocleidomastoid, covered by platysma, deep fascia and skin, through which it is palpable. It is crossed by the suprascapular nerves, the nerve to the subclavius, the inferior belly of the omohyoid, the external jugular vein and the superficial ramus of the transverse cervical artery (6.67). It emerges between the scalenus anterior and medius; its proximal part is superior to the third part of the subclavian artery, the lower trunk pressing on it. The plexus passes posterior to the medial two-thirds of the clavicle, the subclavius and the suprascapular vessels and lies on the first digitation of the serratus anterior and the subscapularis. In the axilla the lateral and posterior cords are lateral to the first part of the axillary artery, the medial cord being behind it. The cords surround the second part of the artery, related according to their names. In the lower axilla the cords divide into nerves for the upper limb. Except for the median nerve's medial root, these nerves are related to the artery's third part as their cords are to the second, i.e. branches of the lateral cord are lateral, of the medial cord medial and of the posterior cord posterior, to the artery.

Close to their exit from the intervertebral foramina, the fifth and sixth cervical ventral rami receive grey rami communicantes from the middle cervical sympathetic ganglion, the seventh and eighth from the cervicothoracic ganglion (p. 1160). The first thoracic ventral ramus also receives a grey ramus from and sometimes a white ramus to the cervicothoracic ganglion.

Branches of the brachial plexus may be described as *supraclavicular* and *infraclavicular*.

SUPRACLAVICULAR BRANCHES

These arise (1) from roots or (2) from trunks.

From roots	1	Nerves to scalenii and longus colli	C5, 6, 7, 8
	2	Branch to phrenic nerve	C5
	3	Dorsal scapular nerve	C5
	4	Long thoracic nerve	C5, 6, 7
From trunks	1	Nerve to subclavius	C5, 6
	2	Suprascapular nerve	C5, 6

Branches to the scalenii and longus colli arise from the lower cervical ventral rami near their exit from the intervertebral foramina. Anterior to the scalenus anterior the phrenic nerve is joined by a branch from the fifth cervical ramus.

The dorsal scapular nerve (5) from the fifth cervical ventral ramus, pierces the scalenus medius, passes behind the levator scapulae, which it occasionally supplies, and runs with the deep branch of the dorsal scapular artery to the rhomboids, which it supplies.

The long thoracic nerve (7) usually formed by roots from the fifth to the seventh cervical rami, the last may be absent. The branches from the roots all three pierce the scalenus medius obliquely, uniting in or lateral to it; the nerve descends dorsal to the brachial plexus and the first part of the axillary artery. Crossing the superior border of serratus anterior to reach its lateral surface, it may be joined by the root from C8, which emerges between the scaleni anterior and medius and descends on the latter's lateral surface. The nerve continues downwards to the lower border of the serratus anterior, supplying branches to each of its digitations.

The nerve to the subclavius (small) arises among the anterior branches of the fifth and sixth cervical ventral rami, crosses anterior to the plexus and the third part of the subclavian artery and is usually connected to the phrenic nerve. It passes above the subclavian vein to supply the subclavius.

The suprascapular nerve (6) (5, 6) is a large branch of the superior trunk that usually arises in common with the nerve to the subclavius. It runs laterally deep to the trapezius and omohyoid, enters the supraspinous fossa through the suprascapular notch inferior to the superior transverse scapular ligament, runs deep to the supraspinatus and curves round the lateral border of the scapular spine with the suprascapular artery to reach the infraspinous fossa, where it gives two branches to the supraspinatus and articular rami to the shoulder and acromioclavicular joints. The suprascapular nerve was found to have a cutaneous branch in six upper limbs out of 61 Japanese cadavers (Taniguchi 1986). When present, it pierced the deltoid muscle close to the tip of the acromion. In the one case where its peripheral distribution was examined, it was found to supply the skin of the proximal third of the arm within the territory of the axillary nerve.

INFRACLAVICULAR BRANCHES

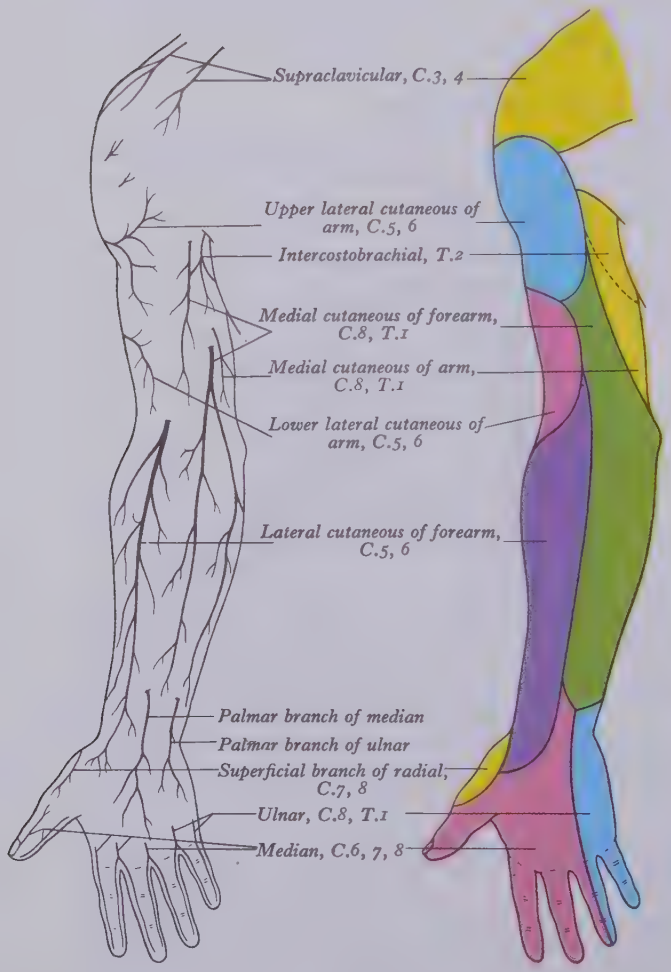
These (small) from the cord, no (four) from (one) may be traced back to the spinal nerves. They are as follows:

Lateral cord:	Lateral pectoral	C5, 6, 7
	Musculocutaneous	C5, 6, 7
	Lateral root of median	C6, 7, 8
Medial cord:	Medial pectoral	C8, T1
	Medial cutaneous of forearm	C8, T1
	Medial cutaneous of arm	C8, T1
	Ulnar	C7, 8, T1
	Medial root of median	C8, T1
Posterior cord:	Upper subscapular	C5, 6
	Thoracodorsal	C6, 7, 8
	Lower subscapular	C5, 6
	Axillary	C5, 6
	Radial	C5, 6, 7, 8, T1

The lateral pectoral nerve (1) (1, 2) (larger than the medial, may arise from the anterior divisions of the upper and middle trunks or by a single root from the lateral cord; its fibres are from the fifth to seventh cervical rami. It crosses anterior to the axillary artery and vein, pierces the clavipectoral fascia and supplies the deep surface of the pectoralis major. It sends a ramus to the medial pectoral nerve forming a loop in front of the first part of the axillary artery (7.67), to supply some fibres to the pectoralis minor.

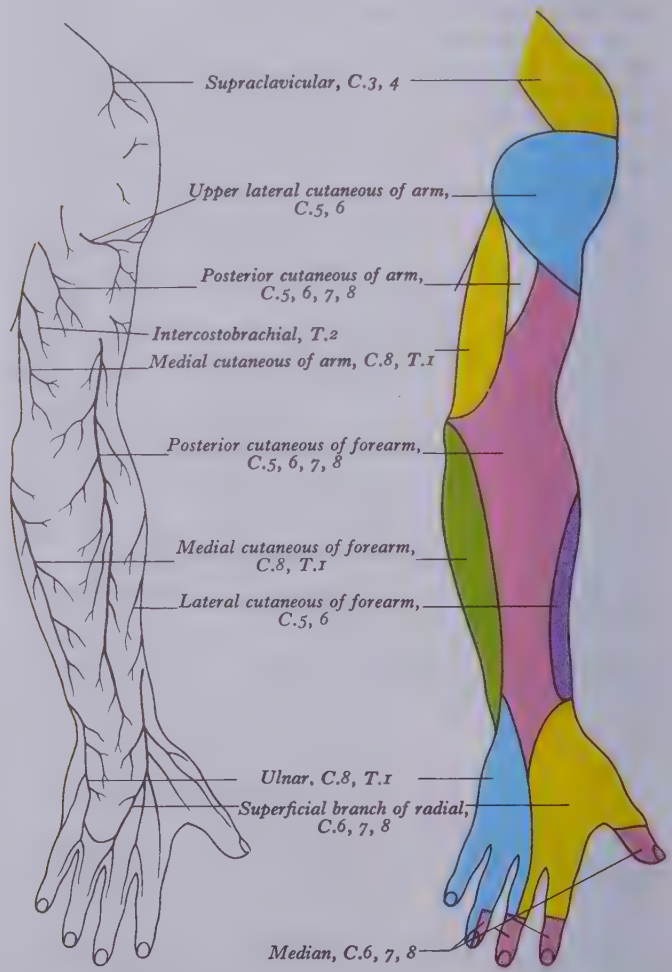
The medial pectoral nerve, derived from eighth cervical and first thoracic ventral rami, branches from the medial cord while this is posterior to the axillary artery. It curves forwards between the axillary artery and vein, anterior to the artery it joins a ramus of the lateral pectoral nerve, entering the deep surface of the pectoralis major to supply it. Two or three branches pierce the pectoralis major and others may pass round its inferior border to end in the pectoralis major.

The superior subscapular nerve, smaller than the inferior, arises from the posterior cord (C5 and 6), enters the subscapularis at a high level and is frequently double.



The inferior subscapular nerve, also from the posterior cord (C5 and 6), supplies the lower part of the subscapularis, ending in the teres major, which is sometimes supplied by a separate branch.

The thoracodorsal nerve, from the posterior cord, derives its fibres from the sixth to eighth cervical ventral rami, arises between the subscapular nerves and accompanies the subscapular artery along the posterior axillary wall to supply the latissimus dorsi, reaching its distal border.



The axillary (circumflex humeral) nerve (7.248) arises from the posterior cord, its fibres being derived from the fifth and sixth cervical ventral rami. It is at first lateral to the radial nerve, posterior to the axillary artery and anterior to the subscapularis, at whose lower border it curves back inferior to the humeroscapular articular capsule and, with the posterior circumflex humeral vessels, traverses a quadrangular space bounded *above* by the subscapularis (anterior) and teres minor (posterior), *below* by teres major, *medially* by the long head of triceps and *laterally* by the humeral surgical neck. The nerve finally divides into anterior and posterior branches. The *anterior branch*, with the posterior circumflex humeral vessels, curves round the humeral neck, deep to the deltoid, to its anterior border, supplying it and giving a few small cutaneous branches which pierce the muscle to ramify in the skin over its lower part. The *posterior branch* supplies the teres minor and the posterior part of the deltoid; on the branch to teres minor an enlargement or pseudoganglion usually exists. The posterior branch pierces the deep fascia low on the posterior border of the deltoid, continuing as the *upper lateral cutaneous nerve of the arm* and supplying the skin over the lower part of the deltoid and the upper part of the long head of triceps (7.244). The axillary trunk supplies a branch to the shoulder joint below the subscapularis.

The musculocutaneous nerve (7.247), from the lateral cord opposite the lower border of the pectoralis minor and derived from the fifth to the seventh cervical ventral rami, pierces the coracobrachialis and descends laterally between the biceps and brachialis to the lateral side of the arm; just below the elbow it pierces the deep fascia lateral to the tendon of biceps, continuing as the *lateral cutaneous nerve of the forearm*. A line drawn from the lateral side of the third part of the axillary artery across the coracobrachialis and biceps to the lateral side of the biceps tendon is a surface projection for the nerve, but this is varied by its point of entry into the coracobrachialis (Latarjet et al 1967). It supplies the coracobrachialis, both heads of biceps and most of the brachialis. The branch to the coracobrachialis leaves the musculocutaneous before it enters the muscle; its fibres are from the seventh cervical ramus and may branch directly from the lateral cord. Branches to the biceps and brachialis leave after the musculocutaneous pierces the coracobrachialis; the branch to the brachialis supplies the elbow joint. The nerve also supplies a small branch to the humerus, entering with the nutrient artery.

The lateral cutaneous nerve of the forearm (7.244) passes deep to the cephalic vein, descending along the radial border of the forearm to the wrist, supplying the skin of the forearm's anterolateral surface and connecting by branches around its radial border with the posterior cutaneous nerve of the forearm and the terminal branch of the radial nerve. Its trunk gives rise to a slender recurrent branch which extends along the cephalic vein as far as the middle third of the upper arm, distributing filaments to the

7.244 The cutaneous nerves of the right upper limb, their areas of distribution and segmental origins, viewed from the anterior aspect.

7.245 The cutaneous nerves of the upper right limb, their areas of distribution and segmental origins, viewed from the posterior aspect.

skin over the distal third of the anterolateral surface of the upper arm close to the vein (Horiguchi 1981). Although observed in the nineteenth century (Arnold 1851, Bolk 1898), this recurrent branch has more recently been omitted from most descriptions of the nerve supply of the upper limb. At the wrist joint the lateral cutaneous nerve of the forearm is anterior to the radial artery and some filaments, piercing the deep fascia and accompanying this to the dorsum of the carpus. The nerve then passes to the base of the thenar eminence, ending in cutaneous rami. It connects with the terminal branch of the radial nerve and the palmar cutaneous branch of the median nerve.

The *musculocutaneous* nerve has frequent variations. It may run behind the coracobrachialis or adhere for some distance to the median nerve and pass behind the biceps. Some fibres of the median nerve may run in the musculocutaneous nerve, leaving it to join their proper trunk; less frequently the reverse occurs, the median nerve sending a branch to the musculocutaneous. Occasionally it supplies the pronator teres and may replace radial branches to the dorsal surface of the thumb.

The medial cutaneous nerve of the forearm (7.247), from the medial cord, is derived from the eighth cervical and first thoracic ventral rami. At first it is between the axillary artery and vein and supplies a ramus piercing the deep fascia to supply the skin over the biceps, almost to the elbow. The nerve descends medial to the brachial artery, pierces the deep fascia with the basilic vein midway in the arm and divides into anterior and posterior branches. The larger, *anterior branch* usually passes in front of, occasionally behind, the median cubital vein, descending anteromedial in the forearm to supply the skin as far as the wrist and connecting with the palmar cutaneous branch of the ulnar nerve (7.244). The *posterior branch* descends obliquely medial to the basilic vein, anterior to the medial epicondyle, and curves round to the back of the forearm, descending on its medial border to the wrist, supplying the skin. It connects with the medial cutaneous nerve of the arm, the posterior cutaneous nerve of the forearm and the dorsal branch of the ulnar (7.245).

The medial cutaneous nerve of the arm, supplying the skin in that area (7.244) and the smallest branch of the plexus, arises from the medial cord and contains fibres from the eighth cervical and first thoracic ventral rami. It traverses the axilla, crossing anterior or posterior to the axillary vein, to which it is then medial, and communicating with the intercostobrachial nerve; it descends medial to the brachial artery and basilic vein (7.247) to a point midway in the upper arm, where it pierces the deep fascia to supply a medial area in the arm's distal third, extending on to its anterior and posterior aspects. Some rami reach the skin anterior to the medial epicondyle, others over the olecranon. It connects with the posterior branch of the medial cutaneous nerve of the forearm. Sometimes the medial cutaneous nerve of the arm and the intercostobrachial nerve are connected in a plexiform manner in the axilla. Sometimes the intercostobrachial nerve is large and reinforced by part of the lateral cutaneous branch of the third intercostal nerve, replacing the arm's medial cutaneous nerve and receiving from the brachial plexus a connection representing the latter; occasionally this connection is absent.

THE MEDIAN NERVE

The median nerve (7.247) has two roots from the lateral (C(5),6,7) and medial (C8, T1) cords, which embrace the third part of the axillary artery, uniting anterior or lateral to it. Some fibres from C7 often leave the lateral root in the lower part of the axilla passing distomedially posterior to the medial root, usually anterior to axillary artery, to join the ulnar nerve (7.263); they may branch from the seventh cervical ventral ramus. Clinically they are believed to be mainly motor to the flexor carpi ulnaris. If the lateral root is small, the musculocutaneous nerve (C5,6,7) connects with the median nerve in the arm.

The median nerve enters the arm at first lateral to the brachial artery; near the insertion of the coracobrachialis it crosses in front of (rarely behind) the artery, descending medial to it to the cubital fossa where it is posterior to the bicipital aponeurosis and anterior to the brachialis, separated by the latter from the elbow joint. It usually enters the forearm between the heads of the pronator teres, crossing to the lateral side of the ulnar artery and separated from it by the deep head of pronator teres. It proceeds behind a tendinous bridge between the humero-ulnar and radial heads of the flexor digitorum superficialis, descending posterior and adherent to the flexor digitorum superficialis and anterior to the flexor digitorum profundus. About 5 cm proximal to the flexor retinaculum it emerges from behind the lateral edge of the flexor digitorum superficialis, becoming superficial just proximal to the wrist between the tendons of the flexors digitorum superficialis and carpi radialis, projecting laterally from behind the tendon of the palmaris longus. It then passes deep to the flexor retinaculum into the palm. In the forearm it is accompanied by the median branch of the anterior interosseous artery. Its course can be marked on the surface by a line from the medial side of the brachial artery in the cubital fossa along the forearm's midline (7.246).

Relations as the median nerve enters the forearm are variable. According to Anson (1963) the route described above occurred in 82·8% of 1000 dissections; in 10·8% the nerve was posterior to the humeral head of the pronator teres, the ulnar slip being absent. In 4·6% the nerve was posterior to both heads, and in 1·8% traversed *through* the humeral head.

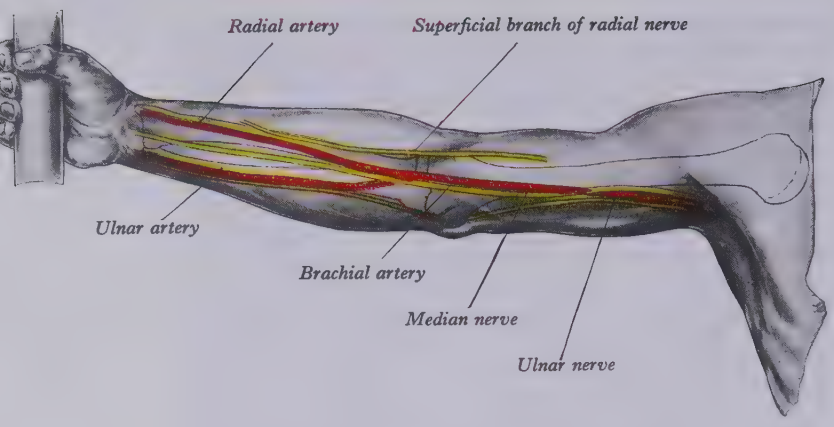
Branches of the Median Nerve in the Arm

These are vascular branches to the brachial artery and usually a branch to the pronator teres, a variable distance proximal to the elbow joint.

Branches of the Median Nerve in the Forearm

These are muscular, articular, anterior interosseous, palmar cutaneous and communicating. **Muscular branches**, except one, are given off proximally (near the elbow) to the superficial flexor muscles (except the flexor carpi ulnaris), i.e. to the pronator teres, flexor carpi radialis, palmaris longus and the flexor digitorum superficialis. The branch to the part of the flexor digitorum superficialis for the index finger arises near mid-forearm but may be from the anterior interosseous nerve. **Articular branches**, arising at or just distal to the elbow joint, supply it and the proximal radio-ulnar joint.

The anterior interosseous nerve branches posteriorly from the median nerve between the two heads of pronator teres, just distal to the origin of branches to the superficial forearm flexors. With the anterior interosseous artery it descends anterior to the interosseous membrane, between and deep to the flexors pollicis longus and digitorum profundus and supplying both; branches to the latter are limited to its lateral part, which sends tendons to the index and middle fingers. Terminally it is posterior to the pronator quadratus, supplying its deep surface, and supplies the distal radio-ulnar, radio-carpal and carpal joints.



The palmar cutaneous branch starts just proximal to the flexor retinaculum, pierces it or the deep fascia and divides into *lateral branches* supplying the thenar skin and connecting with the lateral cutaneous nerve of the forearm; and *medial branches* supplying the central palmar skin and connecting with the palmar cutaneous branch of the ulnar nerve.

A communicating branch, which may be multiple, often arises (sometimes from the anterior interosseous branch) in the proximal forearm and passes medially between flexors digitorum superficialis and profundus and behind the ulnar artery to join the ulnar nerve. It is a factor in explaining anomalous muscular innervation in the hand (p. 1135).

The Median Nerve in the Hand

Proximal to the flexor retinaculum the nerve is lateral to the tendons of flexor digitorum superficialis but further distally it lies between the retinaculum and tendons in the 'carpal tunnel' (see p. 625), i.e. the space between the flexor retinaculum and the anterior carpal surface. The nerve may become compressed here (p. 1137). Distal to the retinaculum the nerve enlarges and flattens, usually dividing into five or six branches but the mode and level of division are variable.

The muscular branch, short and thick, is from the nerve's lateral side; it may be the first palmar or a terminal branch arising level with the digital branches. It runs laterally, just distal to the

7.246 The anterior aspect of the right upper limb, showing the position of the principal nerves and vessels projected on to the surface.

flexor retinaculum, with a slight recurrent curve beneath the part of the palmar aponeurosis covering the thenar muscles. It turns round the distal border of the retinaculum to lie superficial to the flexor pollicis brevis, usually supplying it and either continuing superficial to it or traversing it. It gives a branch to the abductor pollicis brevis, which enters the muscle's medial edge and then passes deep to it to supply the opponens pollicis, entering its medial edge. Its terminal part occasionally gives a branch to the first dorsal interosseous, which may be its sole or partial supply. The muscular branch may arise in the carpal tunnel and pierce the flexor retinaculum, a point of surgical importance (Papathanassion 1968).

The palmar digital branches. (In this account of cutaneous innervation of the digits, the distinction between proximal, penultimate, undivided rami, termed *common palmar digital nerves*, and their ultimate branches to individual digits, the *proper palmar digital nerves*, must be noted. The corresponding terms for the foot are *common plantar digital nerves* and *proper plantar digital nerves*.) The median nerve divides into four or five digital branches, though it often divides first into two: a lateral ramus providing digital branches to the pollex and the radial side of the index finger; and a medial, supplying digital branches to adjacent sides of the index, medius and annularis. Other modes of termination occur (Poisel 1974). Digital branches are commonly arranged as follows. They pass distally, deep to the superficial palmar arch and its digital vessels, at first anterior to the long flexor tendons. Two *proper* palmar digital nerves, sometimes from a common stem, pass to the sides of the pollex, that supplying its lateral side crossing in front of the tendon of flexor pollicis longus. The *proper* palmar digital nerve to the lateral side of the index also supplies the first lumbrical muscle. Two *common* palmar digital nerves pass distally between the long flexor tendons: the lateral divides in the distal palm into two *proper* palmar digital nerves traversing adjacent sides of the index and medius; the medial one divides into two *proper* palmar digital nerves supplying adjacent sides of the medius and annularis. The lateral common digital nerve supplies the second lumbrical muscle; the medial receives a communicating twig from the common palmar digital branch of the *ulnar* nerve and may supply the third lumbrical muscle. In the distal part of the palm, the digital arteries pass deeply between the divisions of the digital nerves; on the sides of the digits the nerves are anterior to the arteries. The median nerve usually supplies palmar cutaneous digital branches to the lateral three and one-half digits (pollex, index, medius and the lateral side of the annularis); sometimes the lateral side of the ring finger is supplied by the ulnar nerve. The proper palmar digital nerves that pass along the medial side of the index, both sides of the medius and the lateral side of the annularis, enter these digits in fat between slips of the central palmar aponeurosis (p. 627). They pass, with the lumbricals and palmar digital arteries, dorsal to the superficial transverse metacarpal ligament (p. 629) and ventral to the deep transverse metacarpal ligament (p. 515). In the digits, the nerves run distally beside the long flexor tendons, outside their fibrous sheaths, level with the anterior phalangeal surfaces and anterior to the digital arteries. Each nerve gives off several branches to the skin on the front and sides of the digit, many ending in lamellated corpuscles (p. 911), and branches to the metacarpophalangeal and interphalangeal joints. They also supply the fibrous sheaths of the long flexor tendons, digital arteries (vasomotor) and sweat glands (secretomotor). Distal to the base of the distal phalanx the digital nerve gives off a branch passing dorsally to the nail bed, the main nerve dividing to supply the pulp and skin of the terminal part of the digit. Distal to the base of the proximal phalanx, each *proper* digital nerve also gives off a dorsal branch to supply the skin over the back of the middle and distal phalanges (7.245). The *proper* palmar digital nerves to the pollex and the lateral side of the index emerge with the long flexor tendons from under the lateral edge of the central palmar aponeurosis and are arranged in the digits as described above; but in the pollex small distal branches supply the skin on the back of the distal phalanx only.

In addition to the branches of the median nerve described above, variable vasomotor branches supply the radial and ulnar arteries and their branches. Some of the intercarpal, carpometacarpal and intermetacarpal joints are said to be supplied by the median nerve or its anterior interosseous branch, the precise details being uncertain.

THE ULNAR NERVE

The ulnar nerve (7.247) arises from the medial cord (C8, T1) but, as described above (p. 1131), it often receives fibres from the ventral ramus of C7. It runs distally through the axilla medial to the axillary artery and between it and the vein, continuing distally medial to the brachial artery as far as mid-arm; here it pierces the medial intermuscular septum, inclining medially as it descends anterior to the medial head of the triceps to the interval between the medial epicondyle and the olecranon, with the superior ulnar collateral artery. At the elbow it is in a groove on the dorsum of the epicondyle. It enters the forearm between the two heads of the flexor carpi ulnaris superficial to the posterior and oblique parts of the ulnar collateral ligament. It descends the medial side of the forearm on the flexor digitorum profundus, covered proximally by the flexor carpi ulnaris; its lower half, covered by skin and fasciae, is lateral to this muscle. In the upper third of the forearm, it is distant from the ulnar artery but distal to this is close to its medial side (7.247). About 5 cm proximal to the wrist it gives off a dorsal branch which continues distally into the hand, anterior to the flexor retinaculum on the lateral to the pisiform bone and posteromedial to the ulnar artery. It passes behind the superficial part of the retinaculum with the artery and divides into superficial and deep terminal branches. Its relation to the brachial artery and medial epicondyle makes it easy to map out in its proximal course; a line from the medial epicondyle to the lateral edge of pisiform represents its distal course (7.246).

Its *branches* are: articular, muscular, palmar cutaneous, dorsal, superficial terminal and deep terminal.

Articular branches to the elbow joint issue from the nerve between the medial epicondyle and olecranon. Others are described below.

Muscular branches, usually two, begin near the elbow; one supplies the flexor carpi ulnaris (p. 617), the other the medial half of the flexor digitorum profundus.

The palmar cutaneous branch arises about mid-forearm, descends on the ulnar artery (7.247), which it supplies, and perforates the deep fascia to end in the palmar skin, after communicating with the palmar branch of the median nerve. It sometimes supplies the palmaris brevis.

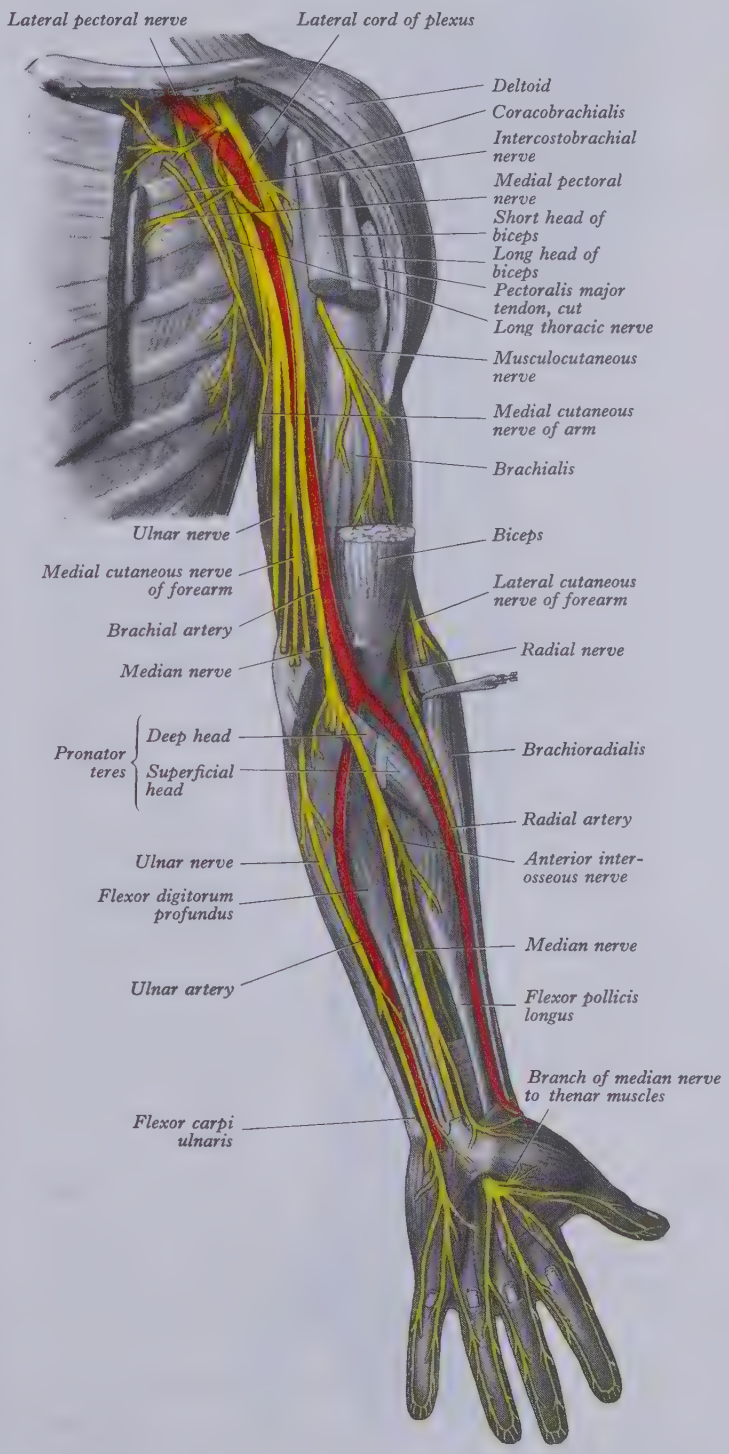
The dorsal branch arises about 5 cm proximal to the wrist, passes distally and backwards, deep to the flexor carpi ulnaris, perforates the deep fascia, descends along the medial side of the back of the wrist and hand and then divides into two, or often three, dorsal digital nerves. One supplies the medial side of the minimus, the second adjacent sides of minimus and annularis, while the third, when present, supplies adjoining sides of the annularis and medius but may be replaced, wholly or partially, by a branch of the radial nerve, always communicating with it on the dorsum of the hand (7.245). In the minimus the dorsal digital

nerves extend only to the base of the distal phalanx and in the annularis to the base of the middle phalanx; more distal parts of these digits are supplied by dorsal branches of the proper digital branches of the ulnar and, on the lateral side of the annularis, medial nerves.

The superficial terminal branch supplies the palmaris brevis and the medial palmar skin, dividing into two palmar digital nerves, which can be palpated against the hook of the hamate bone (p. 418); one of these supplies the medial side of minimus, the other (a *common* palmar digital nerve) sends a twig to the median nerve and divides into two *proper* digital nerves for the adjoining sides of minimus and annularis (7.247). The proper digital branches are distributed like those of the median nerve. Murakami (1969) has described articular branchlets from the superficial terminal branch of the ulnar nerve.

The deep terminal branch, with the deep branch of the ulnar artery, passes between the abductor digiti minimi and flexor digiti minimi and then perforates the opponens digiti minimi to follow the deep palmar arch dorsal to the flexor tendons. At its origin it supplies the three short muscles of the minimus. As it crosses the hand, it supplies the interossei and the third and fourth lumbricals; it ends by supplying the adductor pollicis, the first palmar interosseous and usually (p. 630) the flexor pollicis brevis. It sends articular filaments to the wrist joint.

The medial part of the flexor digitorum profundus is supplied by the ulnar nerve, as are the third and fourth lumbricals which are connected with the tendons of this part of the muscle. Similarly, the lateral part of the flexor digitorum profundus and the first and second lumbricals are supplied by the median nerve. The third lumbrical is often supplied by both nerves. The deep terminal branch is said to give branches to some intercarpal, carpometacarpal and intermetacarpal joints, though, as with the median nerve, precise details are uncertain. Vasomotor branches, arising in the forearm and hand, supply the ulnar and palmar arteries.

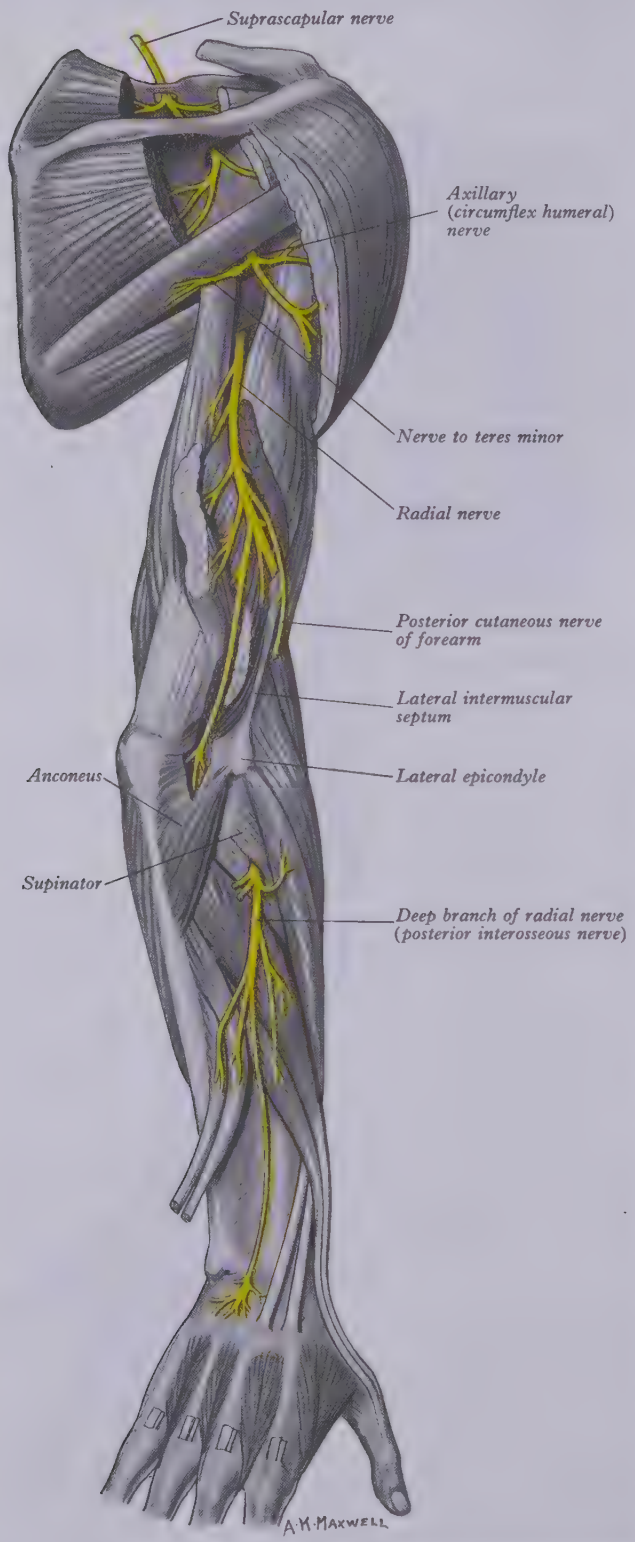


The Anomalous Nerve Supply of the Hand Muscles

The nerve supply to the short thenar muscles varies. From the results of lesions of the median and ulnar nerves in the forearm (Rowntree 1949, Day & Napier 1961) the following variations were deduced, expressed here in percentages of 226 hands examined and regarding innervation of the thenar muscles by median, ulnar or both nerves: flexor pollicis brevis—median 36, ulnar 48, both 17; abductor pollicis brevis—median 95, ulnar 2·5, both 2; opponens pollicis—median 83, ulnar 9, both 7·5. The usual description is that all three are supplied by the median nerve; the results cited are possibly explicable, in part, by the variable connections between the median and ulnar nerves in the axilla, arm or forearm, by which median fibres are aberrantly conveyed in the ulnar nerve. An arcuate connecting nerve has long been recognized between median and ulnar nerves in the substance of the flexor pollicis brevis (Cannieu 1886), either part of which, superficial or deep, may be supplied by both nerves. In a more recent survey (Harness & Sekeles 1971) of the considerable literature, the results of dissections in 35 hands showed a loop in 77%, suggesting that it should be a feature of 'normal' description. Clinically variations are important; even with a complete lesion of the median nerve some of these muscles may escape paralysis, leading to erroneous conclusions. Clinical evidence reveals that the short thenar muscles receive their segmental supply from the eighth cervical and first thoracic spinal cord segments. Variations in both the motor and sensory supply of the thumb have been examined by Fálconer & Spinner (1985).

THE RADIAL NERVE

The radial nerve (7.248) arises from the posterior cord, C5,6,7,8, (T1). The largest branch of the brachial plexus, it descends behind the third part of the axillary artery and the upper part of the brachial, anterior to the subscapularis and the tendons of the latissimus dorsi and teres major. With the arteria profunda brachii and, later, its radial collateral branch, it inclines dorsally between the long and medial heads of the triceps, after which it passes obliquely across the back of the humerus, first between the lateral and medial heads of the triceps, then in a shallow groove deep to the lateral head. On reaching the lateral side of the humerus it pierces the lateral intermuscular septum to enter the anterior compartment; it then descends deep in a furrow between the brachialis and proximally the brachioradialis, then more distally the extensor carpi radialis longus. Anterior to the lateral epicondyle it divides into *superficial* and *deep* terminal rami.



In the arm the radial nerve is indicated by a posterior line from the start of the brachial artery distally and laterally to the junction of the upper and middle thirds of a line between the lateral epicondyle and the deltoid tuberosity; the line is continued anteriorly as far as the lateral epicondyle, 1 cm or less lateral to the biceps tendon.

7.247 The nerves of the left upper limb, dissected from the anterior aspect.

The *branches* of the radial nerve are: muscular, cutaneous, articular and superficial and deep terminal.

Muscular branches supply the triceps, anconeus, brachioradialis, extensor carpi radialis longus and brachialis in *medial*, *posterior* and *lateral* groups. *Medial* muscular branches arise from the radial nerve on the medial side of the arm. They supply the medial and long heads of the triceps, the branch to the medial being a long, slender filament which, lying close to the ulnar nerve as far as the distal third of the arm, is often termed the *ulnar collateral nerve*. A large *posterior* muscular branch arises from the nerve as it lies in the humeral groove. It divides to supply the medial and lateral heads of the triceps and the anconeus, that for the latter being a long nerve which descends in the medial head of the triceps and partially supplies it; it is accompanied by the middle collateral branch of the arteria profunda brachii and passes behind the elbow joint to end in the anconeus. *Lateral* muscular branches arise in front of the lateral intermuscular septum; they supply the lateral part of the brachialis, brachioradialis and extensor carpi radialis longus.

7.248 The suprascapular, axillary and radial nerves of the right upper limb, dissected from the posterior aspect.

The cutaneous branches are the posterior and lower lateral cutaneous nerves of the arm and the posterior cutaneous nerve of the forearm. The small **posterior cutaneous nerve of the arm** arises in the axilla and passes medially to supply the skin on the dorsal surface of the arm nearly as far as the olecranon. It crosses posterior to and communicates with the intercostobrachial nerve. **The lower lateral cutaneous nerve of the arm** perforates the lateral head of the triceps distal to the deltoid tuberosity, passes to the front of the elbow close to the cephalic vein and supplies the skin of the lateral part of the lower half of the arm (7.244). **The posterior cutaneous nerve of the forearm** arises with the preceding nerve. Perforating the lateral head of the triceps, it descends first lateral in the arm, then along the dorsum of the forearm to the wrist, supplying the skin in its course and joining, near its end, with dorsal branches of the lateral cutaneous nerve of the forearm (7.244).

The articular branches are distributed to the elbow joint.

The superficial terminal branch descends from the lateral epicondyle anterolaterally in the proximal two-thirds of the forearm, at first on the supinator, lateral to the radial artery and behind the brachioradialis; in the middle third of the forearm it is behind the brachioradialis, close to the lateral side of the artery, successively anterior to the pronator teres, the radial head of the flexor digitorum superficialis and the flexor pollicis longus. It leaves the artery about 7 cm proximal to the wrist, passes deep to the tendon of the brachioradialis, curves round the lateral side of the radius as it descends, pierces the deep fascia and divides into five, sometimes four, dorsal digital nerves. On the dorsum of the hand it usually communicates with the posterior and lateral cutaneous nerves of the forearm.

The *dorsal digital nerves*, usually four or five, are small. The first supplies the skin of the radial side of the pollex and the adjoining thenar eminence, communicating with branches of the lateral cutaneous nerve of the forearm; the second supplies the medial side of the pollex; the third, the lateral side of the index; the fourth, the adjoining sides of the index and medius; the fifth communicates with a ramus of the dorsal branch of the ulnar nerve and supplies the adjoining sides of the medius and annularis but is frequently replaced by the dorsal branch of the ulnar nerve. The pollicial digital nerves reach only to the root of the nail, those in the index midway along the middle phalanx, those to the medius and the lateral part of the annularis not further than the proximal interphalangeal joints. The remaining distal dorsal areas of the skin in these digits are supplied by palmar digital branches of the median and ulnar nerves (7.245). The superficial terminal branch of the radial nerve may supply the whole dorsum of the hand; for variations consult Sayfi (1967).

The deep terminal branch (posterior interosseous nerve) (7.248) reaches the back of the forearm round the lateral aspect of the radius and between the two planes of the fibres of the supinator. It supplies the extensor carpi radialis brevis and the supinator before entering it; as it traverses the muscle it supplies it with additional branches. The branch to the extensor carpi radialis brevis may arise from the beginning of the superficial branch of the radial nerve. As it emerges from the supinator posteriorly it gives off three short branches, to the extensor digitorum, extensor digiti minimi and extensor carpi ulnaris, and two longer branches, a *medial* to the extensor pollicis longus and extensor indicis and a *lateral*, supplying the abductor pollicis longus and ending in the extensor pollicis brevis. The nerve is at first between the superficial and deep extensor muscles; but at the distal border of the extensor pollicis brevis it passes deep to the extensor pollicis longus and, diminished to a fine thread, descends on the interosseous membrane to the dorsum of the carpus, where

it presents a flattened and somewhat expanded termination or 'pseudoganglion', from which filaments supply the carpal ligaments and articulations (7.248).

Articular branches from the deep branch of the radial nerve supply the carpal, distal radio-ulnar and some intercarpal and intermetacarpal joints; digital branches supply the metacarpophalangeal and proximal interphalangeal joints.

Applied Anatomy. The brachial plexus may be injured in falls on the side of the head and shoulder, nerves in the plexus being violently stretched; its upper trunk sustains the greatest injury and paralysis may be confined to muscles supplied by the fifth cervical ramus: the deltoid, biceps, brachialis and brachioradialis, with sometimes also supraspinatus, infraspinatus and supinator. The arm typically hangs in medial rotation, with the forearm extended and pronated. It cannot be abducted; flexion of the elbow and supination of the forearm are lost. This is *Erb's paralysis* and a similar condition occasionally appears in newborn children, from injury to the upper trunk by obstetric forceps or from traction in breech presentations. A second variety is *Klumpke's paralysis*, in which the eighth cervical and first thoracic rami are injured, before or after they join to form the lower trunk. Paralysis mainly affects the intrinsic muscles of the hand and the flexors of the wrist and fingers.

The plexus may also be injured by direct violence or gunshot wounds, by violent traction on the arm or in reducing a glenohumeral dislocation. The extent of paralysis depends on the injury. When the entire plexus is involved, the whole of the upper extremity is paralysed and anaesthetic. Sometimes injury appears to be an avulsion of nerves from the spinal cord; where this involves the first thoracic ramus the ipsilateral pupil may be constricted, due to damage to the preganglionic fibres in it which supply the dilatator pupillae. The plexus is often damaged in the axilla by pressure of a crutch, producing '*crutch paralysis*', in which the radial is most frequently implicated, followed by the ulnar. The median and radial nerves often suffer '*sleep palsies*', paralysis due to pressure during alcoholic or narcotic stupor.

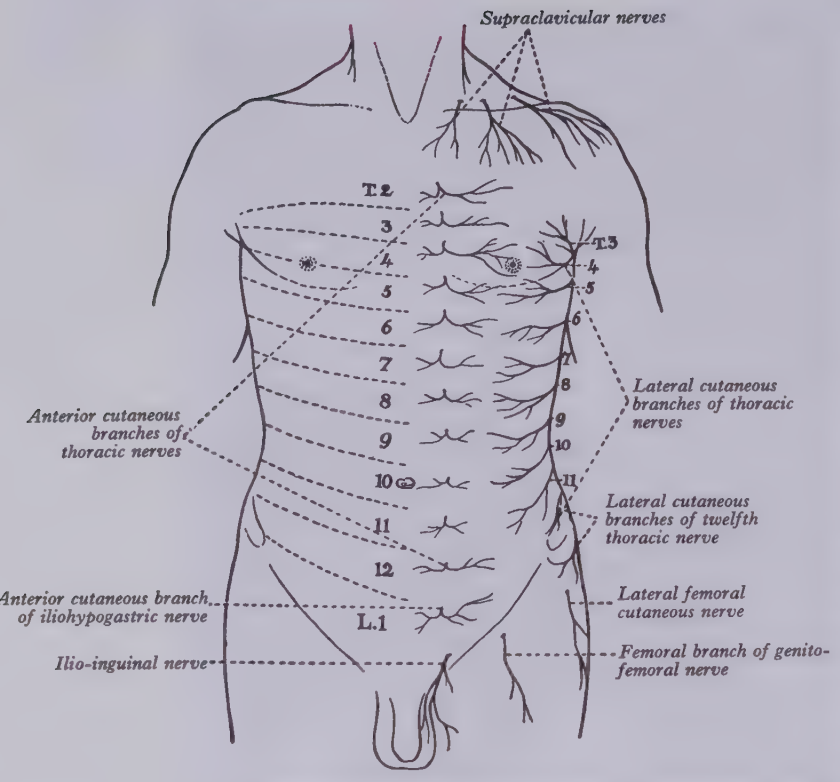
Damage of the long thoracic nerve paralyses the serratus anterior; it may afflict porters carrying heavy weights on the shoulder, the nerve being exposed to injury in the posterior triangle of the neck. The inferior scapular angle is drawn medially by unopposed action of the rhomboids and the levator scapulae and tends to project ('winging' of the scapula) when the horizontal arm is used for forward pushing movements. The arm cannot be raised above the horizontal.

The *axillary* (*circumflex humeral*) *nerve*, in its course round the surgical neck of the humerus, is liable to injury in fractures and dislocations; paralysis of the deltoid and anaesthesia of the skin over the lower part of the muscle result. Effective abduction of the arm is impossible. Paralysis of the teres minor occurs but is not easily demonstrated.

The *median nerve* may be involved in forearm injury. When it is divided proximal to its muscular and anterior interosseous branches, flexion of the second phalanges in all digits is lost, and of the terminal phalanges of the index and medius. Terminal phalanges in the annularis and minimus are flexed by the part of the flexor digitorum profundus supplied by the ulnar nerve. Proximal phalanges may be flexed by the interossei. The pollex cannot be opposed or abducted, nor flexed at its interphalangeal joint (see p. 1134); it remains extended and adducted. Forearm pronation is weakened, for the brachioradialis can effect only mid-pronation. The wrist can be flexed by the flexor carpi ulnaris but this is combined with adduction. Sensation is lost or impaired on the palmar surfaces of all except the medial one and a half digits and on dorsal surfaces of the same over the distal two phalanges, except in the pollex where loss is limited to the dorsum of the distal phalanx. Owing to paralysis of pollicial intrinsic muscles and the unopposed action of the extensor pollicis longus, an '*ape-like*' hand exists. Injury of the median nerve in the mid-forearm may cause only weakness in flexion of the index ('*pointing*' index finger), since the branch to the part of the flexor digitorum superficialis distributed to this finger arises at about that level (p. 1133); more commonly the nerve is injured proximal to the flexor retinaculum, when flexion of the fingers and pronation of the forearm remains intact, unless the flexor tendons are also divided; the main effect of such lesions is usually an inability to oppose the pollex, though the intact abductor pollicis longus and adductor pollicis may combine to imitate this. Deep to the flexor retinaculum the median nerve is in the restricted space between the retinaculum and the carpal bones (carpal tunnel, p. 625). Any condition diminishing this space (e.g. carpal dislocation, arthritis, tenosynovitis, etc.) may cause pressure on the nerve with resultant pain and slight sensory impairment in the digits supplied and sometimes slight wasting of the thenar muscles—the '*carpel tunnel syndrome*'. Commonly no cause is apparent; division of the retinaculum is curative.

The *ulnar nerve* may also be injured in forearm wounds, the commonest site of complete or partial division being behind the medial epicondyle, leading to impaired adduction; in attempts to flex the wrist the hand is abducted by the flexor carpi radialis; owing to paralysis of the dorsal interossei the fingers cannot be spread or flexed at the metacarpophalangeal joints or extended at the interphalangeal joints (especially the annularis and minimus); the hand assumes a 'clawed' shape from the active opposing muscles. Flexion in the fourth and fifth digits is weakened and the pollex cannot adduct. Hypothenar muscles waste. Sensation is lost or impaired, in skin supplied by the nerve.

The *radial nerve* also is often injured but seldom torn in fractures of the humerus, due to its close relationship to this bone. In repair callus formation seldom interferes with the nerve. In fractures of the mid-humerus, the triceps is not paralysed, since its nerve supply arises more proximally from the radial nerve. It may also be contused against bone by kicks or blows or be divided in incised wounds. When paralysed, the hand is flexed at the wrist and flaccid, a condition known as *wrist drop*. The digits are also flexed and in attempted extension only the middle and distal phalanges are extended (by lumbrical and interosseous muscles), the proximal phalanges remaining flexed. Carpal extension is impossible. Supination is completely lost in the extended forearm, but flexion allows the biceps to act as a supinator. Extension of the forearm is lost if injury near the nerve's origin causes the triceps to be paralysed. As the radial nerve has only a small area of exclusive supply, anaesthesia is similarly small and confined to a limited lateral region on the dorsum of the hand.



Dislocations and epiphysial separations at the elbow and supracondylar fractures of the humerus in children often lead to ulnar, median or posterior interosseous injury.

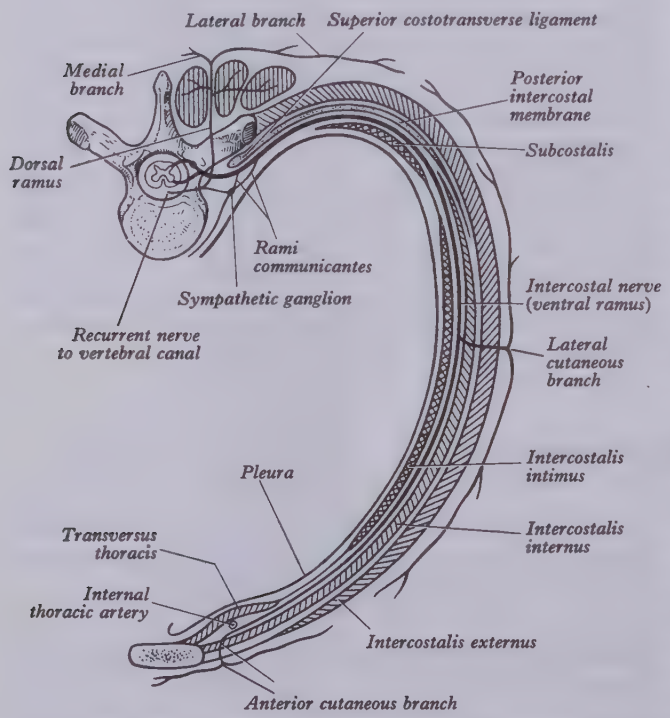
THORACIC VENTRAL RAMI

There are twelve pairs of thoracic ventral rami (7.249, 250); all but the twelfth are between the ribs (*intercostal nerves*), the twelfth being below the last rib (*subcostal nerve*). Each is connected with an adjacent sympathetic ganglion by grey and white rami communicantes: the grey ramus joins the nerve proximal to the exit of the white ramus. Intercostal nerves are distributed chiefly to the thoracic and abdominal walls; the first two supply the upper limb in addition, the next four are limited to the thoracic wall, while the lower five supply the thoracic and abdominal walls (p. 1138). The subcostal nerve supplies the abdominal wall and gluteal skin. Communicating branches link intercostal nerves posteriorly in the intercostal spaces; the lower five communicate freely in the abdominal wall (Davies et al 1932).

The First to the Sixth Thoracic Ventral Rami

The first thoracic ventral ramus divides unequally; a large branch ascends across the first rib's neck, lateral to the superior intercostal

7.249 The approximate segmental distribution of the cutaneous nerves on the front of the trunk. The contribution from the first thoracic spinal nerve is not shown and the considerable overlap which occurs between adjacent segments is not indicated. For the latter see 7.264.



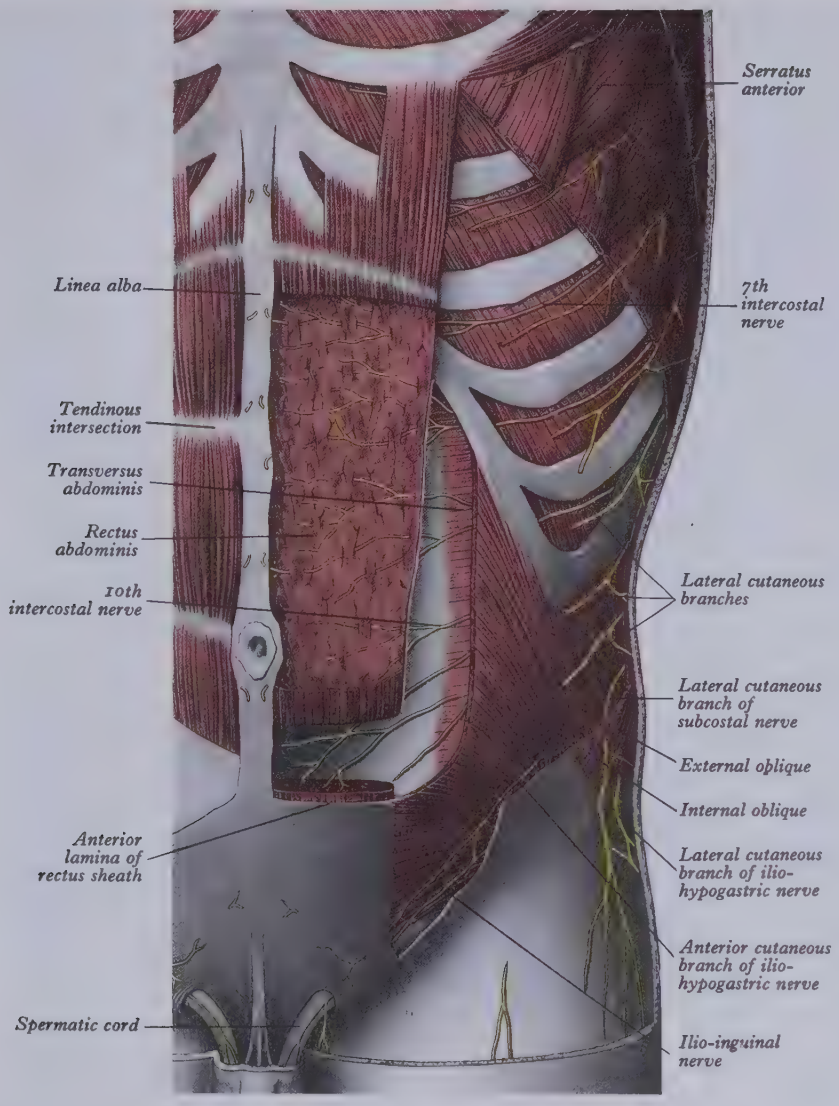
artery, to enter the brachial plexus (p. 1130). The smaller *first intercostal nerve* runs in the first intercostal space and ends as the first anterior cutaneous nerve of the thorax. A lateral cutaneous branch pierces the chest wall in front of the serratus anterior to supply the axillary skin; it may communicate with the intercostobrachial nerve and sometimes joins with the medial cutaneous nerve of the arm (Cave 1929). The first thoracic ramus often connects with the second across the neck of the second rib.

The second to sixth thoracic ventral rami proceed (7.244) in their intercostal spaces below the intercostal vessels. Posteriorly they are between the pleura and posterior intercostal membranes but in most of their course run between the internal intercostals and the subcostales and intercostales intimi (7.249). Near the sternum, they cross anterior to the internal thoracic vessels and the transversus thoracis, pierce the internal intercostals, external intercostal membrane and pectoralis major, ending as the **anterior cutaneous nerves of the thorax**, which supply the skin on the front of the thorax. The second anterior cutaneous nerve may be connected to the medial supraclavicular nerves; twigs from the sixth supply abdominal skin in the upper part of the infrasternal angle.

Branches. Numerous muscular rami supply the intercostals, serratus posterior superior and transversus thoracis. Anteriorly some cross the costal cartilages from one intercostal space to another.

From each intercostal nerve a collateral and a lateral cutaneous branch leave before the main nerve reaches the costal angle. The *collateral branch* follows the inferior border of its space in the same intermuscular plane as the main nerve, which it may rejoin before distribution as an additional anterior cutaneous nerve. The *lateral cutaneous branch* accompanies the main nerve a little way and then pierces the intercostal muscles obliquely; except for the first and second, each divides into anterior and posterior rami which pierce the serratus anterior. *Anterior branches* run forwards over the border of the pectoralis major to supply the overlying skin, the fifth and sixth also supplying twigs to a variable number of upper digitations of the obliquus abdominis externus. *Posterior branches* run back to supply the skin over the scapula and latissimus dorsi.

The second lateral cutaneous branch is the *intercostobrachial nerve* (7.247). It crosses the axilla to the medial side of the arm, joins with a branch of the medial cutaneous nerve of the arm, pierces the deep fascia and supplies the skin of the upper half of the posterior and medial aspects of the arm, connecting with the posterior brachial cutaneous branch of the radial nerve. Its size is in inverse proportion to the size of the medial brachial cutaneous nerve. A second intercostobrachial nerve often branches off from the anterior part of the third lateral cutaneous nerve; it supplies the axilla and the medial side of the arm.



7.250 The course of a typical intercostal nerve. The muscular and the collateral branches are not shown.

The Seventh to the Twelfth Thoracic Ventral Rami

These lower thoracic ventral rami continue anteriorly from the intercostal spaces into the abdominal wall. Approaching the anterior ends of their spaces, the seventh and eighth curve *superomedially* across the deep costal surface between the digitations of the transverse abdominis to reach the deep aspect of the posterior layer of the internal oblique aponeurosis. Piercing this they are posterior to the rectus abdominis and continue (7.251) for a short distance parallel with the costal margin. Both supply the rectus abdominis and, having traversed it near its lateral edge, pierce its anterior sheath to supply the skin. Both the seventh and eighth nerves cross the costal margin medial to the lateral border of the rectus abdominis and hence enter its sheath from behind.

The ninth to eleventh intercostal nerves pass between digitations of the diaphragm and transversus abdominis to gain the interval between the transversus and the internal oblique. Here the ninth nerve runs forwards almost *horizontally*, while the tenth and eleventh pass *inferomedially*. At the lateral edge of the rectus abdominis they pierce the posterior layer of the internal oblique aponeurosis and pass behind the muscle, ending like the seventh and eighth intercostal nerves. The tenth supplies a band of skin which includes the umbilicus (7.249, 264).

These lower intercostal nerves supply intercostal, subcostal and abdominal muscles and the last three supply the serratus posterior inferior. They also provide sensory fibres to the costal

7.251 The course of the lower intercostal and the cutaneous branches of some lumbar nerves. Portions of the muscles of the anterior abdominal wall have been removed, including most of the anterior layer of the rectus sheath and parts of the rectus abdominis.

parts of the diaphragm and related parietal pleura and peritoneum. Like the upper intercostal nerves they give off *collateral* and *lateral cutaneous branches* before they reach the costal angles. The collateral may rejoin its nerve but, if it does, it leaves it again near lateral border of the rectus abdominis to run forward below it (7.251), piercing the muscle and its anterior sheath near the linea alba to supply the skin. The lateral cutaneous branches pierce the intercostals and external oblique in the same line as the upper branches, dividing also into anterior and posterior rami, distributed to the skin of the abdomen and back; the anterior also supply digitations of the external oblique, extending antero-inferiorly nearly to the margin of the rectus abdominis; the posterior branches pass back to supply the skin over the latissimus dorsi. Each lateral cutaneous nerve descends as it pierces the external oblique and superficial fascia, reaching the skin on a level with the segment's anterior and posterior cutaneous nerves (p. 1126 and 7.239).

The ventral ramus of the **twelfth thoracic nerve** (subcostal nerve) is larger than the others; it connects with the first lumbar ventral ramus (*dorsolumbar nerve*). Like an intercostal nerve it has a collateral branch. It accompanies the subcostal vessels along the inferior border of the twelfth rib, passing behind the lateral arcuate ligament and kidney (8.168), anterior to the upper part of the quadratus lumborum, perforates the aponeurosis of the origin of the transversus and proceeds between the transversus and the obliquus internus, to be distributed like the lower intercostal nerves. It connects with the iliohypogastric nerve and supplies the pyramidalis. Its *lateral cutaneous branch* pierces the internal and external oblique muscles, supplies the latter's lowest slip, crosses the iliac crest about 5 cm behind the anterior superior iliac spine (7.258) and supplies the anterior gluteal skin, some filaments reaching the greater trochanter of the femur.

Applied Anatomy. In many conditions affecting spinal rami at or near their origins, pain is referred to their peripheral distributions. Thus, in tuberculosis of the lower thoracic vertebrae, pain is referred to the abdominal wall. When confined to a single pair of nerves the sensation is constrictive, as if a cord were tied round the abdomen; the site of of the fenur this sensation may help to localize vertebral diseases. Where two or more nerves are involved, the pain is more diffused.

Subluxation of the interchondral joints between the lower costal cartilages may trap the intercostal nerves, causing referred abdominal pain. Abrahams (1976) has reviewed the literature on this subluxation or 'clicking rib syndrome'.

Nerves supplying the abdominal skin also supply the planes of underlying muscle, an important fact in protection of the abdominal viscera. A forceful blow will not injure the viscera if the muscles are contracted; but when a blow is unexpected, with the abdominal muscles relaxed, a force insufficient to

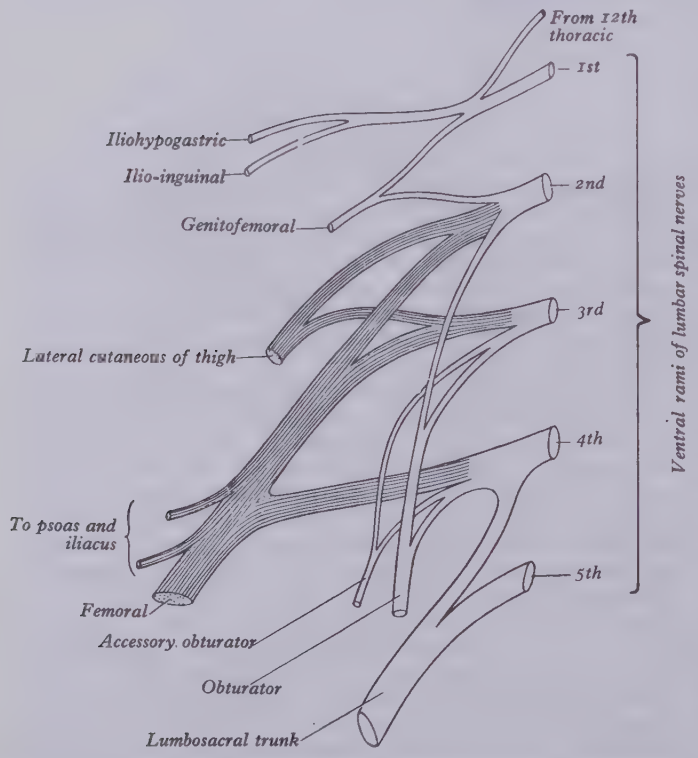
damage the abdominal wall may rupture some of these viscera. Immediate reflex contraction is obviously important; the origin of the cutaneous and motor fibres from the same spinal segments accelerates the response.

Branches supplying abdominal muscles and skin, derived from from the lower intercostal nerves, are intimately connected with the sympathetic nerves supplying the abdominal viscera through the lower thoracic ganglia, from which the splanchnic nerves are derived. Hence in injuries or acute infection of the abdominal viscera, the muscles of the abdominal wall become firmly contracted, resting and protecting the abdominal contents.

LUMBAR VENTRAL RAMI

Lumbar ventral rami increase in size from first to last and are joined, near their origins, by *grey rami communicantes* from the four lumbar sympathetic ganglia. These rami, long and slender, accompany the lumbar arteries round the sides of the vertebral bodies, behind the psoas major. Their arrangement is irregular: one ganglion may give rami to two lumbar nerves, one lumbar nerve may receive rami from the ganglia; rami often leave the sympathetic trunk between ganglia. The first and second, sometimes the third, lumbar ventral rami are each connected with the lumbar sympathetic trunk by a *white ramus communicans*.

The lumbar ventral rami descend laterally into the psoas major. The first three and most of the fourth form the *lumbar plexus*; the smaller moiety of the fourth joins the fifth as a *lumbosacral trunk*, which joins the *sacral* plexus. The fourth is often termed the *nervus furcalis*, being divided between the two plexuses; but the third is occasionally the nervus furcalis; or both third and fourth may be furcal nerves, when the plexus is termed *prefixed*. More frequently the fifth nerve is furcal, the plexus then being termed *postfixed*. These variations modify the sacral plexus. Piasecka-Kacperska & Gladyskowska-Rzeczycka (1972) have reviewed the variations in primates, including mankind.



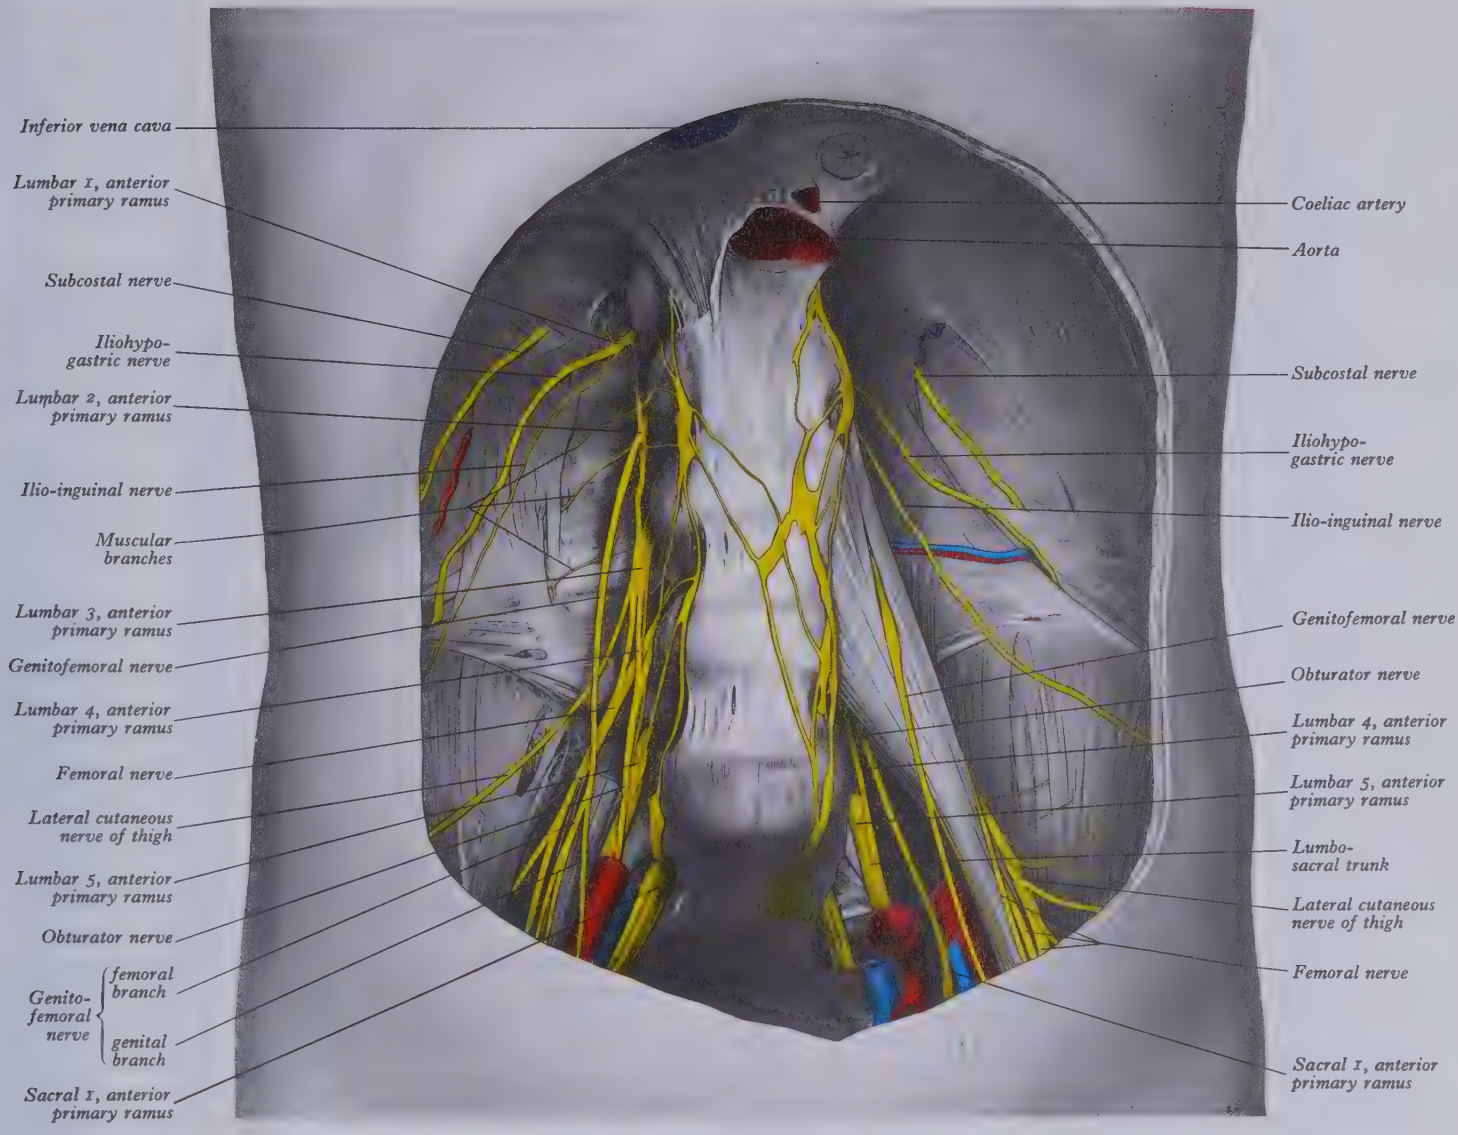
The Lumbar Plexus

This plexus (7.252, 253) is in the posterior part of the psoas major, anterior to the lumbar transverse processes and formed by the first three lumbar ventral rami and most of the fourth; the first receives a branch from the last thoracic. The *paravertebral* part of psoas major has a *posterior* mass attached to the transverse processes and an *anterior* mass attached to the lips of the vertebral bodies, intervertebral discs and tendinous arches (p. 635); the lumbar plexus is between these masses and hence in 'line' with the intervertebral foramina.

The plexus varies; in its usual arrangement the first lumbar ramus, joined by a branch from the twelfth thoracic, bifurcates; the upper and larger part divides again into iliohypogastric and ilio-inguinal nerves; the lower unites with a second lumbar branch to form the genitofemoral nerve. The remainder of the second, third and the part of the fourth ramus joining the plexus divide into ventral and dorsal branches. Ventral branches of the second to fourth rami form the obturator nerve. Dorsal branches of the second and third rami each divide into smaller and larger parts; the smaller parts unite as the lateral femoral cutaneous nerve, the larger join with the dorsal branch of the fourth to form the femoral nerve. The accessory obturator, when it exists, arises from the third and fourth ventral branches. For details of the blood supply of the lumbar plexus see Day (1964).

The *branches* of the lumbar plexus may be summarized as follows:

Muscular	T12, L1, 2, 3, 4
Iliohypogastric	L1
Ilio-inguinal	L1
Genitofemoral	L1, 2
	Dorsal divisions:
Lateral femoral cutaneous	L2, 3
Femoral	L2, 3, 4
	Ventral divisions:
Obturator	L2, 3, 4
Accessory obturator	L3, 4

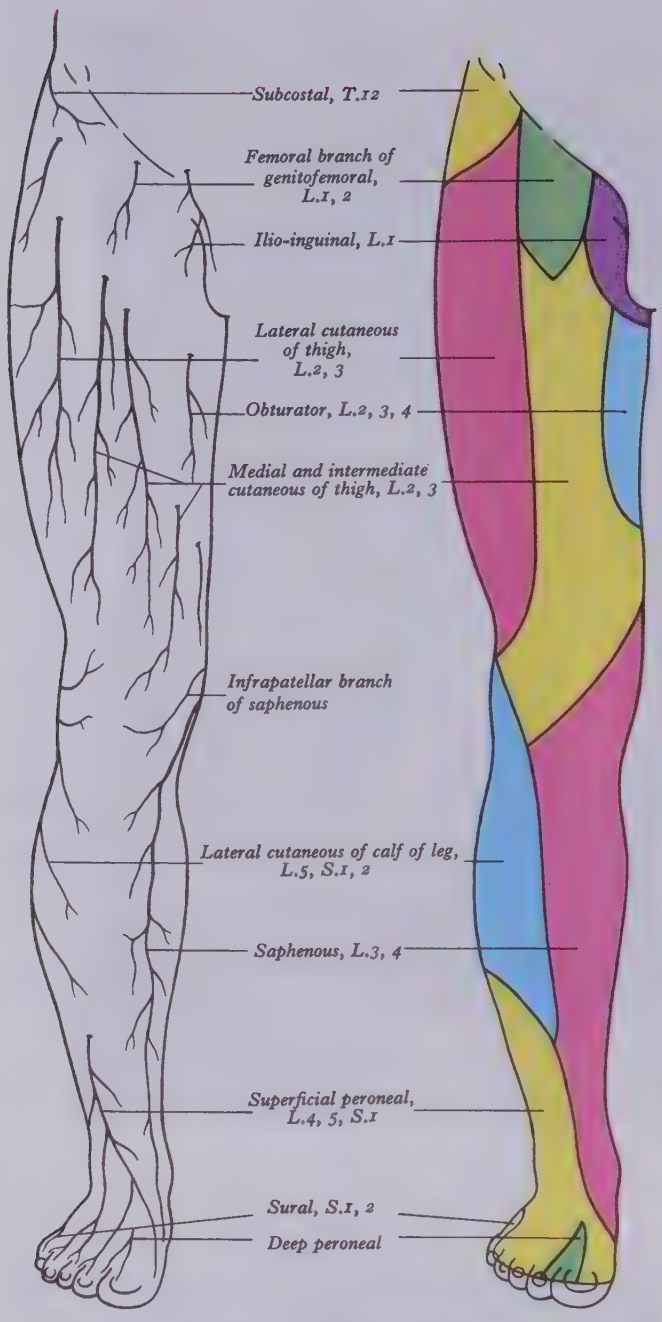


7.252 A plan of the lumbar plexus. The *dorsal divisions* of the second, third and fourth lumbar nerves are shaded.

Muscular branches supply the quadratus lumborum (T12, L1–4), psoas minor (L1), psoas major (L2, 3(4)) and iliacus (L2, 3).

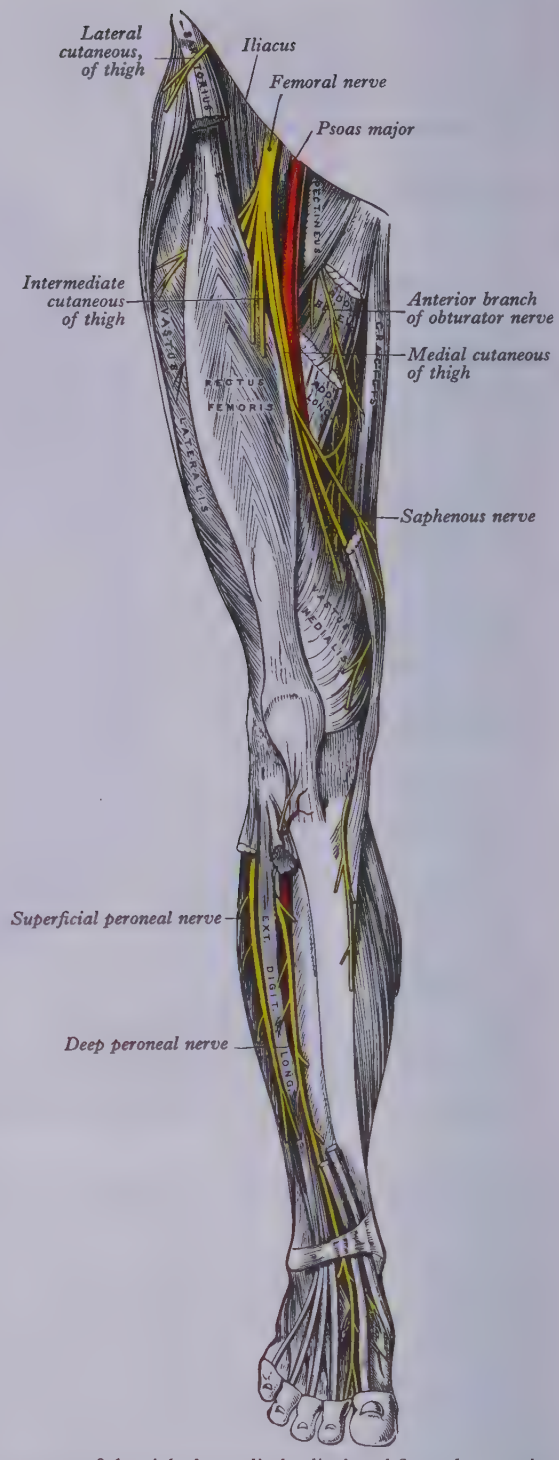
The iliohypogastric nerve (L1) (7.247) emerges from the upper lateral border of the psoas major, crosses obliquely behind the lower renal pole and in front of the quadratus lumborum (7.253, 8.168). Above the iliac crest it perforates the posterior part of the transversus abdominis, dividing between this and the internal oblique into lateral and anterior cutaneous branches, also supplying both muscles. The *lateral cutaneous branch* pierces the internal and external oblique muscles above the iliac crest a little behind the iliac branch of the twelfth thoracic nerve; it is distributed to the posterolateral gluteal skin. The *anterior cutaneous branch* (7.249) runs between and supplies the internal oblique and the transversus, pierces the internal oblique about 2 cm medial to the anterior superior iliac spine, and the external oblique aponeurosis about 3 cm above the superficial inguinal ring; it is distributed to the suprapubic skin. The iliohypogastric nerve connects with the subcostal and ilio-inguinal nerves.

The ilio-inguinal nerve, smaller than the iliohypogastric, arises with it from the first lumbar ventral ramus (7.252), emerges from the lateral border of the psoas major, with or just caudal to the iliohypogastric, passes obliquely across the quadratus lumborum and the upper part of the iliacus and perforates the transversus abdominis near the anterior end of the iliac crest, sometimes connecting with the iliohypogastric. It then pierces the internal oblique, supplying it, traverses the inguinal canal below



7.253 A dissection of the posterior abdominal wall to show the lumbar plexus and sympathetic trunks. The right psoas major has been removed.

the spermatic cord, emerging with it from the superficial inguinal ring to supply the proximomedial skin of the thigh and either that over the penile root and upper part of the scrotum (7.249) or that covering the mons pubis and the adjoining labium majus.



The ilio-inguinal and iliohypogastric nerves are reciprocal in size. The former is occasionally very small and ends by joining the iliohypogastric, a branch of the latter taking its place; or the ilio-inguinal may be absent. By analogy the ilio-inguinal may be regarded as the collateral branch of the first lumbar nerve (Davies 1935) and the iliohypogastric as the main trunk, providing the lateral cutaneous branch.

The genitofemoral nerve (L1, 2) (7.252) descends obliquely forwards through the psoas major, emerging on the abdominal surface near its medial border, opposite the third or fourth lumbar vertebra; it descends subperitoneally on the psoas major, crosses obliquely behind the ureter, dividing variably above the inguinal ligament into genital and femoral branches. It often divides close to its origin, its branches then emerging separately from the psoas major. The *genital branch* crosses the lower part of the external iliac artery, enters the inguinal canal by its deep ring and supplies the cremaster and the scrotal skin. In females it accompanies the round ligament and ends in the skin of the mons pubis and labium majus. The *femoral branch* descends lateral to the external iliac artery, sending a few filaments round it; it then crosses the deep circumflex iliac artery, passes behind the inguinal ligament, enters the femoral sheath lateral to the femoral artery, pierces the anterior layer of the femoral sheath and fascia lata and supplies the skin anterior to the upper part of the femoral triangle (7.254). It connects with the femoral intermediate cutaneous nerve and supplies the femoral artery.

The lateral femoral cutaneous nerve, from the dorsal branches of the second and third lumbar ventral rami (7.252), emerges from the lateral border of psoas major, crossing the iliacus obliquely towards the anterior superior iliac spine. It supplies the parietal peritoneum in the iliac fossa. The right nerve passes posterolateral to the caecum, separated from it by the fascia iliaca and peritoneum; the left passes behind the lower part of the descending colon. Both pass behind or through the inguinal ligament, variably medial to the anterior superior iliac spine (commonly about 1 cm) and anterior to or through the sartorius into the thigh, dividing into anterior and posterior branches (7.254). The *anterior branch* becomes superficial about 10 cm distal to the anterior superior iliac spine, supplying the skin of the anterior and lateral thigh as far as the knee. It connects terminally with the cutaneous branches of the anterior division of the femoral nerve and the infrapatellar branch of the saphenous nerve, forming the *patellar plexus*. The *posterior branch* pierces the fascia lata higher than the anterior, dividing to supply the skin on the lateral surface from the greater trochanter to about mid-thigh. It may also supply the gluteal skin.

7.254 The cutaneous nerves of the right lower limb, their areas of distribution and segmental origins, viewed from the anterior aspect.

7.255 The nerves of the right lower limb, displayed from the anterior aspect.

THE OBTURATOR NERVE

The obturator nerve arises from the ventral branches of the second to fourth lumbar ventral rami (7.252, 253), that from the third being the largest, the one from the second often very small. It descends in the psoas major, emerging from its medial border at the pelvic brim to pass behind the common iliac and lateral to the internal iliac vessels. It then descends forwards along the lesser pelvic lateral wall on the obturator internus, anterosuperior to the obturator vessels, to the obturator foramen, entering the thigh by its upper part. Near the foramen it divides into anterior and posterior branches, separated at first by part of the obturator externus, lower down by the adductor brevis.

The *anterior branch* (7.255) leaves the pelvis anterior to the obturator externus, descending in front of the adductor brevis, behind the pectineus and adductor longus; at the latter's lower border it communicates with the medial cutaneous and saphenous branches of the femoral nerve, forming a *subsartorial plexus*, which supplies the skin on the medial side of the thigh (7.254). It descends on the femoral artery, which its termination supplies. Near the obturator foramen the anterior branch supplies the hip joint. Behind the pectineus it innervates the adductor longus, gracilis, usually the adductor brevis and often the pectineus; it connects with the accessory obturator nerve when present. Occasionally the communicating branch to the femoral medial cutaneous and saphenous branches continues as a cutaneous branch to the thigh and leg, emerging from behind the distal border of the adductor longus to descend along the posterior margin of the sartorius to the knee, where it pierces the deep fascia, connects with the saphenous nerve and supplies the skin halfway down the medial side of the leg. The *posterior branch*

pierces the obturator externus anteriorly, supplies it and passes behind the adductor brevis to the front of the adductor magnus, dividing into branches to this and the adductor brevis when the latter is not supplied by the anterior division. It usually sends an *articular filament* to the knee joint which perforates the adductor magnus distally or traverses its opening with the femoral artery to enter the popliteal fossa. Here it descends on the popliteal artery to the back of the knee, pierces its oblique posterior ligament and supplies the articular capsule. It gives filaments to the popliteal artery.

The accessory obturator nerve (7.252), occasionally present, is small and arises from the ventral branches of the third and fourth lumbar ventral rami. It descends along the medial border of the psoas major, crosses the superior pubic ramus behind the pectineus and divides into branches, one entering the deep surface of the pectineus, another supplying the hip joint and a third connecting with the obturator nerve's anterior branch; sometimes the accessory obturator nerve is very small and supplies only the pectineus. Any branch may be absent and others occur, one sometimes supplying the adductor longus. An accessory obturator nerve appeared in 69 of 800 dissections (p. 640, Woodburne 1960).

THE FEMORAL NERVE

The femoral nerve (7.252, 253), the largest branch of the lumbar plexus, arises from the dorsal branches of the second to fourth lumbar ventral rami. It descends through the psoas major, emerging low on its lateral border, and then passes between the psoas and iliacus, deep to the iliac fascia; passing behind the inguinal ligament into the thigh, it splits into anterior and posterior divisions. Behind the inguinal ligament it is separated from the femoral artery by part of the psoas major. In the abdomen the nerve supplies small branches to the iliacus and pectineus and a branch to the proximal part of the femoral artery; the latter branch may arise in the thigh.

The nerve to the pectineus branches from the medial side of the femoral nerve near the inguinal ligament, passes behind the femoral sheath and enters the muscle's anterior aspect.

Anterior division

The *anterior division* of the femoral nerve supplies intermediate and medial cutaneous femoral nerves (7.254, 255) and branches to the sartorius.

The intermediate femoral cutaneous nerve pierces the fascia lata about 8 cm below the inguinal ligament, either as two branches or as one trunk which quickly divides into two; these descend on the front of the thigh, supplying the skin as far as the knee and ending in the patellar plexus (p. 1141). The lateral branch of the intermediate cutaneous communicates with the femoral branch of the genitofemoral, frequently piercing the sartorius and sometimes supplying it.

The medial femoral cutaneous nerve, at first lateral to the femoral artery, crosses anterior to it at the apex of the femoral triangle, dividing into anterior and posterior branches. Before this it sends a few rami through the fascia lata to supply the skin of the medial side of the thigh, near the long saphenous vein; one ramus emerges via the saphenous opening, another becomes subcutaneous about mid-thigh. The *anterior branch* descends on the sartorius, perforates the fascia lata beyond mid-thigh and divides into a branch supplying the skin as low as the medial side of the knee and another which crosses to the lateral side of the patella and connects with the saphenous nerve's infrapatellar branch. The *posterior branch* descends along the posterior border of the sartorius to the knee, pierces the fascia lata, connects with the saphenous nerve and supplies several cutaneous rami, some as far as the medial side of the leg. Deep to the fascia lata, at the lower border of the adductor longus, it forms a *subsartorial plexus* with branches of the saphenous and obturator nerves. When the obturator nerve's communicating branch is large and reaches the leg, the posterior branch of the medial cutaneous nerve is small, ending in the plexus and giving rise to a few cutaneous filaments.

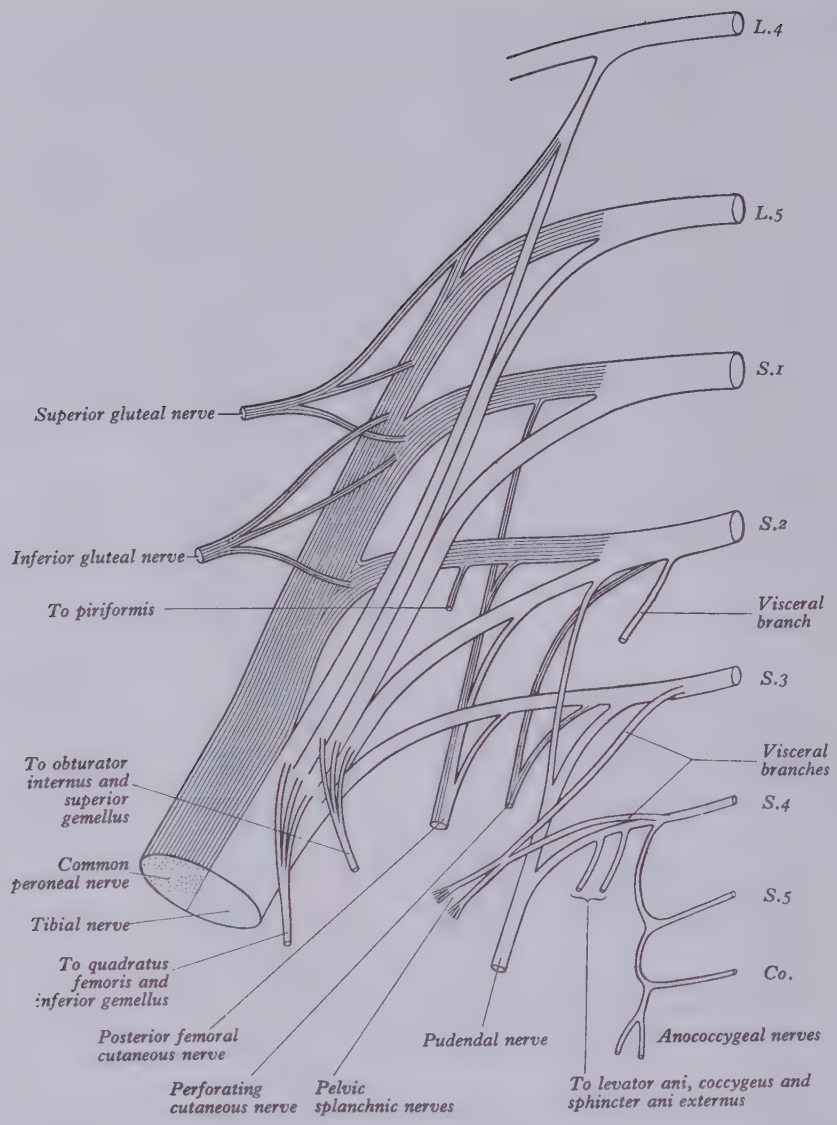
The nerve to the sartorius arises in common with the intermediate femoral cutaneous nerve.

Posterior division

The *posterior division* of the femoral nerve supplies the saphenous nerve and branches to the quadriceps femoris and the knee joint.

The saphenous nerve (7.255), the largest femoral cutaneous branch, descends lateral to the femoral artery into the adductor canal (p. 781), where it crosses anteriorly to become medial to the artery. At the canal's distal end it leaves the artery, emerging through the aponeurotic covering with the saphenous branch of the descending genicular artery. It proceeds vertically along the medial side of the knee behind the sartorius, pierces the fascia lata between the tendons of the sartorius and gracilis and becomes subcutaneous. Thence it descends the leg's medial side with the long saphenous vein along the medial tibial border and divides distally into a branch continuing along the tibia to the ankle and into another passing anterior to the ankle to supply the skin on the medial side of the foot, often as far as the hallucial metatarsophalangeal joint; it connects with the medial branch of the superficial peroneal nerve. Near mid-thigh the saphenous nerve gives a branch to the subsartorial plexus. As it leaves the adductor canal an *infrapatellar branch* (7.254) pierces the sartorius and fascia lata to supply the prepatellar skin; proximal to the knee it connects with medial and intermediate femoral cutaneous nerves while distal to it, it connects with other branches of the saphenous nerve; laterally it connects with the lateral cutaneous femoral nerve, forming a *patellar plexus*.

Muscular branches of the posterior division of the femoral nerve supply the quadriceps femoris. A branch to the rectus femoris enters its proximal posterior surface, also supplying the hip joint. A larger branch to the vastus lateralis forms a neurovascular bundle with the descending branch of the lateral circumflex femoral artery in its distal part and also supplies the knee joint. A branch to the vastus medialis descends through the proximal part of the adductor canal, lateral to the saphenous nerve and femoral vessels; it enters the muscle at about its midpoint, sending a long articular filament distally along the muscle to the knee. Two or three branches to the vastus intermedius enter its anterior surface about mid-thigh; a branchlet from one descends through the muscle to the articularis genu and the knee joint.



Vascular branches of the femoral nerve supply the femoral artery and its branches (p. 1163).

SACRAL AND COCCYGEAL VENTRAL RAMI

The ventral rami of the sacral and coccygeal spinal nerves form the *sacral and coccygeal plexuses*. The upper four sacral ventral rami enter the pelvis by the anterior sacral foramina, the fifth between the sacrum and coccyx, while that of the coccygeal nerve curves forwards below the rudimentary transverse process of the first coccygeal segment. The first and second sacral ventral rami are large, the third to fifth diminish progressively and the coccygeal is the smallest. Each receives a *grey ramus communicans* from a corresponding sympathetic ganglion. *Visceral efferent rami* leave the second to fourth sacral rami as *pelvic splanchnic nerves* (7.277) containing parasympathetic fibres which reach minute ganglia in the walls of the pelvic viscera (p. 1156).

The Sacral Plexus

The sacral plexus (7.256) is formed by the lumbosacral trunk, the first to third sacral ventral rami and part of the fourth, the remainder of the last joining the coccygeal plexus.

7.256 A plan of the sacral and coccygeal plexuses. L4–5, S1–5 and Co, indicate the *ventral rami* of these lumbar, sacral and coccygeal spinal nerves. The *ventral divisions* of these rami are unshaded, the *dorsal divisions*, and nerves derived from them, are shaded. The contribution from S2 to the pelvic splanchnic nerves is shown before joining those from 3 and 4.

The lumbosacral trunk comprises part of the fourth and all the fifth lumbar ventral rami; it appears at the medial margin of the psoas major, descending over the pelvic brim anterior to the sacro-iliac joint to join the first sacral ramus. These rami converge to the greater sciatic foramen and unite with little intermingling to form upper and lower bands. The upper, larger one is the union of the lumbosacral trunk with the first, second and greater part of the third sacral rami; it becomes the *sciatic nerve*. The lower band, smaller and more plexiform, is mainly the junction of the smaller part of the third sacral ramus with part of the fourth; it becomes the *pudendal nerve*; it has a small contribution from the second sacral ramus. The sciatic comprises tibial and common peroneal nerves, which usually separate in the thigh but can be pulled apart to their origins, when it can be demonstrated that the tibial is formed by the union of the ventral divisions of the lumbosacral trunk and the first three sacral rami, while the common peroneal is formed by dorsal divisions of the lumbosacral trunk and the first two sacral rami. The sciatic nerve may, however, divide anywhere; when division is at the plexus the common peroneal nerve usually pierces the piriformis in the greater sciatic foramen. (For the blood supply of the sacral plexus see Day 1964.)

Relations of the Sacral Plexus

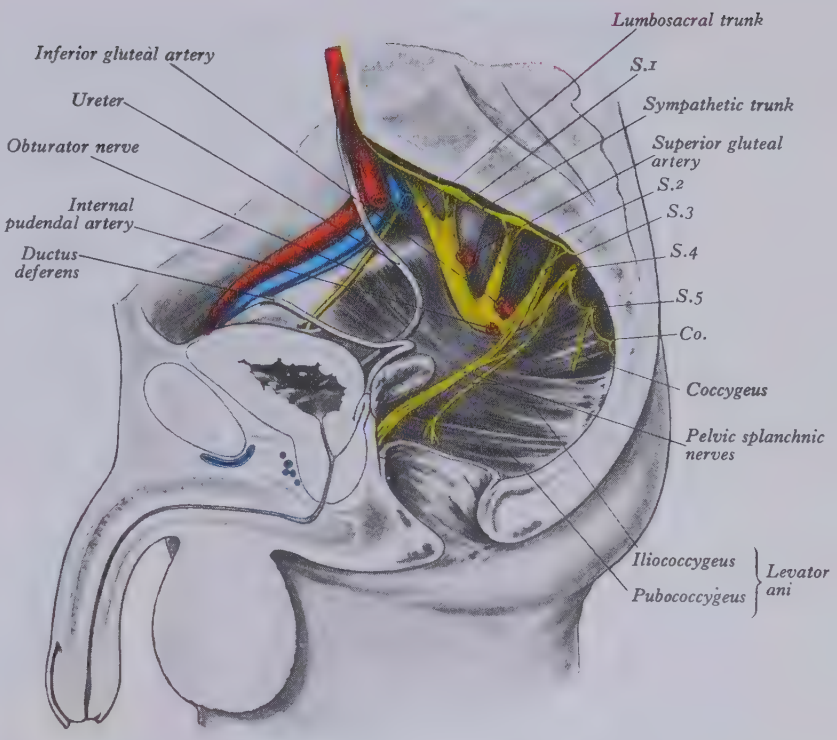
The sacral plexus adjoins the posterior pelvic wall anterior to the piriformis (7.257), posterior to the internal iliac vessels and ureter and to the sigmoid colon on the left and the terminal ileal coils on the right. The superior gluteal vessels lie between the lumbosacral trunk and first sacral ventral ramus or between the first and second sacral rami, while the inferior gluteal vessels lie between the first and second or second and third sacral rami.

Branches of the Sacral Plexus

These may be summarized as follows:

	Ventral Divisions	Dorsal divisions
To quadratus femoris and gemellus inferior	L4, 5, S1	
To obturator internus and gemellus superior	L5, S1, 2	
To piriformis		S(1), 2
Superior gluteal		L4, 5, S1
Inferior gluteal		L5, S1, 2
Posterior femoral cutaneous	S2, 3	S1, 2
Sciatic—tibial	L4, 5, S1, 2, 3	
—common peroneal		L4, 5, S1, 2
Perforating cutaneous		S2, 3
Pudendal	S2, 3, 4	
To levator ani, coccygeus and sphincter ani externus	S4	
Pelvic splanchnic	S2, 3, (4)	

The nerve to the quadratus femoris and gemellus inferior arises from the ventral branches of the fourth lumbar to the first sacral ventral rami (7.256), leaves the pelvis via the greater sciatic foramen below the piriformis, descends on the ischium deep to the sciatic nerve, gemelli and the tendon of the obturator internus and supplies the gemellus inferior, quadratus femoris and the hip joint.



The nerve to the obturator internus and gemellus superior arises from the ventral branches of the fifth lumbar and first and second sacral ventral rami (7.256), leaves the pelvis similarly to the above, supplies a branch to the upper posterior surface of the gemellus superior, crosses the ischial spine lateral to the internal pudendal vessels, re-enters the pelvis via the lesser sciatic foramen and enters the pelvic surface of the obturator internus.

The nerve to the piriformis usually arises from the dorsal branches of the first and second sacral ventral rami (sometimes only the second) and enters the anterior surface of the piriformis.

The superior gluteal nerve from the dorsal branches of the fourth and fifth lumbar and first sacral ventral rami (7.256) leaves the pelvis via the greater sciatic foramen above the piriformis with the superior gluteal vessels, dividing into superior and inferior branches. The *superior* branch accompanies the upper branch of the deep division of the superior gluteal artery to supply the gluteus medius and occasionally the gluteus minimus. The *inferior* branch runs with the lower ramus of the deep division of the superior gluteal artery across the gluteus minimus, supplying the glutei medius and minimus and ending in the tensor fasciae latae.

The inferior gluteal nerve, from the dorsal branches of the fifth lumbar and first and second sacral ventral rami, leaves the pelvis via the greater sciatic foramen below the piriformis, dividing into branches which enter the deep surface of the gluteus maximus.

The posterior femoral cutaneous nerve, from the dorsal branches of the first and second and the ventral branches of the second and third sacral rami (7.256), issues via the greater sciatic foramen below the piriformis, descends under the gluteus maximus with the inferior gluteal vessels, lying posterior or medial to the sciatic nerve. It descends in the back of the thigh superficial to the long head of the biceps femoris, deep to the fascia lata; behind the knee it pierces the deep fascia and accompanies the short saphenous vein to mid-calf, its terminal twigs connecting with the sural nerve. Its branches are all cutaneous, distributed to the gluteal region, perineum and the flexor aspect of the thigh and leg. Three or four *gluteal branches* curl round the lower border of the gluteus maximus to supply the skin over its inferolateral area. The *perineal branch* supplies the superomedial skin in the thigh, curves forwards across the hamstrings below the ischial tuberosity, pierces the fascia lata and runs in the superficial perineal fascia to the scrotal or labial skin, communicating with the inferior rectal and posterior scrotal branches of the perineal nerve. *Branches to the back of the thigh and leg* are numerous and from both sides of the posterior femoral cutaneous nerve; they supply the skin of the back and medial side of the thigh, the popliteal fossa and the proximal part of the back of the leg (7.258).

7.257 A dissection of the side wall of the pelvis, showing the sacral and coccygeal plexuses. S.1–5 indicate the ventral rami of the sacral spinal nerves; Co. indicates the ventral ramus of the coccygeal spinal nerve.

The Sciatic Nerve

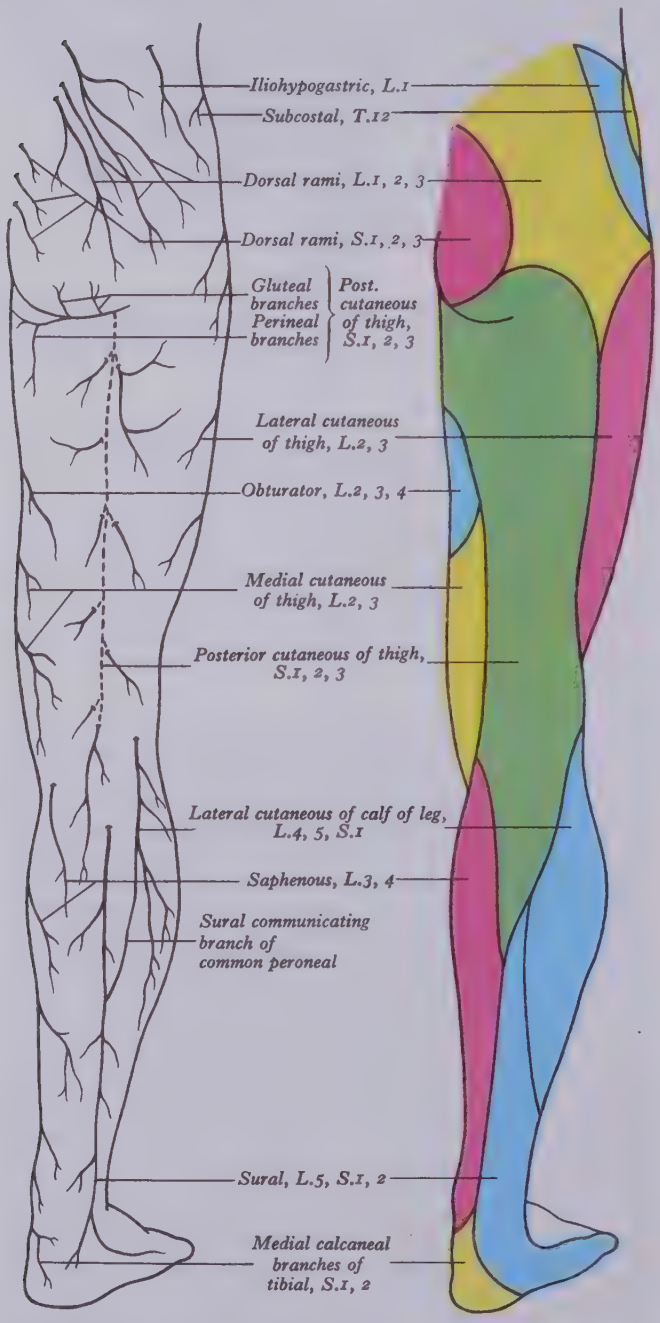
The sciatic nerve (7.256, 259), 2 cm broad at its origin and the broadest in the body, is the continuation of the upper band of the sacral plexus. It leaves the pelvis via the greater sciatic foramen below the piriformis and descends between the greater trochanter and ischial tuberosity, along the back of the thigh, dividing into the tibial and common peroneal (fibular) nerves, proximal to the knee. Superiorly it is deep to the gluteus maximus, resting first on the posterior ischial surface with the nerve to quadratus femoris between them; it then crosses posterior to the obturator internus and the gemelli, then on to the quadratus femoris, separated by it from obturator externus and the hip joint; it is accompanied medially by the posterior femoral cutaneous nerve and the inferior gluteal artery. More distally it is behind the adductor magnus and is crossed posteriorly by the long head of the biceps femoris. It corresponds to a line from just medial to the midpoint between the ischial tuberosity and greater trochanter to the apex of the popliteal fossa.

Articular branches arise proximally to supply the hip joint through its posterior capsule; these are sometimes derived directly from the sacral plexus. *Muscular branches* are distributed to the biceps femoris, semitendinosus, semimembranosus and the ischial part of the adductor magnus (p. 641), as detailed below.

THE TIBIAL NERVE

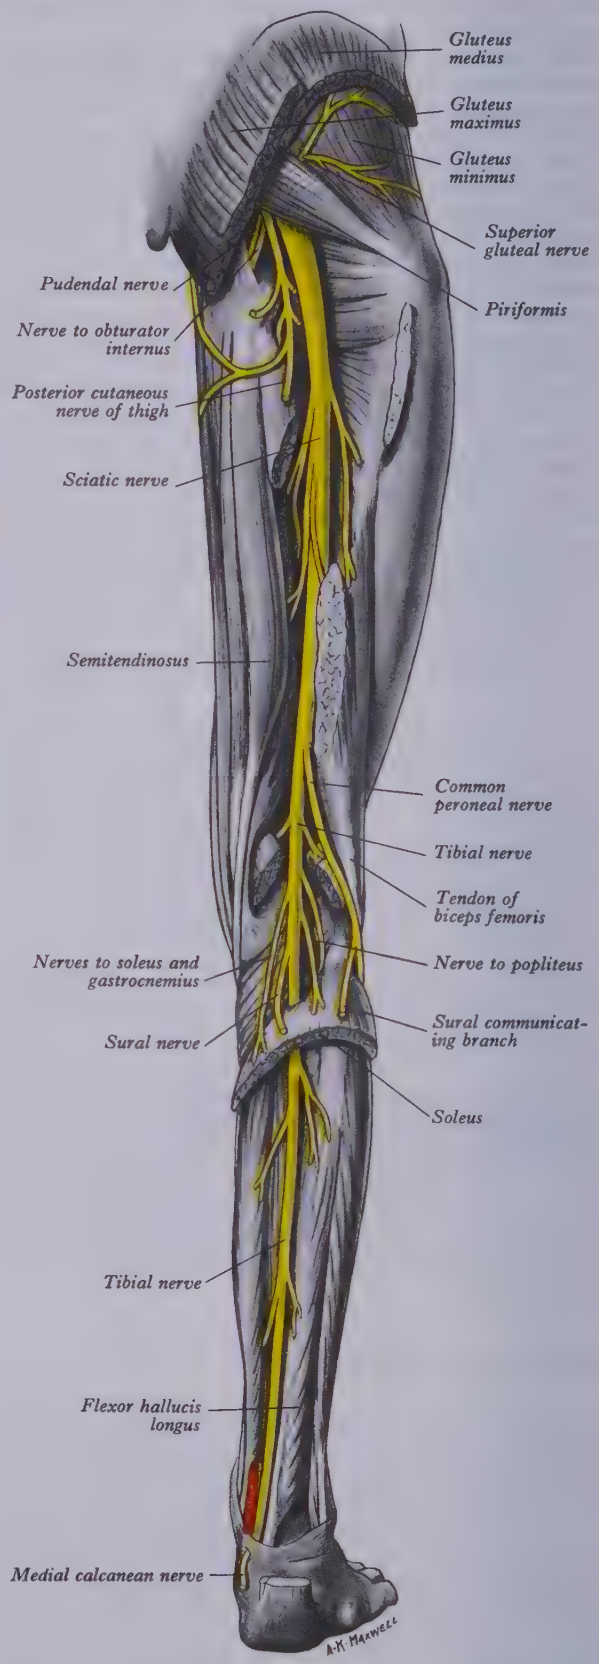
The tibial (medial popliteal) nerve (7.259), the larger sciatic division (from the ventral branches of the fourth and fifth lumbar and first to third sacral ventral rami), descends along the back of the thigh and popliteal fossa to the distal border of popliteus, passing anterior to the arch of soleus with the popliteal artery and continuing into the leg. In the thigh it is overlapped proximally by the hamstring muscles, but becomes more superficial in the popliteal fossa, where it is lateral to the popliteal vessels, becoming superficial to them at the knee and crossing to the medial side of the artery (7.260). Distally in the fossa it is overlapped by the junction of the two heads of gastrocnemius. Its surface projection is a line in the midline of the limb, vertical from the apex of the popliteal fossa to the level of the fibular neck and thence to a point midway between the medial malleolus and calcanean tendon.

In the leg the tibial nerve descends with the posterior tibial vessels to lie between the heel and the medial malleolus, ending under the flexor retinaculum by dividing into medial and lateral plantar nerves. Proximally it is deep to the soleus and gastrocnemius, but in its distal third is covered only by skin and fasciae, overlapped sometimes by the flexor hallucis longus. At first medial to the posterior tibial vessels, it crosses behind them, descending lateral to them until it bifurcates. It lies on the tibialis posterior for most of its course, except distally, where it adjoins the posterior surface of the tibia.



Its branches are articular, muscular, sural, medial calcanean and medial and lateral plantar.

Articular branches accompany the superior, inferior medial and middle genicular arteries to the knee joint. The three form a



plexus with an obturator branch, supplying the oblique posterior ligament; those with the superior and inferior medial genicular arteries supply the medial part of the capsule. Just before the tibial nerve bifurcates it supplies the ankle joint. Champetier & Déscours (1968) have surveyed these articular nerves. Gardner & Lenn (1977) assessed the ratios of myelinated to non-myelinated fibres in genual articular nerves in monkeys as about 4:1; they suggested that most are nociceptive.

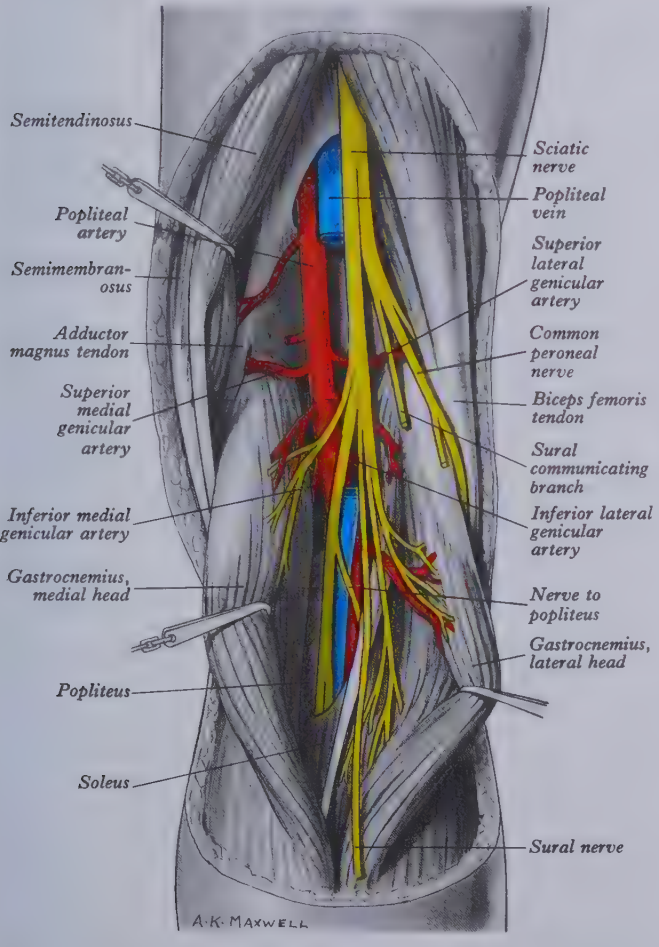
Muscular branches, arising between the heads of the gastrocnemius, supply this, the plantaris, soleus and popliteus. The nerve to the soleus enters its superficial aspect; the branch to the popliteus descends obliquely across the popliteal vessels, curling round the muscle's distal border to its anterior surface and also supplying the tibialis posterior, the proximal tibiofibular joint, the tibia and an interosseous branch which descends near the fibula to reach the distal tibiofibular joint.

Muscular branches in the leg, independent or by a common trunk, supply the soleus (on its deep surface), the tibialis posterior, flexor digitorum longus and flexor hallucis longus, the branch to the last-named accompanying the peroneal vessels.

7.258 The cutaneous nerves of the right lower limb and their areas of distribution and segmental origins, viewed from the posterior aspect. The major part of the trunk of the posterior cutaneous nerve of the thigh lies deep to the deep fascia and is therefore shown by an interrupted line.

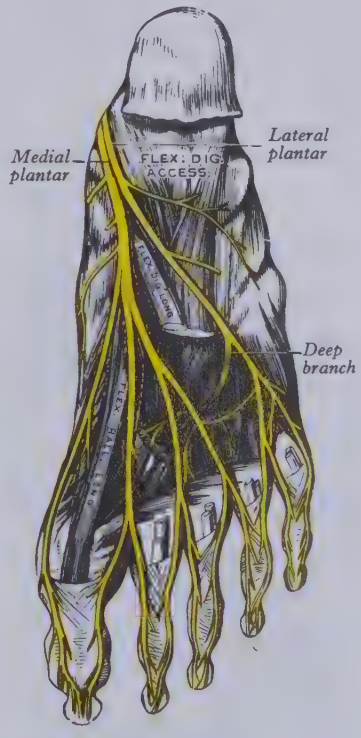
7.259 The nerves of the right lower limb: posterior aspect. In this figure the gluteus maximus, the gluteus medius and the superficial muscles of the calf of the leg have been removed and the middle part of the long head of the biceps femoris has been excised.

The sural nerve descends between the heads of the gastrocnemius, pierces the deep fascia proximally in the leg and is joined by a sural communicating branch of the common peroneal (7.258). It descends lateral to the tendo calcaneus, near the small saphenous vein, to the region between the lateral malleolus and the calcaneus; it supplies the posterior and lateral skin of the leg's distal third, proceeding distal to the lateral malleolus along the lateral side of the foot and little toe; it connects on the dorsum of the foot with the superficial peroneal nerve, and in the leg with the posterior femoral cutaneous nerve. The fibre spectrum and ultrastructure of fetal sural nerves were described by Ochoa (1971) and in adults by Ochoa & Mair (1969a, b). The three-dimensional distribution of Schwann cells associated with unmyelinated nerve fibres in adult human sural nerves has been analysed by Carlsen & Behse (1980).



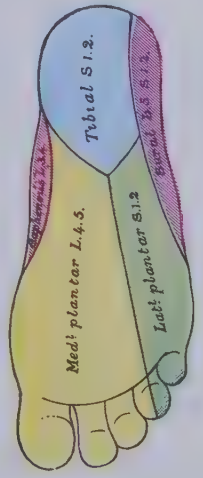
Medial calcanean branches perforate the flexor retinaculum to supply the skin of the heel and medial side of the sole.

Vascular branches supply arteries accompanying the tibial nerve and its branches (p. 1163).



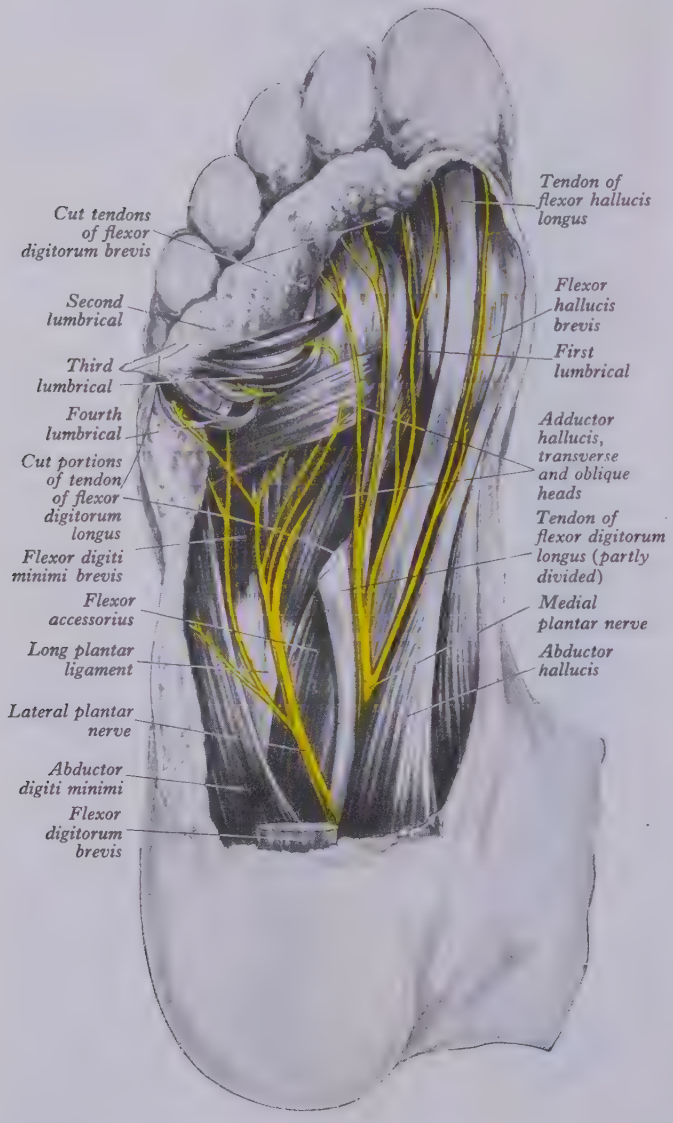
The medial plantar nerve (7.261), the larger terminal division of the tibial nerve, lies lateral to the medial plantar artery. From its origin under the flexor retinaculum it passes deep to the abductor hallucis, appears between it and the flexor digitorum brevis, gives off a medial proper digital nerve to the hallux and divides near the metatarsal bases into three common plantar digital nerves.

Cutaneous branches pierce the plantar aponeurosis between the abductor hallucis and the flexor digitorum brevis to supply the skin of the sole of the foot. *Muscular branches* supply the abductor hallucis, flexor digitorum brevis, flexor hallucis brevis and the first lumbrical; the first two arise near the nerve's origin and enter the deep surfaces of the muscles; the branch to the flexor hallucis brevis is from the hallucial medial digital nerve, and that to the first lumbrical from the first common plantar digital nerve. *Articular branches* supply the joints of the tarsus and metatarsus.



Three common plantar digital nerves pass between the slips of the plantar aponeurosis, each dividing into two proper digital branches, the first supplying adjacent sides of the hallux and secundus, the second adjacent sides of the secundus and tertius, the third adjacent sides of the tertius and quartus and also connecting with the lateral plantar nerve. The first gives a branch to the first lumbrical. Each proper digital nerve has cutaneous and articular branches; near the distal phalanges a dorsal branch supplies structures around the nail; the end of each nerve supplies the ball of the toe. Note that the common digital branches of the medial plantar *are like those of the median nerve*; muscles supplied by both correspond closely. In the hand the median nerve supplies the abductor and flexor pollicis brevis, the opponens pollicis and the first and second lumbricals. The opponens is absent in the foot but the abductor hallucis, flexor hallucis brevis and the first lumbrical are all supplied by the medial plantar.

7.260 A dissection of the right popliteal fossa. The two heads of gastrocnemius and the semitendinosus and semimembranosus have been retracted in order to expose the contents of the fossa more fully.



7.261 The plantar nerves of the right foot.

7.262 A diagram showing the distribution of the cutaneous nerves in the sole of the right foot.

Since the flexor digitorum brevis and flexor digitorum superficialis (median nerve) correspond, only the innervation of the second lumbrical differs.

The lateral plantar nerve (7.261) supplies the skin of the digitus quintus, and of the lateral half of the quartus and most deep muscles, *like the ulnar nerve in the hand*. It passes laterally forwards with the lateral plantar artery lateral to it, towards the fifth metatarsal's tubercle and then between the flexores digitorum brevis and accessorius, to end between the former and the abductor digiti minimi, dividing into superficial and deep branches. Before division it supplies the flexor digitorum accessorius and abductor digiti minimi and gives rise to small branches which pierce the plantar fascia to supply the skin of the lateral part of the sole (7.262). The *superficial branch* splits into two common plantar digital nerves: the *lateral* supplies the lateral side of the digitus quintus, flexor digiti minimi brevis and the two interossei in the fourth intermetatarsal space; the *medial* connects with the third common plantar digital branch of the medial plantar nerve, dividing into two to supply the adjoining sides of the digitus quartus and quintus. The *deep branch* accompanies the lateral plantar artery deep to the flexor tendons and the adductor hallucis, supplying the second to fourth lumbricals, the adductor hallucis and all interossei (except those of the fourth intermetatarsal space); branches to the second and third lumbricals pass distally deep to the transverse head of the adductor hallucis, curling round its distal border to reach them (7.263).

7.263 A dissection of the lateral and medial plantar nerves of the right foot. Most of the flexor digitorum brevis has been removed. The flexor digitorum longus has been partially divided and its distal end has been displaced together with the second, third and fourth lumbricals.

THE COMMON PERONEAL (FIBULAR) NERVE

The common peroneal (fibular or lateral popliteal) nerve (7.260), about half the size of the tibial, is derived from the dorsal branches of the fourth and fifth lumbar and first and second sacral ventral rami. It descends obliquely along the popliteal fossa's lateral side to the fibular head, medial to the biceps femoris and lying between its tendon and the lateral head of the gastrocnemius. It curves lateral to the fibular neck deep to the peroneus longus and divides into superficial and deep peroneal nerves. Its course can be indicated by a line from the fossa's apex, passing distally medial to the biceps tendon to the back of the fibula's head, where the nerve can be rolled against the bone. Before division it gives off articular and cutaneous branches.

Of the three *articular branches* two accompany the superior and inferior lateral genicular arteries; they may arise in common. The third, termed the recurrent articular nerve, arises near the division of the common peroneal and ascends with the anterior recurrent tibial artery through the tibialis anterior to supply the anterolateral part of the genual capsule and the proximal tibiofibular joint. Two *cutaneous branches* (7.258), often from a common trunk, are the lateral sural and sural communicating nerves.

The *lateral sural nerve* (*lateral cutaneous nerve of the calf*) supplies the skin on the anterior, posterior and lateral surfaces of the proximal leg. The *sural communicating nerve* arises near the fibula's head and crosses the lateral head of the gastrocnemius to join the sural nerve (p. 1147). It may descend separately as far as the heel.

The deep peroneal (anterior tibial) nerve (7.255) begins at the common peroneal bifurcation, between the fibula and the proximal part of the peroneus longus and passes obliquely forwards deep to the extensor digitorum longus to the front of the interosseous membrane, reaching the anterior tibial artery in the proximal third of the leg; it descends with it to the ankle, dividing there into lateral and medial terminal branches. It is first lateral to the artery, then anterior and again lateral at the ankle. It supplies *muscular branches* to the tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius and an *articular branch* to the ankle joint.

The *lateral terminal branch* crosses the tarsus deep to the extensor digitorum brevis, enlarges as a pseudoganglion (cf. other sites p. 1132) and supplies the extensor digitorum brevis. From the enlargement three minute *interosseous branches* supply the tarsal and metatarsophalangeal joints of the middle three toes; the first branch supplies the second dorsal interosseous muscle.

The *medial terminal branch* runs distally on the dorsum of the foot lateral to the arteria dorsalis pedis, connecting at the first interosseous space with the medial branch of the superficial peroneal nerve and dividing into two dorsal digital nerves to supply adjacent sides of the hallux and secundus; before dividing it gives off an *interosseous branch* which supplies the hallucial metatarsophalangeal joint and the first dorsal interosseous. The deep peroneal nerve may end as *three* terminal branches (Geller & Barbato 1970).

The superficial peroneal (musculocutaneous) nerve (7.254) begins at the common peroneal bifurcation. It is at first deep to the peroneus longus, passing antero-inferiorly between the peronei and extensor digitorum longus to pierce the deep fascia in the leg's distal third, where it divides into medial and lateral branches. Between the muscles it supplies the peroneus longus, peroneus brevis and the skin of the lower leg. The *medial branch* passes anterior to the ankle, dividing into two dorsal digital nerves, one supplying the medial side of the hallux and the other the adjacent sides of the secundus and tertius. It communicates with the saphenous nerve and deep peroneal nerves (7.254). The smaller *lateral branch* traverses the dorsum of the foot laterally, dividing into dorsal digital branches which supply the contiguous sides of the third to fifth toes, also supplying the skin of the ankle's lateral aspect and connecting with the sural nerve (7.254).

Superficial peroneal branches supply the dorsal skin of all the toes except that of the lateral side of the fifth and adjoining sides of the hallux and secundus, the former being supplied by the sural, the latter by the medial terminal branch of the deep peroneal. Frequently some of the superficial peroneal lateral rami are absent and replaced by sural branches.

Remaining Branches of the Sacral Plexus

The perforating cutaneous nerve (usually from the posterior aspects of the second and third sacral ventral spinal rami) pierces the sacrotuberous ligament, curves round the inferior border of the gluteus maximus and supplies the skin over the inferomedial aspect of this muscle. The nerve may arise from the pudendal or, if absent, may be replaced by a branch from the posterior femoral cutaneous nerve or from the third and fourth or fourth and fifth sacral ventral rami.

The pudendal nerve (6.121) (derived from the ventral divisions of the second, third and fourth sacral ventral rami) (7.255) leaves the pelvis via the greater sciatic foramen between the piriformis and coccygeus to enter the gluteal region, crossing the sacrospinous ligament close to the attachment to the ischial spine, sited medial to the internal pudendal vessels on the spine. It accompanies the internal pudendal artery through the lesser sciatic foramen into the pudendal canal (p. 606) on the ischiorectal fossa's lateral wall. In the posterior part of the canal it gives off the inferior rectal nerve, which divides into the perineal nerve and the dorsal nerve of the penis (or clitoris).

The *inferior rectal nerve* pierces the medial wall of the pudendal canal, crosses the ischiorectal fossa with the inferior rectal vessels and supplies the sphincter ani externus, the lining of the lower part of the anal canal and the circumanal skin. Its branches connect with the perineal branch of the posterior femoral cutaneous nerve and with the scrotal (or labial) nerves. It sometimes arises directly from the sacral plexus, may perforate the sacrospinous ligament (in 8 out of 40 dissections according to Roberts & Taylor 1973) and may re-connect with the pudendal nerve.

The *perineal nerve*, the inferior and larger terminal pudendal branch, runs forwards below the internal pudendal artery. It accompanies the perineal artery, dividing into posterior scrotal (labial) and muscular branches.

Posterior scrotal or *labial nerves*, medial and lateral, pierce or pass over the inferior fascia of the urogenital diaphragm and run forwards in the lateral part of the urethral triangle with the scrotal (or labial) branches of the perineal artery; they supply scrotal skin or that of the labius majus, connecting with the perineal branch of the posterior femoral cutaneous and inferior rectal nerve.

Muscular branches supply: the transversus perinei superficialis, bulbospongiosus, ischiocavernosus, transversus perinei profundus, sphincter urethrae and the anterior parts of the external sphincter and levator ani. In males a *nerve to the urethral bulb* leaves the nerve to the bulbospongiosus, piercing it to supply the corpus spongiosum penis; it ends in the urethral mucosa.

The *dorsal nerve of the penis* runs forwards in males above the internal pudendal artery along the ischial ramus and the margin of the inferior pubic ramus, deep to the inferior fascia of the urogenital diaphragm. It supplies the corpus cavernosum penis and, at the urogenital diaphragm's apex, is lateral in the hiatus between this diaphragm and the inferior pubic ligament. It accompanies the dorsal penile artery between the layers of the suspensory ligament to the dorsum of the penis, ending in the glans. In females the homologous *dorsal nerve of the clitoris* is very small.

Clinical evidence indicates that the pudendal nerve supplies sensory branches to the lower part of the vagina, probably by fibres in the inferior rectal nerve and posterior labial branches of the perineal nerve. Pudendal nerves can be 'blocked' by infiltration with a local anaesthetic applied via a needle passed through the vaginal wall towards the ischial spine and sacrospinous ligament, both palpable per vaginam (Huntingford 1959, Nakanishi 1967).

Sacral visceral branches arise from the second to fourth sacral ventral rami to innervate the pelvic viscera; they are termed *pelvic splanchnic nerves* (p. 1056).

Sacral muscular branches, from the fourth sacral ventral ramus, supply the levator ani, coccygeus and sphincter ani externus. Those to the levator ani and coccygeus enter the pelvic surfaces of the muscles; the ramus to the sphincter ani externus (*perineal branch of the fourth sacral nerve*) reaches the ischiorectal fossa through the coccygeus or between that muscle and the levator ani, supplying the skin between the anus and coccyx via its cutaneous branches.

The Coccygeal Plexus

The coccygeal plexus is formed by a small descending branch from the fourth sacral ventral ramus and by the fifth sacral and coccygeal ventral rami. The fifth sacral ventral ramus emerges from the sacral hiatus, curving round the lateral margin of the sacrum below its cornu and piercing the coccygeus to reach its pelvic surface, where it is joined by a descending branch of the fourth sacral ventral ramus; the small trunk so formed descends on the pelvic surface of the coccygeus to join the minute coccygeal ventral ramus emerging from the sacral hiatus and curves round the lateral coccygeal margin to pierce the coccygeus and reach the pelvis. This small trunk is the *coccygeal plexus*. *Anococcygeal nerves* arise from it, a few fine filaments piercing the sacrotuberous ligament to supply the adjacent skin.

APPLIED ANATOMY OF LUMBAR, SACRAL AND COCCYGEAL PLEXUSES

The *iliohypogastric nerve* may be cut (p. 1140) by an incision for appendicectomy; consequent muscular weakness may predispose to the development of a direct inguinal hernia.

The *lateral femoral cutaneous nerve* may be compressed in the inguinal ligament (p. 596) or in the dense fascia lata; the consequent irritation is supposedly a cause of *meralgia paraesthetica*, a rare condition of pain on the lateral side of the thigh.

The *femoral nerve* is occasionally damaged, resulting in paralysis of the quadriceps femoris and sensory loss on the anterior and lateral aspects of the thigh.

The *obturator nerve* is sometimes divided to relieve adductor spasm in spastic paralysis, paraplegia or multiple sclerosis. Because it supplies the hip and knee joints and the medial side of the thigh. hip joint disease may cause referred pain in the thigh (medial side) or knee.

The *sacral plexus* and *lumbosacral trunk* may be compressed by pelvic tumours or the fetal head, causing pain in the lower limbs which, in the former case, may be most severe.

The *sciatic nerve* may be injured in posterior dislocations or fracture dislocations of the hip; if the lesion is complete, which is rare, all the muscles distal to the knee are paralysed and all cutaneous sensibility lost, except in the area supplied by the saphenous nerve. In sciatic nerve lesions in the mid-thigh, flexor muscles often escape because of their more proximal supply.

The *common peroneal* is the most commonly injured nerve in the lower limb because of its exposed position at the fibular neck. Injury here paralyses all the dorsiflexor and evertor muscles of the foot, i.e. the tibialis anterior, extensor hallucis longus, extensor digitorum longus, extensor digitorum brevis, peroneus longus and peroneus brevis, producing a 'drop foot'. There is a variable cutaneous loss on the anterolateral aspect of the leg and dorsum of the foot.

Owing to its deep position the *tibial nerve* is rarely injured although wounds in the popliteal fossa or posterior dislocation of the knee joint may damage it, producing paralysis of the flexors in the leg and of the intrinsic muscles in the sole; loss of sensation in the sole renders it liable to pressure sores.

Loss of sensation in the skin of the gluteal and coccygeal regions through damage to the nerves of supply (vide supra) can also lead to the development of pressure sores.

Morphology of the Spinal Nerves and Limb Plexuses

Spinal nerves conforming to a more primitive arrangement are naturally located in segments largely retaining a *metameric* (segmental) structure, e.g. the thoracic region. Such typical spinal nerves show a common plan. The dorsal, epaxial ramus passes back lateral to the articular processes and divides into medial and lateral branches penetrating the deeper muscles of the back; both innervate the adjacent muscles and supply a band of skin from the posterior median line to the scapular line (vide infra). The ventral, hypaxial ramus is connected to a corresponding sympathetic ganglion by white and grey rami communicantes. It innervates the prevertebral muscles and curves round in the body wall supplying the lateral muscles of the trunk; near the mid-axillary line it gives off a lateral branch which pierces the muscles to divide into anterior and posterior cutaneous branches. The main nerve advances in the body wall, supplying the ventral muscles and terminating in branches to the skin.

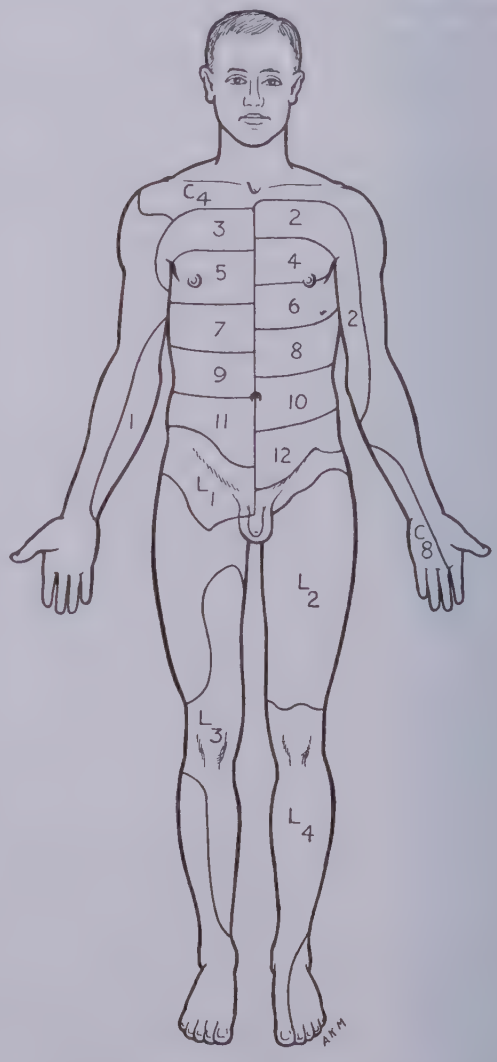
The arrangement of ventral rami in segments which have lost their obvious metamerism is greatly modified, especially by the union of adjacent nerves to form cervical, brachial, lumbosacral and coccygeal plexuses.

The cervical plexus. The cutaneous branches are homologous with the anterior terminal and lateral branches of ventral rami of typical spinal nerves. The cervical transverse cutaneous nerve and the medial supraclavicular nerves represent the anterior terminal branches; the lesser occipital and lateral supraclavicular represent lateral branches; the great auricular and intermediate supraclavicular probably represent elements of both.

The brachial plexus. Division of constituent ventral rami into ventral (anterior, flexor) and dorsal (posterior, extensor) branches occurs in both brachial and lumbosacral plexuses. In the brachial plexus division affects all three trunks (p. 1130) and conforms closely to the differentiation of the primitive musculature of the limb into ventral (flexor) and dorsal (extensor) groups. Branches of the ventral divisions largely supply *dorsal* skin in the limb, a discrepancy tentatively explained (Harris 1939) by assuming that each ventral ramus originally divided into ventral and dorsal branches and that, in human evolution, dorsal fibres entered the ventral branches of the *trunks*. As a result, fibres of the median and ulnar nerves have a wide dorsal area of supply in the hand.

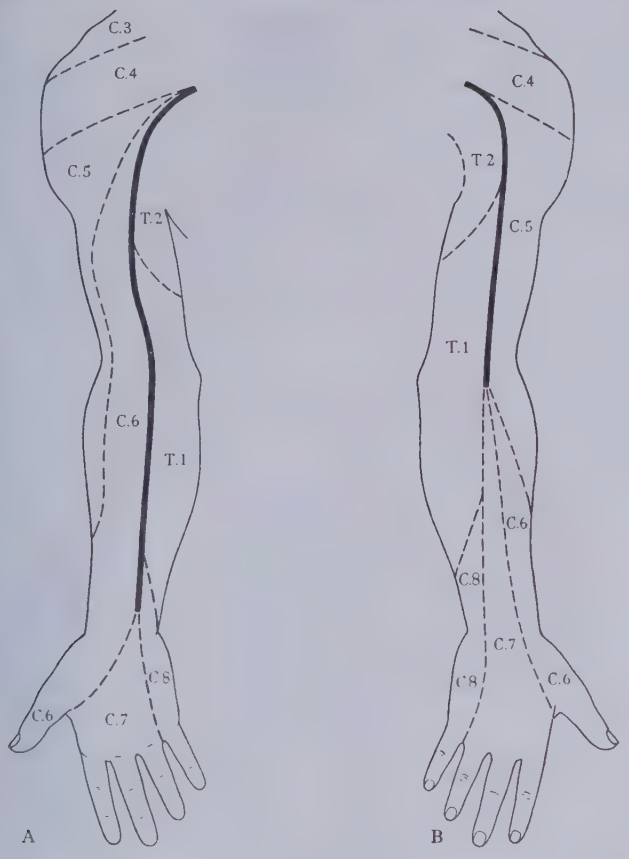
The ventrolateral position of the limb buds and the arrangement of the first and second thoracic nerves support the view that the nerves of limb plexuses are only the *lateral* branches of typical ventral rami. The second thoracic ventral ramus gives off a lateral cutaneous branch which goes to the upper limb as the intercostobrachial nerve, its size inversely related to that of the *direct* contribution from the second thoracic to the brachial plexus. The second thoracic is otherwise typical. The first thoracic ventral ramus gives a large contribution to the brachial plexus and this could be homologous with a lateral branch; the remainder, despite its small size, is typical, but its anterior cutaneous branch is reduced and often absent.

The lumbosacral plexus. Division of constituent ventral rami into ventral and dorsal branches is not as clear here as in the brachial plexus, but anatomically the obturator and tibial nerves arise from ventral and the femoral and peroneal nerves from dorsal divisions. Lateral branches of the twelfth thoracic and first lumbar ventral rami are drawn into the gluteal skin but otherwise these nerves are typical. The second lumbar ramus is difficult to interpret; it not only contributes substantially to the lumbar plexus but also has an anterior terminal branch (genital branch of the genitofemoral) *and* a lateral cutaneous branch (lateral femoral cutaneous nerve and the femoral branch of the genitofemoral). Anterior terminal branches of the third to fifth lumbar and first sacral rami are suppressed but the corresponding parts of the second and third sacral rami supply the skin, etc. of the perineum. The posterior femoral cutaneous nerve poses an interesting problem: it arises from both ventral and dorsal divisions and supplies 'flexor' femoral skin *and* 'extensor' gluteal skin.



Segmental Innervation of the Skin

The cutaneous area supplied by *one* spinal nerve, through both rami, is a **dermatome**; typically, dermatomes extend round the body from the posterior to the anterior median line (7.249, 264, 267A,B). Dermatomes of adjacent spinal nerves overlap markedly, particularly in the segments least affected by development of the limbs, i.e. the second thoracic to the first lumbar (7.264, 267A,B).



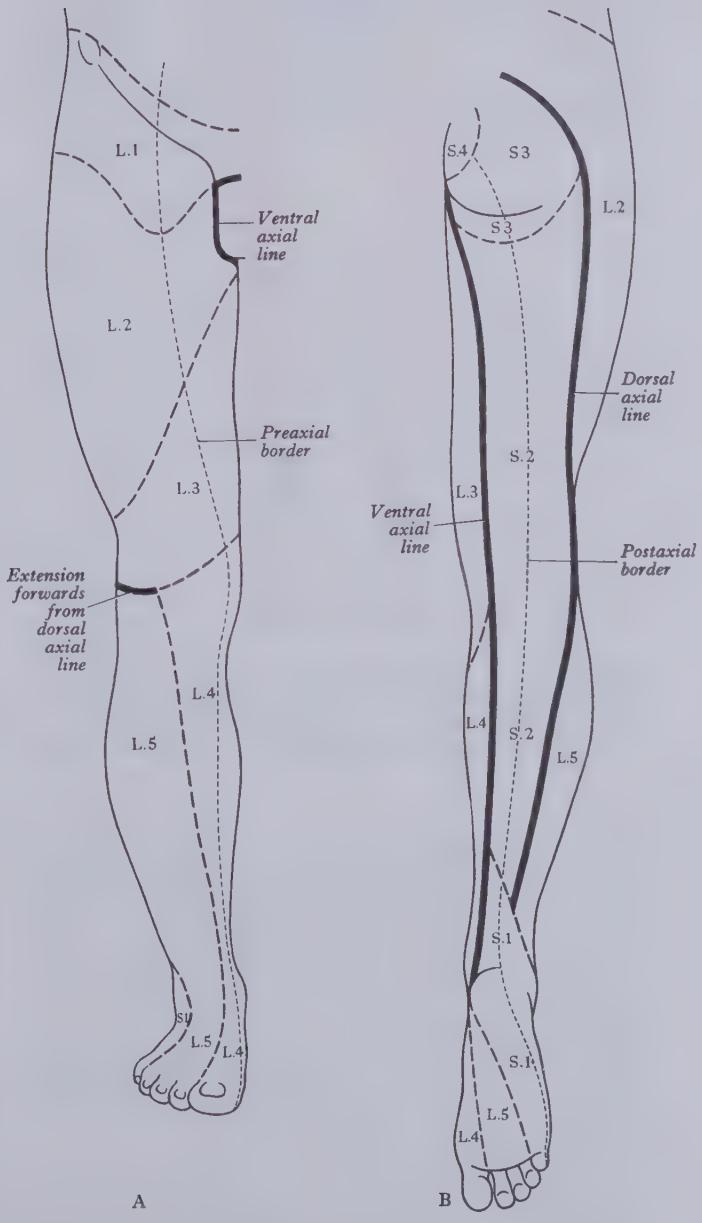
In some regions, e.g. the upper anterior thoracic wall, cutaneous nerves supplying adjoining areas are *not* from consecutive spinal nerves and the overlap is minimal. When the second thoracic spinal ramus is severed, anaesthesia is sharply demarcated but some overlap for painful and thermal sensibility may exist. Likewise, after section of a peripheral nerve (e.g. the ulnar nerve at the wrist) the area of tactile loss is always greater than that for pain and thermal sensibilities. Hence the area of total anaesthesia and analgesia following section of peripheral nerves is always less than might be anticipated from their anatomical distribution (Foerster 1933, Wollard et al 1940).

Cutaneous Innervation of the Neck and Upper Limbs

The first cervical spinal nerve supplies no skin. The second cervical usually supplies the skin of the head from the vertex to the superior nuchal line, almost all of the lateral aspect of the ear and the skin over the mandibular angle and below the chin (7.224). The third cervical supplies an oblique band from the back of the

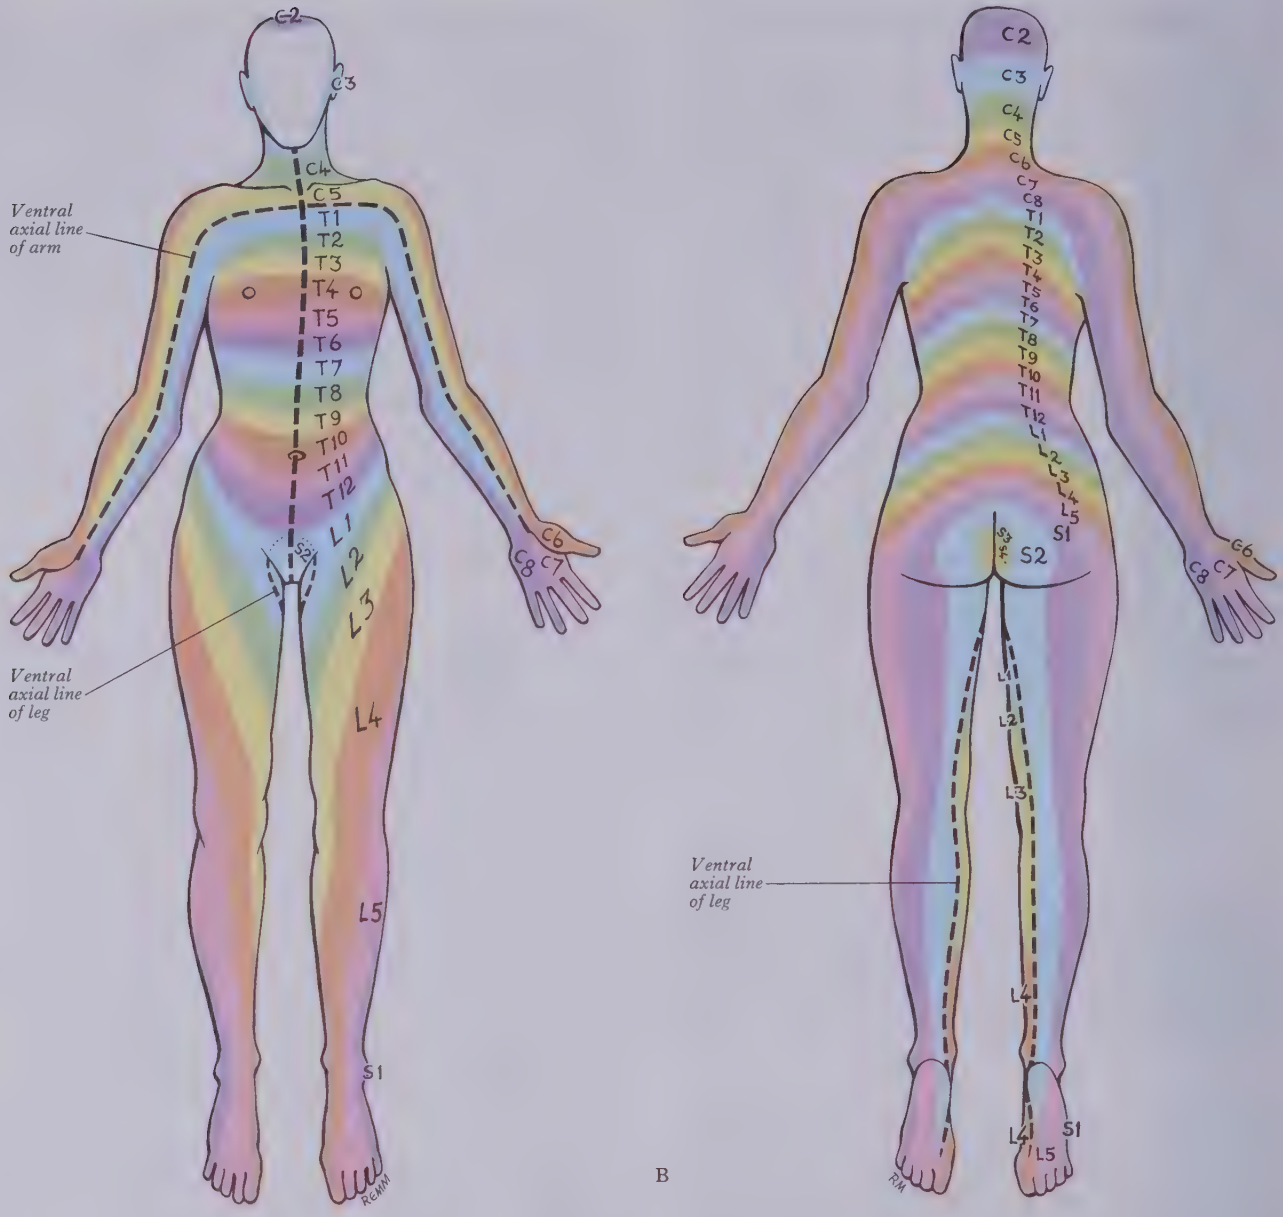
7.264 The cutaneous areas supplied by the ventral rami of the thoracic and upper four lumbar nerves (after Foerster 1933). By comparing both sides the degree of overlapping and the area of exclusive supply of any individual nerve may be estimated. See text for the areas supplied by T1 on the trunk.

7.265 A. The arrangement of the dermatomes on the anterior aspect of the upper limb. The heavy black line represents the *ventral axial line* and the overlap across it is *minimal*. Across the interrupted lines, the overlap is considerable. B. The arrangement of the dermatomes on the posterior aspect of the upper limb. The heavy black line represents the *dorsal axial line* and the overlap across it is *minimal*. Across the interrupted lines the overlap may be, and often is, considerable.



scalp and upper neck, descending across the side of the neck and increasing in width, to the ventral median line from the hyoid bone to the first rib. The fourth cervical supplies the upper half of the back of the neck and an area widening down and forwards round the neck to the anterior thoracic aspect, supplying the skin over the clavicle, first intercostal space, acromion and the upper part of the deltoid. Each of these three areas is overlapped by the succeeding; the overlap is slight but greater for dorsal rami than for ventral.

The cutaneous distribution of those spinal nerves contributing to the brachial plexus is explained by the early development of the upper limbs. In human embryos at the fourth week the upper limb is a small, flattened ventrolateral elevation on the trunk, level with the lower four cervical and first thoracic segments; its ectoderm is continuous with that of the trunk, taking its supply from the nerves of corresponding segments; its mesoderm is also continuous with that in the same segments. Lower limb buds appear slightly later and always lag behind the upper limb buds until after birth.



Limb buds have ventral and dorsal surfaces and *preaxial* (cranial) and *postaxial* (caudal) borders. In the upper limbs the *fifth cervical* ventral ramus supplies a strip of skin on the ventral and dorsal surfaces along the *pre*axial border; the *first thoracic nerve* has a similar distribution along the *post*axial border. Intervening nerves supply almost parallel strips on the ventral and dorsal surfaces. As the limb elongates, central nerves of the plexus (C6, 7 and 8) become buried proximally, reaching the skin only in distal parts; nerves of segments C4 and T2 and 3 are drawn in to supply proximal skin, i.e. at the root of the limb. During growth the lengthening limb is rotated laterally through about 90° and adducted to the trunk (p. 175). Hence the *preaxial border* runs distally on the lateral aspect of a supinated limb to the thumb, the *preaxial digit*, while the *postaxial border* runs along the medial aspect to the digitus minimus, the *postaxial digit*. Therefore the cutaneous supply of the lateral aspect of adult limbs is from C4, drawn in at the root of the limb, then from C5 and C6; and its medial aspect is from T2, T1 and C8 (7.265). On the *front of the limb*, areas supplied by C5 and C6 adjoin those supplied by T2, T1 and C8; but at their frontier, the *ventral axial line*, overlap is minimal, for C7 is buried proximally and only reaches the skin a little proximal to the wrist (7.265). On the *back of the limb* the condition is similar; but C7 (in the posterior cutaneous nerve of the forearm) reaches the skin near the elbow, the *dorsal axial line* ending at a more proximal level 7.265). Pronation of the forearm affects these lines (p. 398).

Cutaneous Innervation of the Trunk

The skin of the trunk is supplied by spinal nerves T1–L1, S2–4 and Co1 in consecutive (7.249, 264, 267A,B), curved zones, the upper almost horizontal, the lower oblique. The upper half of

7.266 A. The segmental distribution of the nerves of the lumbar and sacral plexuses to the skin of the anterior aspect of the lower limb. B. The segmental distribution of the nerves of the lumbar and sacral plexuses to the skin of the posterior aspect of the lower limb. For the significance of the markings see caption to 7.265.

7.267 Ventral (A) and dorsal (B) views of the distributions of dermatomic innervation, modified from the studies of Keegan & Garrett (1948). Diagrams of this kind can only be approximate and cannot clearly indicate the degree of overlap; e.g., the overlap of the supraclavicular nerves (C4 and 5) into the upper pectoral region is not shown and it is possible that the pectoral area assigned to the first thoracic spinal nerve is here exaggerated.

each zone is supplemented by the nerve above, the lower half by the nerve below. No appreciable loss of sensibility follows section of any one spinal nerve. The zone including the subcostal angle is supplied by the seventh thoracic nerve; the umbilicus is in the upper part of a zone supplied by the tenth thoracic.

The area supplied by dorsal rami of these nerves is limited laterally by the dorsolateral line, descending laterally from the occiput to the medial end of the acromion, continued to the posterior aspect of the greater trochanter and curving medially to the coccyx (7.266). Cutaneous strips supplied by dorsal rami do not correspond exactly to those served by ventral rami, differing both in breadth and position.

On the upper ventral thoracic aspect, the third and fourth cervical areas adjoin the first and second thoracic areas (7.249), since the muscles and skin areas supplied by the intervening nerves have grown into the upper limb; a similar, less extensive posterior gap exists.

Similar arrangements exist in the lower trunk, but less obviously, due to approximation of the lower limbs, though apparent in the gluteal region. The first lumbar adjoins the second sacral area at the root of the penis and scrotum in the male and their homologues in the female (see p. 1446), intervening nerves having been drawn away into the lower limbs during development.

Cutaneous Innervation of the Lower Limb

The skin in the lower limb is innervated by the nerves of its segments of origin, T12–S3 (7.266, 267A,B). The arrangement developmentally begins like that in the upper limbs but its identification in adults is obscured by rotation of the lower limb in early development (p. 175). Initially the *preaxial border* follows the cranial border of the limb bud to the hallux, the *preaxial digit*, the *postaxial border* following its caudal margin to the digitus minimus, the *postaxial digit*. The limb undergoes *medial* rotation, bringing the hallux to lie on the medial side of the foot. The tibia, though homologous with the radius, is also medial. Since rotation occurs at the hip, the gluteal region retains its dorsal (extensor) position.

The *preaxial border* starts near the thigh's mid-point and descends to the knee; it then curves medially, descending to the medial malleolus and the medial side of the foot and hallux. The

postaxial border commences in the gluteal region and descends to the centre of the popliteal fossa, deviating laterally to the lateral malleolus and the lateral side of the foot. *Ventral* and *dorsal axial lines* exhibit corresponding obliquity, the ventral starting proximally at the medial end of the inguinal ligament, descending the posteromedial aspect of the thigh and leg to end proximal to the heel; the dorsal axial line commences in the lateral gluteal region and descends posterolaterally in the thigh to the knee, inclining medially to end proximal to the ankle (7.266). The segmental cutaneous distribution of the nerves to the lower limb is shown in 7.266.

Knowledge of the extent of individual dermatomes, especially in the limbs, is largely based on clinical evidence, different authorities mapping variable areas for the same dermatomes, partly due to failure to adopt a common method in neurological examination and partly to individual differences in patients with similar lesions. There is more disagreement over dermatomes in the leg, perhaps because injuries to the brachial plexus are more frequent, affording greater opportunities of correlation between cutaneous defects and neural lesions. The figures for limb dermatomes inserted in 7.265, 266 are based on the Medical Research Council's *Report on Peripheral Nerve Lesions* 1942.

In using these figures it must be understood that *broken lines* indicate that the nerves on each side extend considerably beyond them, the overlap being difficult to define. But along *ventral* and *dorsal axial lines*, in *heavy black*, overlap is minimal; the nerves flanking a line are *not* derived from consecutive spinal nerves, the intervening nerve or nerves being buried in the limb and reaching the skin only at more distal points.

Some (Keegan & Garrett 1948) maintain that during the embryonic development of dermatomes in limbs, the sensory nerves grow spirally from the dorsal surface of each limb bud around its preaxial and postaxial borders, to meet anteriorly along the ventral axial line; they deny the existence of a dorsal axial line. By plotting areas of hyposensitivity, particularly hypalgesia following damage to *individual* nerve roots, they have constructed charts of limb dermatomes differing from those in 7.265, 266. Their views (7.267A,B) were based on many observations in hypalgesia due to herniation of intervertebral discs, including 165 cases in the upper limbs (47 verified surgically) and 1264 in the lower limbs (707 verified). They show dermatomes as more continuous strips extending from the trunk along the limbs.

Segmental Innervation of the Muscles

Each spinal nerve originally supplies the musculature derived from its own myotome. Where myotomal derivatives remain entities they retain the original segmental supply; but when derivatives from adjoining myotomes fuse, the resulting muscles do not always retain a supply from each corresponding spinal nerve, although they often do. Since muscles develop in situ in mesodermal cores of developing limbs, it is impossible to identify their original segments merely by a developmental study. The union of spinal nerves and branches in brachial and lumbosacral plexuses renders identification of segmental values impossible. The very concept of immutability of neuromuscular linkage, originally promoted by Furbinger (1873), has been criticized and exceptions recorded (Haines 1935, Minkoff 1974).

Segmental Innervation of the Muscles in Limbs

Most muscles in limbs are innervated from more than one segment of the spinal cord; the segments involved for individual muscles are noted in Myology (p. 569). In the list below the *predominant segmental origin* of the nerve supply is stated; damage to these segments or their motor roots results in maximum paralysis. Data are based chiefly on clinical evidence (Bumke & Foerster 1936, Villiger 1946, Sharrard 1955) but opinion differs for some muscles and not all are included. Though evidence for some muscles is incontrovertible, it is scant and uncertain in many instances. An important example is provided by the intrinsic muscles of the hand, often regarded clinically as innervated solely by the first thoracic spinal segment, though the eighth cervical is also involved (vide infra).

Upper Limb Muscles

C3, 4 Trapezius, levator scapulae.

C5 Rhomboids, deltoids, supraspinatus, infraspinatus, teres minor, biceps.

C6 Serratus anterior, latissimus dorsi, subscapularis, teres major, pectoralis major (clavicular head), biceps, coracobrachialis, brachialis, brachioradialis, supinator, extensor carpi radialis longus.

C7 Serratus anterior, latissimus dorsi, pectoralis major (sternal head), pectoralis minor, triceps, pronator teres, flexor carpi radialis, flexor digitorum superficialis, extensor carpi radialis longus, extensor carpi radialis brevis, extensor digitorum, extensor digiti minimi.

C8 Pectoralis major (sternal head), pectoralis minor, triceps, flexor digitorum superficialis, flexor digitorum profundus, flexor pollicis longus, pronator quadratus, flexor carpi ulnaris, extensor carpi ulnaris, abductor pollicis longus, extensor pollicis longus, extensor pollicis brevis, extensor indicis, abductor pollicis brevis, flexor pollicis brevis, opponens pollicis.

T1 Flexor digitorum profundus, intrinsic muscles of the hand (except abductor pollicis brevis, flexor pollicis brevis, opponens pollicis).

Lower Limb Muscles

L1 Psoas major, psoas minor.

L2 Psoas major, iliacus, sartorius, gracilis, pectineus, adductor longus, adductor brevis.

L3 Quadriceps, adductors (magnus, longus, brevis).

L4 Quadriceps, tensor fasciae latae, adductor magnus, obturator externus, tibialis anterior, tibialis posterior.

L5 Gluteus medius, gluteus minimus, obturator internus, semimembranosus, semitendinosus, extensor hallucis longus, extensor digitorum longus, peroneous tertius, popliteus.

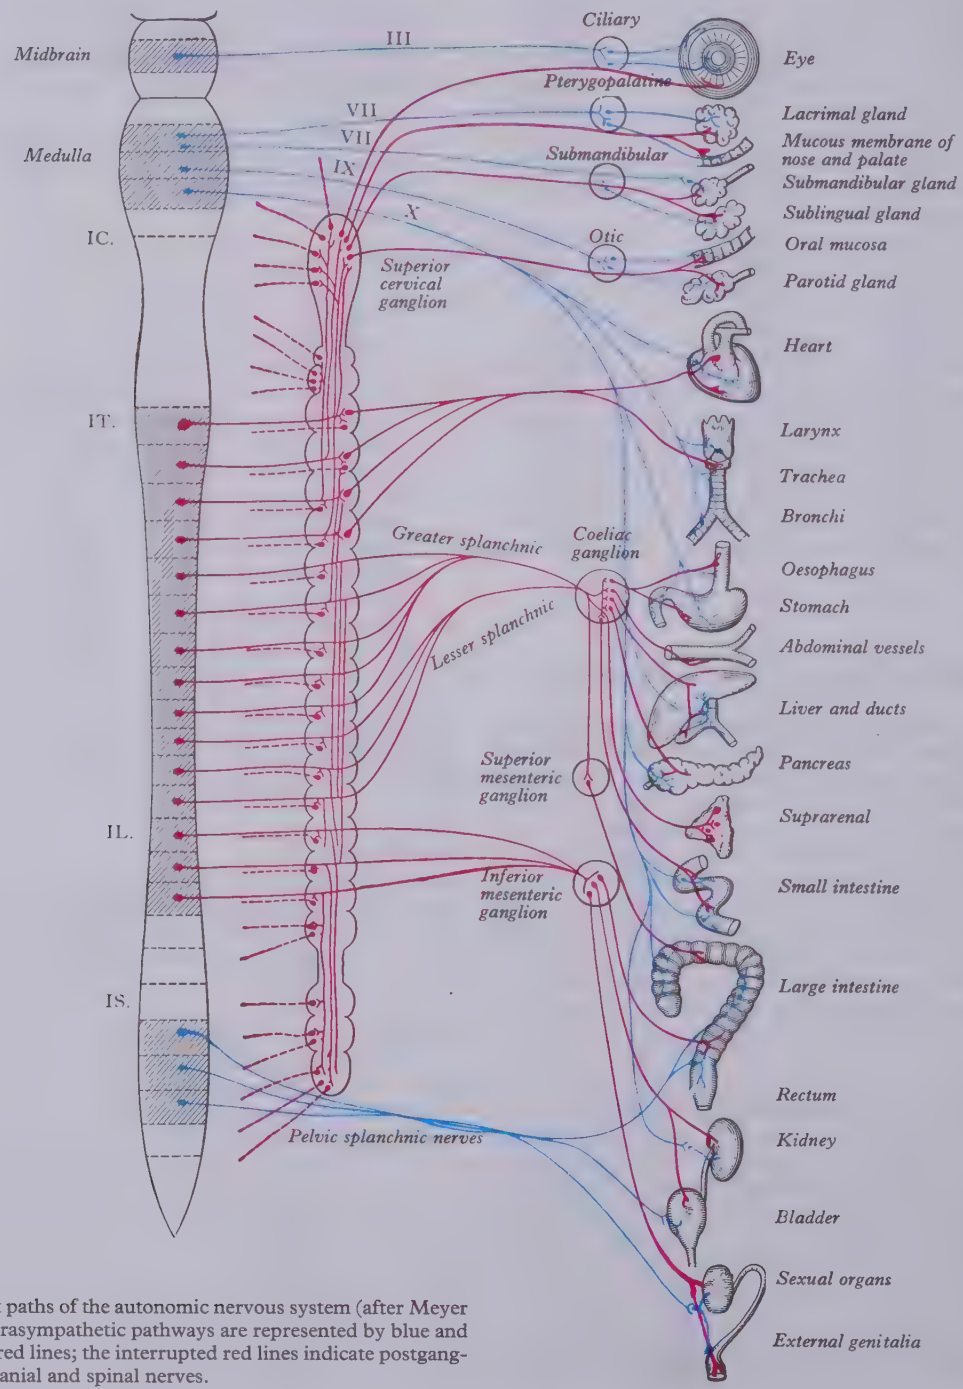
S1 Gluteus maximus, obturator internus, piriformis, biceps femoris, semitendinosus, popliteus, gastrocnemius, soleus, peronei (longus and brevis), extensor digitorum brevis.

S2 Piriformis, biceps femoris, gastrocnemius, soleus, flexor digitorum longus, flexor hallucis longus, some intrinsic foot muscles.

S3 Some intrinsic foot muscles (except abductor hallucis, flexor hallucis brevis, flexor digitorum brevis, extensor digitorum brevis).

(See also p. 930 for table of lower limb innervation.)

Joint Movements



In terms of movements of joints, segmental innervation of limb muscles may be expressed in general as follows:

Shoulder:	Abductors and lateral rotators.	C5
	Abductors and medial rotators.	C6, 7, 8
Elbow:	Flexors.	C5, 6
	Extensors.	C7, 8
Forearm:	Supinators.	C6
	Pronators.	C7, 8
Wrist:	Flexors and extensors.	C6, 7
Digits:	Long flexors and extensors.	C7, 8
Hand:	Intrinsic muscles.	C8, T1
Hip:	Flexors, adductors, medial rotators.	L1, 2, 3
	Extensors, abductors, lateral rotators.	L5, S1
Knee:	Extensors.	L3, 4
	Flexors.	L5, S1
Ankle:	Dorsiflexors.	L4, 5
	Plantar flexors.	S1, 2
Foot:	Invertors.	L4, 5
	Evertors.	L5, S1
	Intrinsic muscles	S2, 3

THE AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system possesses includes both central and peripheral components, the latter being concerned with the innervation of the viscera, glands, blood vessels and non-striated muscle. It therefore forms the visceral (splanchnic) component of the nervous system. The term 'autonomic' is a convenient rather than appropriate title. The *autonomy* of this part of the nervous system is illusory, since it is intimately responsive to changes in somatic activities; while its connections with somatic elements are not always structurally clear, the functional evidence for visceral reflexes stimulated by somatic events is abundant. (For general information consult Sheehan 1936, White et al 1952, Kuntz 1953, Mitchell 1953, 1956, Pick 1970.)

Visceral efferent paths differ from their somatic equivalents in being interrupted by peripheral synapses, at least two neurons being interposed between the central nervous connections and visceral effectors (7.268). The somata of the primary neurons are in the visceral efferent nuclei of cranial nerves and in the spinal lateral grey columns; their axons, variably but usually finely myelinated, traverse the cranial and spinal nerves to the peripheral ganglia, where they synapse with the dendrites of somata of secondary neurons. Axons of secondary, effector neurons are usually non-myelinated and supply non-striated muscle or glandular cells. There are therefore in peripheral efferent pathways *preganglionic* and *postganglionic neurons*, the latter being more numerous; one preganglionic neuron may synapse with 15–20 postganglionic neurons, permitting the wide diffusion of many autonomic effects. This disproportion between preganglionic and postganglionic neurons is said to be greater in the sympathetic than in parasympathetic parts of the autonomic nervous system. (In an investigation into human superior cervical ganglia, a ratio of preganglionic

7.268 The efferent paths of the autonomic nervous system (after Meyer & Gottlieb). The parasympathetic pathways are represented by blue and the sympathetic by red lines; the interrupted red lines indicate postganglionic rami to the cranial and spinal nerves.

to postganglionic fibres of 1 to 196 was claimed, Ebbesson 1968.) Terminations of postganglionic neurons are described on p. 905. For the structure of sympathetic ganglia and details of other neuronal types, including interneurons, see p. 1157 et seq.

Visceral afferent paths resemble somatic afferent paths; the cells of origin of their peripheral fibres are unipolar neurons in cranial and dorsal root ganglia. Peripheral processes are distributed through autonomic ganglia or plexuses, or possibly through somatic nerves, without interruption. Their central processes (axons) accompany the somatic afferent fibres through dorsal spinal roots to the central nervous system (p. 1167).

The autonomic nervous system has two complementary parts, *parasympathetic* and *sympathetic*, which differ in structure and function. Parasympathetic preganglionic efferent fibres emerge through certain cranial and sacral spinal nerves as a *craniosacral outflow*, while sympathetic preganglionic efferent fibres emerge through thoracic and upper lumbar spinal nerves as a *thoracolumbar outflow*. The somata of parasympathetic postganglionic neurons are peripheral, sited distant from the central nervous system either in discrete ganglia near to the structures innervated or often dispersed in the walls of viscera. The somata of sympathetic postganglionic neurons are located mostly in ganglia of the sympathetic trunk or ganglia in more peripheral plexuses but they are almost always nearer to the spinal cord than to the effectors innervated.

It has been considered in the past that physiologically the two systems differed in that parasympathetic reactions are generally localized, whereas sympathetic reactions are mass responses. However, even though widespread activation of the sympathetic nervous system may occur, e.g. in association with fear or rage, it is now recognized that the sympathetic nervous system is also capable of discrete activation and many different patterns of activation of sympathetic nerves throughout the body occur in response to a wide variety of stimuli.

Parasympathetic activity results in cardiac slowing and an increase in intestinal glandular and peristaltic activities, which may be considered to conserve body energies. Sympathetic activities result, e.g. in the general constriction of cutaneous arteries (increasing blood supply to the heart, muscles and brain), cardiac acceleration, increase in blood pressure, contraction of sphincters and depression of peristalsis, all of which mobilize body energies for dealing with increased activity.

Whereas the passage of nervous impulses along *all* preganglionic fibres and also parasympathetic postganglionic and somatic efferent fibres results in the liberation of *acetylcholine* at their terminals, at sympathetic postganglionic terminals *noradrenalin* or *adrenalin* is usually liberated. Hence these nerves are termed *cholinergic* or *adrenergic* respectively. As an exception to the above, the sweat glands are supplied only by postganglionic sympathetic nerves but these are cholinergic. (See also peripheral *purinergic* fibres, p. 906.)

THE PARASYMPATHETIC NERVOUS SYSTEM

Efferent Pathways

Preganglionic parasympathetic axons are myelinated and occur in the oculomotor, facial, glossopharyngeal, vagal and accessory cranial nerves and in the second to fourth sacral spinal nerves. In the cranial part of the parasympathetic system there are four small peripheral ganglia: *ciliary* (p. 1097), *pterygopalatine* (p. 1102), *submandibular* (p. 1111) and *otic* (p. 1113), all described in this account with their cranial nerves. These are solely efferent parasympathetic ganglia, unlike the trigeminal, facial, glossopharyngeal and vagal ganglia, all of which are concerned exclusively with afferent impulses and contain the somata of sensory neurons only. The cranial parasympathetic ganglia are *traversed* by afferent fibres, postganglionic sympathetic fibres and, in the otic, even by branchial efferent fibres, but none of these are interrupted in the ganglia. Postganglionic parasympathetic fibres are usually non-myelinated and shorter than the sympathetic, since the ganglia in which they synapse are in or near the viscera they supply. Baumann & Gajisin (1975) have emphasized the occurrence of small subsidiary ganglia near those mentioned above, confirming reports by others; they also described minute ganglia at many other sites in fetal material, e.g. along the middle meningeal artery and in some petrosal nerves.

(1) *Oculomotor* preganglionic parasympathetic fibres commence in the midbrain at the accessory oculomotor (Edinger-Westphal) nuclei (p. 1097) and travel in the nerve to leave in its branch to the inferior oblique to reach the *ciliary ganglion*. There they synapse, the postganglionic fibres leaving in the short ciliary nerves which pierce the sclera to run forwards in the perichoroidal space to the ciliary muscle (p.1188) and the sphincter pupillae (p. 1193). These postganglionic axons are thinly myelinated.

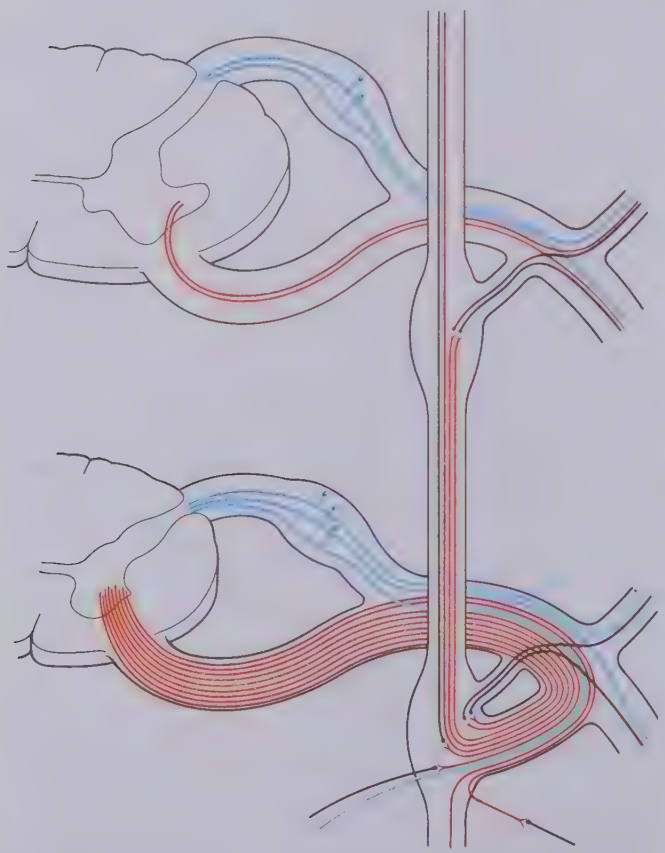
(2) The *facial nerve* contains preganglionic parasympathetic axons of neurons with their somata in the superior salivatory nucleus (p. 1108), emerging from the medulla oblongata in the nervus intermedius. These fibres leave the main facial trunk above the stylomastoid foramen in the *chorda tympani*, which traverses the tympanic cavity to reach the *lingual nerve* (p. 1110). Thus they are conveyed to the *submandibular ganglion*, in which arise postganglionic secretomotor fibres for the submandibular salivary gland. Some preganglionic fibres may synapse around cells in the gland's hilum (pp. 1293, 1297). Postganglionic secretomotor fibres for the sublingual gland continue in the lingual nerve from the submandibular ganglion (pp. 1111, 1293). Stimulation of chorda tympani dilates the arterioles in both glands in addition to having a direct secretomotor effect. The facial nerve is also usually said to contain efferent parasympathetic lacrimal secretomotor axons, which travel in its greater petrosal ramus and in the nerve of the pterygoid canal, relaying in the pterygopalatine ganglion. Postganglionic axons are said to travel by the zygomatic nerve to the lacrimal gland (p. 1102) and by ganglionic branches to the nasal and palatal glands. Evidence refuting the zygomatic route has been reported by Ruskell (1971), who favours direct *lacrimal rami* from a *retro-orbital plexus* of parasympathetic branches from the pterygopalatine ganglion. Clinical evidence suggests that some facial parasympathetic fibres reach the parotid gland (Diamant & Wiberg 1965 and p. 1108).

(3) The *glossopharyngeal nerve* contains preganglionic parasympathetic secretomotor fibres for the parotid gland. These start in the inferior salivatory nucleus (p. 1113) and travel in the glossopharyngeal nerve and its tympanic branch. They traverse the tympanic plexus and lesser petrosal nerve to reach the otic ganglion where they relay, the postganglionic fibres passing by communicating branches to the auriculotemporal nerve, which conveys them to the parotid gland. Stimulation of the lesser petrosal nerve produces vasodilator and secretomotor effects.

(4) The *vagus nerve* contains preganglionic parasympathetic fibres which arise in its dorsal nucleus (p. 1114) and travel in the nerve and its pulmonary, cardiac, oesophageal, gastric, intestinal and other branches. Some cardiac parasympathetic fibres may originate from neurons in or near the nucleus ambiguus (p. 956). The proportion of efferent parasympathetic fibres in the vagus varies at different levels but is small relative to its sensory content. Efferent fibres relay in minute ganglia in the visceral walls. The disproportion in the numbers of preganglionic to postganglionic fibres is greater in the vagus than in other cranial nerves; this cannot as yet be explained. Cardiac branches slow the cardiac cycle, joining the cardiac plexuses (p. 1164) and relaying in ganglia distributed freely over both atria in the subepicardial tissue (**6**.57), terminal fibres being distributed to the atria and the atrioventricular bundle and concentrated around the SA and (to a lesser extent) the AV nodes. It has been claimed in the past that only through the latter can the vagi influence ventricular muscle (Cullis & Tribe 1913). The smaller branches of the coronary arteries are innervated mainly via the vagus; larger arteries, with

a dual innervation, are chiefly supplied by sympathetic fibres (Woollard 1926). *Pulmonary branches* are motor to the circular non-striated muscle fibres of the bronchi and bronchioles and are therefore bronchoconstrictor; synaptic relays occur in the ganglia of the pulmonary plexuses. *Gastric branches* are secretomotor and motor to the non-striated muscle of the stomach, with the exception of the pyloric sphincter, which they inhibit. *Intestinal branches* have a corresponding action in the small intestine, caecum, vermiform appendix, ascending colon, right colic flexure and most of the transverse colon; they are secretomotor to the glands, motor to the intestinal muscular coats but inhibitory to the ileocaecal sphincter. The synaptic relays are situated in the myenteric (Auerbach's) and the submucosal (Meissner's) plexuses (p. 1331).

(5) The anterior rami of the *second*, *third* and often *fourth sacral spinal nerves* issue *pelvic splanchnic nerves* (7.277) to the pelvic viscera. These nerves unite with branches of the sympathetic pelvic plexuses. Minute ganglia occur at the points of union and in the visceral walls. In these ganglia the sacral preganglionic parasympathetic fibres relay synaptically.



The pelvic splanchnic nerves are motor to the muscle of the rectum and bladder wall but inhibitory to the vesical sphincter, supply vasodilator fibres to the penile and clitoridic erectile tissue and are probably vasodilator to the testes and ovaries and vasodilator (and possibly inhibitory) to the uterine tubes and uterus. Filaments from the pelvic splanchnic nerves ascend in the hypogastric plexus to supply the sigmoid and descending colon, the left colic flexure and terminal transverse colon with visceromotor fibres (Telford & Stopford 1934, Mitchell 1935).

THE SYMPATHETIC NERVOUS SYSTEM

The sympathetic system, which is the larger autonomic division, includes the two ganglionated trunks and their branches, plexuses and subsidiary ganglia. It has a much wider distribution than the parasympathetic, for it innervates: all sweat glands, the arrectores pilorum, the muscular walls of many blood vessels, the heart, lungs and respiratory tree, the abdomino-pelvic viscera, the oesophagus, the muscles of the iris in the eye, and non-striated muscle of the urogenital tract, the eyelids and elsewhere.

Efferent Pathways

The *preganglionic fibres* are axons of somata in the lateral grey column of all the thoracic and the upper two or three lumbar spinal segments, where they form intermediomedial and intermediolateral neuronal groups (p. 927). The axons are myelinated, with diameters of 1·5–4·0 μm, and emerge from the spinal cord through the ventral spinal roots, passing into the spinal nerves at the start of their ventral rami, which they soon leave in *white rami communicantes*, to join either the corresponding ganglia of the sympathetic trunks or their interganglionic segments. This outflow is confined to the thoracolumbar region, the white rami communicantes being restricted to these 14 pairs of spinal nerves, although a limited outflow in other spinal nerves has been suggested. Neurons like those in the lateral grey column exist at other levels of the cord above and below the thoracolumbar outflow (Mitchell 1953) and small numbers of their fibres issue in other ventral roots. Dorsal spinal roots may also contain vasodilator fibres. Reaching the sympathetic trunk, preganglionic fibres may behave in several ways (7.269): (1) They may synapse with neurons in the nearest ganglion. (2) They may traverse this, ascending or descending in the sympathetic chain to end in another ganglion; note however that preganglionic fibres do not *divide* into ascending and descending branches. A single preganglionic fibre may, through collateral and terminal branches, synapse with neurons in several ganglia or terminate in only one ganglion. (3) They may traverse the nearest ganglion, ascend or descend and, without synapsing, emerge in one of the medially-directed branches of the sympathetic trunk to end at synapses in the ganglia of autonomic plexuses (mainly situated in the midline, e.g. around the coeliac and mesenteric arteries, p.1165). Occasionally preganglionic fibres relay in ganglia situated proximal to the sympathetic trunks; these '*intermediate ganglia*' are most numerous on grey rami communicantes (vide infra) at cervical and lower lumbar levels (Boyd & Munro 1940); they may be of microscopic size and sometimes occur in spinal ventral roots or trunks. More than one preganglionic fibre may synapse with a single postganglionic neuron (vide infra).

7.269 The constitution of a typical spinal nerve. In the upper part of the diagram the spinal nerve roots show the somatic components; in the lower part the spinal roots show the visceral components. Red = somatic and preganglionic visceral nerve fibres, blue = somatic and visceral afferent fibres, black = postganglionic afferent visceral fibres.

The nervi terminales (p. 1095) may be rostral extensions of the sympathetic system, containing efferent postganglionic fibres distributed to the blood vessels and glands of the nasal cavity, although this view has been challenged (Bojsen-Møller 1975).

The sympathetic ganglia include collections of cells on the sympathetic trunks, in the autonomic plexuses and the 'intermediate' ganglia; some ganglionic cells are dispersed in the plexuses. Originally ganglia on the trunks correspond numerically to the ganglia on the dorsal spinal roots (p. 1125); but adjoining ganglia may fuse and in man there are rarely more than 22 or 23 and sometimes less. Subsidiary ganglia in the major autonomic plexuses (e.g. coeliac, superior mesenteric ganglia, etc.) are derivatives of the ganglia of the trunks. The functional properties of sympathetic ganglia have been investigated extensively over many decades, their peripheral location providing a valuable means of studying interneuronal communication, as well as other aspects of neurobiology (for reviews of the earlier literature, see p. 1154; more recent accounts are given by Gabella (1976) and Eränkö (1978).

The structure of sympathetic ganglia. The classic studies by Langley and his successors led to the view that the autonomic ganglia are relay stations, a concept largely corroborated by anatomical observation, although it was soon recognized that a minor fraction of the fibres traversed one or more ganglia without synapse, some being efferent fibres en route to another ganglion and others afferents from the viscera and glands. This concept remains substantially true but has been modified and extended by electron microscopy, neurohistochemistry and electrophysiology, e.g. a considerable variation in the ratio between pre- and postganglionic fibres has been found. The superior cervical sympathetic ganglion, the most extensively studied, has ratios varying from 1:28 to 1:176 in different mammalian species (Billingsley & Ranson 1918, Samuel 1953, Ebbeson 1968). It has long been accepted that preganglionic axons may synapse with many postganglionic neurons for the wide *dissemination* and perhaps *amplification* of sympathetic activity, a characteristic not shared to the same degree by parasympathetic ganglia. Dissemination may be achieved: (1) by multiple synapses of preganglionic nerve fibres; (2) by the mediation of interneurons; (3) by the diffusion within the ganglion of transmitter substances locally produced (*paracrine effect*) or by a local response to a substance produced elsewhere (*endocrine* effect). There is evidence that all of these mechanisms are involved.

The connective tissue capsule of each ganglion, continuous with the epineurium of its connecting rami, also extends as septa into the ganglion, the surrounding groups of neurons and their fibres. More delicate extensions of this stroma spread amongst the cells, each of which is surrounded by a collagenous intercellular matrix containing a few fibroblasts and many small vessels including capillaries. Satellite cells (amphicytes) encapsulate the somata of ganglionic neurons and their processes. Externally this thin sheath of satellite cells has a continuous basal lamina and the two elements screen neurons from contact with the ganglionic extracellular matrix. Neurons thus have direct access only to the internal faces of satellite cells, the two being separated only by a narrow perineuronal space of 15–20 nm which is, however, linked to the extracapsular spaces by narrow channels between the satellite cells, providing possible routes for the movement of neurotransmitter and hormonal substances between the somata of neurons and the vascular compartment.

Attempts to classify the neurons of the sympathetic (and parasympathetic) ganglia, often on inadequate criteria, have entailed disagreements and confusion. Most are multipolar, with somata ranging from 25–50 μm in mankind; a smaller type, of about 15–20 μm, less angular in shape and present in much smaller numbers, is often clustered in groups (De Castro & Herneros 1945) and probably corresponds to 'small intensely fluorescent' (SIF) cells (vide infra). Multipolar neurons display much more dendritic variation; according to McLachland (1974) they have (in guinea pigs) a mean of 13 dendrites per cell. The complexity of these dendrites, especially those ramifying in the capsular perikaryal space, is greater in human ganglion cells. Dendritic glomeruli have been observed in many ganglia. In general ultrastructure these glomeruli resemble others (p. 888); clusters of small, granular vesicles, adrenergic in type, are dispersed superficially in the perikaryon and also in the dendrites, probably representing the storage of catecholamines. Ganglionic neurons receive many axodendritic synapses from preganglionic nerve fibres, the axosomatic synapses being less numerous. Each preganglionic fibre forms several synapses with several separate dendrites, providing a mechanism for the dissemination and/or amplification of neural signals. Postganglionic fibres (vide infra) commonly arise from the initial stem of a large dendrite and produce few or no collateral neurites.

The existence of *interneurons* in sympathetic ganglia has been amply confirmed (Williams 1967, Williams & Palay 1969, Libet & Crowman 1974), consisting of the 'small intensely fluorescent' (SIF) cells identified in sympathetic ganglia in many mammals, including mankind (Eränkö & Harkonen 1965, Jacobowitz 1970). Small chromaffin cells also occur in sympathetic ganglia, as recognized by Kohn in 1898. Coupland (1965), amongst other modern workers, has ascribed them to all ganglia of the sympathetic trunk and to other sites in human neonatal material. The distinction between SIF cells and chromaffin cells appears uncertain in many accounts. The supposed two types have been identified in ganglia by separate techniques (chromaffin reaction and formalin-induced fluorescence) which cannot be applied together to a single cell. In the sympathetic ganglia of rats (Santer et al 1975) SIF cells were found to be more numerous than chromaffin cells and their modes of distribution showed some differences. Both contain catecholamines, some possibly only enough to be revealed by the more sensitive formaldehyde-induced fluorescence technique (Falck-Hillarp), whereas others may have sufficient to produce a positive chromaffin reaction (Gabella 1976). Both types may be interneurons (Santer et al 1975, Gabella 1976). Greengard & Kebabian (1974) have hypothecated that the SIF cells release dopamine, which is then bound by dopamine receptors on ganglionic neurons causing hyperpolarization via a cyclic AMP-dependent 'second messenger' system (p. 887). In the ganglia of some species, two types of SIF cell have been described (Williams 1975): a minority, with long processes end near ganglionic neurons and hence can be regarded as interneurons (Type I), while the more numerous Type II cells have shorter processes ending near blood vessels (Chiba et al 1975). In bovine superior cervical sympathetic ganglia, 24% of SIF cells were described as Type I and 20% in cats. Although the secretory granules in Type I cells may act directly on ganglionic neurons, some SIF cells, presumably Type II, may secrete into local blood vessels (Polonyi et al 1977), exerting more distant effects. The functions of SIF cells in neurotransmission in sympathetic ganglia have been reviewed by Eränkö (1978), and quantification of numbers, dimensions and packing density of ganglionic neurons are reported by Gabella (1976).

The axons of the principal ganglionic cells are narrow, non-myelinated *postganglionic fibres*, distributed to effector organs in various ways: (1) Those from a ganglion of the sympathetic trunk may return to the spinal nerve of preganglionic origin through a *grey ramus communicans*, usually joining the nerve just proximal to the white ramus, to be distributed through ventral and dorsal spinal rami to blood vessels, sweat glands, hairs, etc. in their zone of supply. Segmental areas vary in extent and overlap considerably. The extent of innervation of different effector systems, e.g. vasomotor, sudomotor, etc. by a particular nerve may not be the same. (2) Postganglionic fibres may pass in a medial branch of a ganglion direct to particular viscera. (3) They may innervate adjacent blood vessels or pass along them externally to their peripheral distribution. (4) They may ascend or descend before leaving the sympathetic trunk as (1), (2) or (3). Many fibres are distributed along arteries and ducts as plexuses to distant effectors.

Fusion of grey and white rami may also occur, e.g. in the thoracic region; grey rami may also contain fasciculi of thick myelinated fibres which are somatic efferents using a grey ramus to reach the prevertebral muscles (p. 1158) e.g. in the cervical region. For details of rami communicantes and their variations consult Winckler (1961).

Functional significance. Postganglionic fibres which return to the spinal nerves supply vasoconstrictor fibres to blood vessels, are secretomotor to sweat glands and motor to the arrectores pilorum in their dermatomes. Those which accompany the motor nerves to voluntary muscles are probably only vasodilatory. Most, if not all, peripheral nerves contain postganglionic sympathetic fibres. Those reaching the viscera are concerned with general vasoconstriction, bronchial and bronchiolar dilatation, modification of glandular secretion, pupillary dilatation, inhibition of alimentary muscle contraction, etc. A single preganglionic fibre probably synapses with the postganglionic neurons in only one effector system; hence effects such as sudomotor and vasomotor actions can be separate. This is not necessarily true of visceral *afferent* fibres. Sympathetic and parasympathetic nerves usually exert antagonistic influences on many viscera; but in the urinary bladder normal emptying *and* filling are controlled by parasympathetic innervation, the sympathetic being only vasomotor.

Higher autonomic control. Peripheral autonomic activity is integrated at higher levels in the brain stem and cerebrum, including various nuclei of the brain-stem reticular formation, thalamus and hypothalamus, the limbic lobe and prefrontal neocortex, together with the ascending and descending pathways which interconnect these regions (see details of these given earlier in this section).

The sympathetic trunks are two ganglionated, irregular nerve cords extending from the cranial base to the coccyx. In the neck each lies posterior to the carotid sheath and anterior to the cervical transverse processes; in the thorax it is anterior to the heads of the ribs, in the abdomen anterolateral to the lumbar vertebral bodies and in the pelvis anterior to the sacrum and medial to the anterior sacral foramina. Anterior to the coccyx the two trunks meet in the single, median, terminal *ganglion impar*.

Cervical sympathetic ganglia are usually reduced to three by fusion; from the superior ganglion's cranial pole issues the internal carotid nerve, as a continuation of the sympathetic trunk, accompanying the internal carotid artery through its canal into the cranial cavity. There are from 10–12 (usually 11) thoracic ganglia, four lumbar and four or five in the sacral region.

CRANIAL PART OF THE SYMPATHETIC SYSTEM

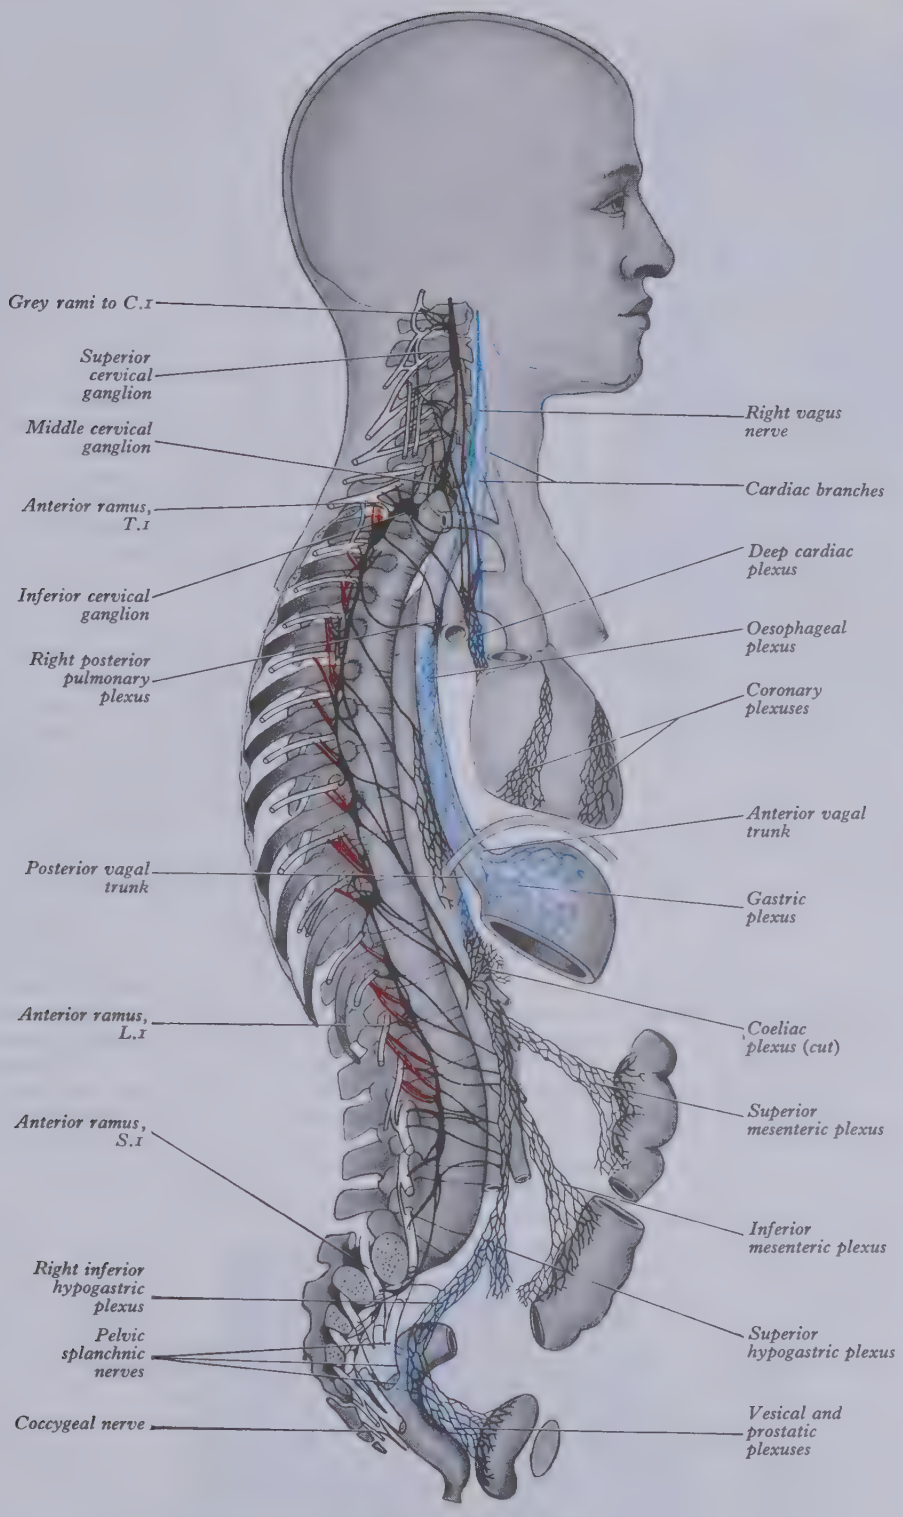
This begins on each side as the **internal carotid nerve**, a branch of the superior cervical ganglion containing the postganglionic fibres of its neurons. Ascending behind the internal carotid artery it divides in the carotid canal into branches, one medial and the other lateral to the artery. The larger, *lateral branch* gives filaments to the internal carotid and forms the lateral part of the internal carotid plexus; the *medial branch* also gives filaments to the artery and, continuing on, forms the medial part of the internal carotid plexus.

The internal carotid plexus surrounds its artery and occasionally contains a small, medial *carotid ganglion*; elsewhere it has some scattered postganglionic neurons. Laterally the plexus communicates with the trigeminal and pterygopalatine ganglia, the abducent nerve and tympanic branch of the glossopharyngeal; it also distributes filaments to the wall of the internal carotid artery. One or two filaments join the abducent nerve as it lies on the lateral side of the internal carotid artery. The branch to the pterygopalatine ganglion is the *deep petrosal nerve*, which perforates the cartilage filling the foramen lacerum and forms with the greater petrosal nerve the *nerve of the pterygoid canal*, traversing the canal to the pterygopalatine ganglion. The communication with the tympanic branch of the glossopharyngeal nerve is effected by the *superior* and *inferior caroticotympanic nerves* in the posterior wall of the carotid canal.

The medial part of the internal carotid plexus is inferomedial to the part of the internal carotid artery which indents the cavernous sinus lateral to the sella turcica; it gives branches to the artery and to the oculomotor, trochlear, ophthalmic and abducent nerves and the ciliary ganglion. It also sends vasomotor rami along branches of the internal carotid to the hypophysis cerebri (p. 1455).

The branch to the oculomotor nerve joins the nerve near its point of division and the branch to the trochlear joins it in the lateral wall of the cavernous sinus; filaments also connect with the medial side of the ophthalmic nerve and with the abducent. The filament to the ciliary ganglion, from the anterior part of the plexus, enters the orbit via the superior orbital fissure; this ramus may join the ciliary ganglion directly or unite with the communicating branch from the nasociliary nerve (p. 1097); or it may travel in the ophthalmic nerve and its nasociliary branch. Its fibres traverse the ganglion without synapse and enter the short ciliary nerves to be distributed to the blood vessels of the eyeball. Fibres supplying the dilatator pupillae usually travel via the ophthalmic, nasociliary and long ciliary nerves but occasionally via the short ciliary. Some fibres may also innervate the ciliaris muscle. The preganglionic fibres concerned leave the spinal cord predominantly in T1, pass to and through the cervicothoracic ganglion and ascend in the cervical sympathetic trunk to relay in the superior cervical ganglion.

The internal carotid plexus is prolonged around the anterior and middle cerebral arteries and the ophthalmic arteries, reaching the pia mater along the cerebral vessels; along the ophthalmic artery they pass into the orbit where the plexus accompanies each branch of that vessel. Filaments on the anterior communicating artery connect the sympathetic nerves of the right and left sides and may be associated with a small ganglion. Much of this detail depends on rather old observations; continued disagreement and discrepancy have been reviewed by Mitchell (1953) and Purves (1972). It can, however, be said that the old controversy over the autonomic innervation of the cerebral arterial tree is now settled. Electron microscopy shows that the innervation is like that of other vascular systems and the terminals are confirmed histochemically as adrenergic in various mammals, including man (Iwayama 1970). The sources of these sympathetic vasoconstrictor fibres are the internal carotid and vertebral plexuses but their precise distribution from each is unresolved. (Though cholinergic terminals have been noted in cerebral arterial walls, the existence of a vasodilator mechanism has not been clearly demonstrated.) Falck et al (1965) and Edvinsson et al (1973) have also claimed that some adrenergic axons accompanying pial and intracerebral arteries are *not* derived from known sympathetic sources but from nerve cells at present merely presumed to be intracranial in location.

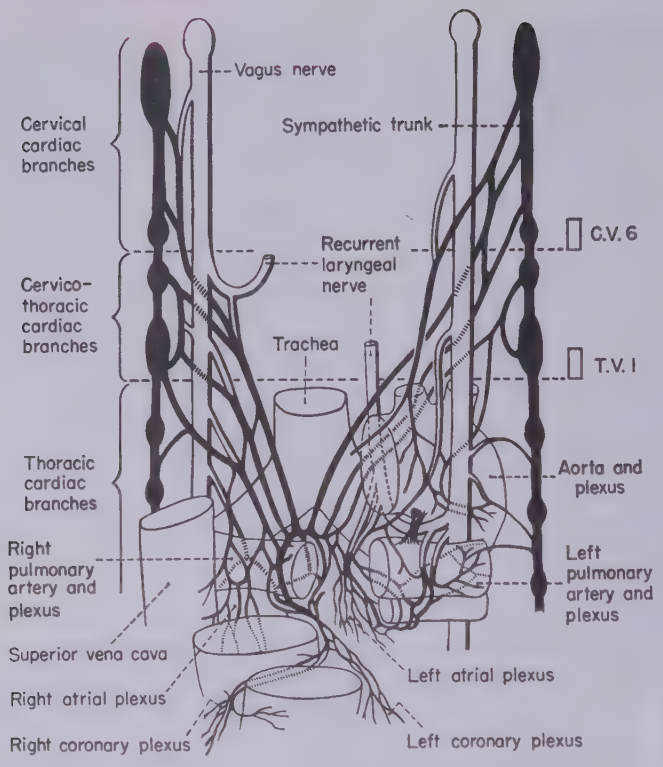


CERVICAL PART OF THE SYMPATHETIC SYSTEM

The cervical part of each sympathetic trunk contains three interconnected ganglia, the superior, middle and cervicothoracic (7.270), which send grey rami communicantes to all the cervical spinal nerves but receive no white rami communicantes from them; their spinal preganglionic fibres emerge in the white rami communicantes of the upper thoracic spinal nerves which enter the corresponding thoracic sympathetic ganglia, through which they ascend into the neck. In their course, the grey rami communicantes may pierce the longus capitis or the scalenus anterior. For details of the cervical grey rami see Potts (1925), Oxford (1928), Pick & Sheehan (1946), Sunderland & Bedbrook (1949).

The superior cervical ganglion, the largest of the three, adjoins the second and third cervical vertebrae and is probably formed from four fused ganglia corresponding to C1–4. Anterior to it is the internal carotid artery and sheath, while posterior to it is the longus capitis. The internal carotid nerve (vide supra) ascends from it into the cranial cavity; the lower end of the ganglion is united by a connecting trunk to the middle cervical ganglion. Its branches consist of lateral, medial and anterior groups.

The *lateral branches* are the grey rami communicantes to the upper four cervical spinal nerves and to some of the cranial nerves; delicate filaments pass to the inferior vagal ganglion and to the hypoglossal nerve; a branch, *the jugular nerve* ascends to the cranial base and divides into two, one part joining the inferior glossopharyngeal ganglion and the other the superior vagal ganglion; other twigs pass to the superior jugular bulb and associated jugular glomus or glomera and some to the meninges in the posterior cranial fossa.

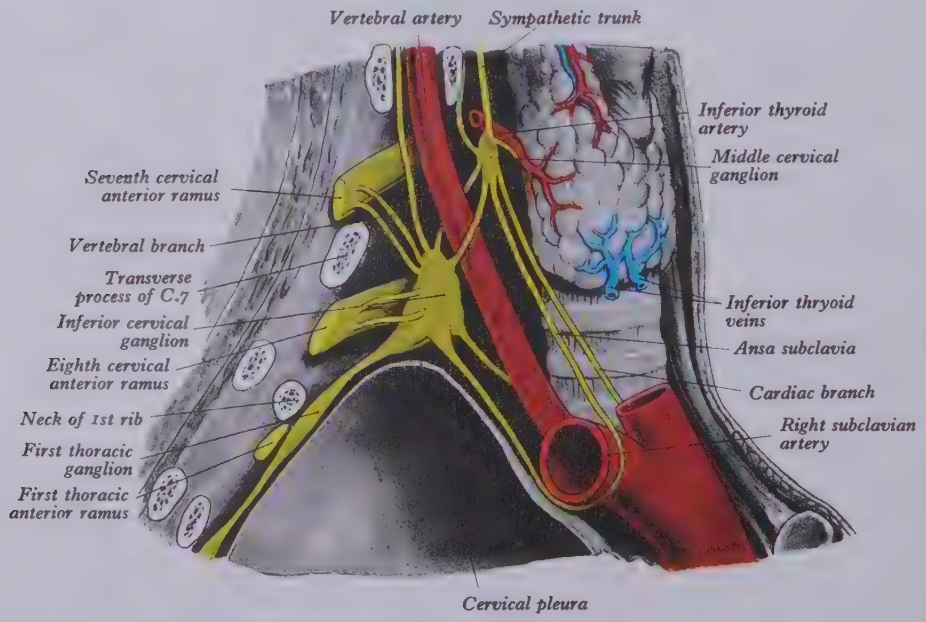


The *medial branches* of the superior cervical ganglion are the laryngopharyngeal and cardiac. The *laryngopharyngeal branches* supply the carotid body and pass to the side of the pharynx, joining glossopharyngeal and vagal rami to form the *pharyngeal plexus* (p. 1117). A *cardiac branch* arises by two or more filaments from the lower part of the superior cervical ganglion, occasionally receiving a twig from the trunk between the superior and middle cervical ganglia. It is thought to contain only efferent fibres, the preganglionic outflow being from the upper thoracic segments of the spinal cord, and to be devoid of pain fibres from the heart (p. 1164). It descends behind the common carotid artery, in front of the longus colli, crossing anterior to the inferior thyroid artery and recurrent laryngeal nerve. The courses on the two sides then differ. The *right cardiac branch* usually passes behind or sometimes in front of the subclavian artery and posterolateral to the brachiocephalic trunk to the back of the aortic arch where it joins the deep (dorsal) part of the cardiac plexus. It has other sympathetic connections: about mid-neck it receives filaments from the external laryngeal nerve; inferiorly, one or two vagal cardiac branches join it; as it enters the thorax it is joined by a filament from the recurrent laryngeal nerve. Filaments from the

7.270 The right sympathetic trunk and its connections with the thoracic, abdominal and pelvic plexuses. Blue = parasympathetic fibres, black = sympathetic trunk and branches, red = white rami communicantes.

nerve also communicate with the thyroid branches of the middle cervical ganglion. The *left cardiac branch*, in the thorax, is anterior to the left common carotid artery and crosses in front of the left side of the aortic arch to reach the superficial (ventral) part of the cardiac plexus. Sometimes it descends on the right of the aorta to end in the deep (dorsal) part of the cardiac plexus. It communicates with the cardiac branches of the middle cervical and cervicothoracic sympathetic ganglia and sometimes with the inferior cervical cardiac branches of the left vagus; branches from these mixed nerves form a plexus on the ascending aorta.

The *anterior branches* of the superior cervical ganglion ramify on the common and external carotid arteries and the latter's branches, forming a delicate plexus around each in which small ganglia are occasionally found. The plexus around the facial artery supplies a filament to the submandibular ganglion; the plexus on the middle meningeal artery sends one ramus to the otic ganglion and another, *the external petrosal nerve*, to the facial ganglion. Many of the fibres coursing along the external carotid and its branches ultimately leave them to travel to facial sweat glands via trigeminal nerve branches.



7.271 The human cardiac plexus, a semi-diagrammatic representation of its source from the cervical parts of the vagus nerves and sympathetic trunks and of its extensions: the pulmonary, atrial and coronary plexuses. Note the numerous junctions between sympathetic and parasympathetic (vagal) rami which form the plexus. For further information, particularly concerning the frequent variations, consult Mizeres 1963, to the author and publisher of which we are indebted for permission to use this diagram.

The middle cervical ganglion (7.272–274), the smallest of the three, is occasionally absent and may then be replaced by minute ganglia in the sympathetic trunk or may be fused with the superior ganglion. It is usually found at the sixth cervical vertebral level, anterior or just superior to the inferior thyroid artery, or it may adjoin the cervicothoracic ganglion (vide infra); it is probably a coalescence of the ganglia of the fifth and sixth cervical segments, judging by its postganglionic rami, which join the fifth and sixth cervical spinal nerves but sometimes also the fourth and seventh. The ganglion also has thyroid and cardiac branches. It is connected to the cervicothoracic ganglion by two or more very variable cords: the posterior usually splits to enclose the vertebral artery; the anterior loops down anterior to and then below the first part of the subclavian artery, medial to the origin of its internal thoracic branch, and supplies rami to it. This loop is the *ansa subclavia*; it is frequently multiple, lies closely in contact with the cervical pleura and generally connects with the phrenic nerve. Similar connections with the vagus nerve are of uncertain significance.

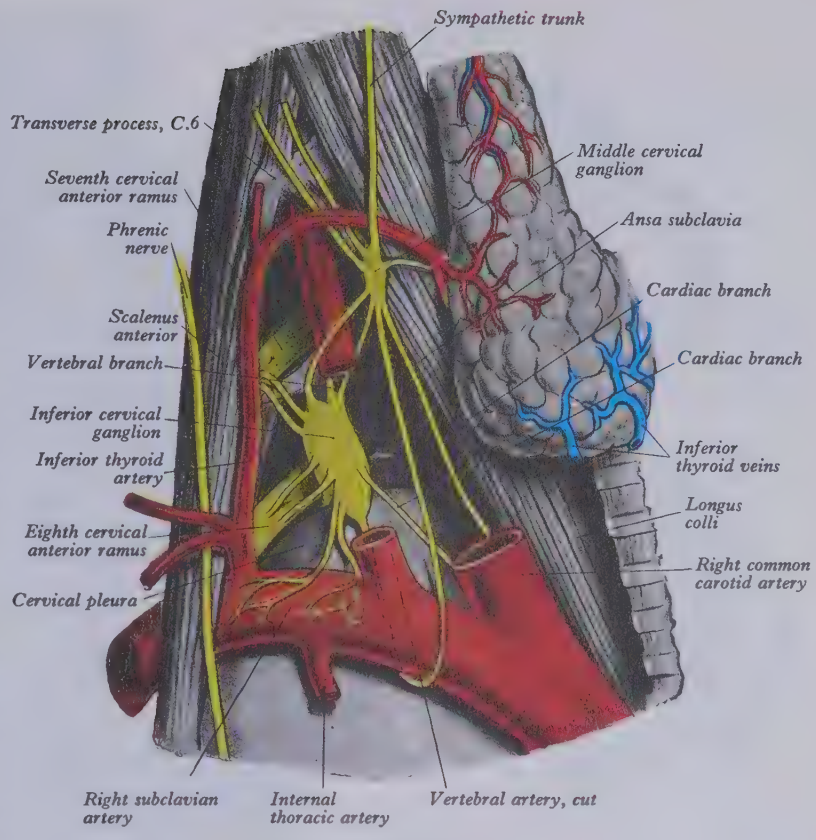
Thyroid branches accompany the inferior thyroid artery to the thyroid gland, communicating with the superior cardiac, external laryngeal and recurrent laryngeal nerves, and send branches to the parathyroid glands. Fibres to both glands are in part vasomotor but some reach the secretory cells (Raybuck 1952).

The *cardiac branch*, the largest sympathetic cardiac nerve, either arises from the ganglion itself or more often from the sympathetic trunk cranial or caudal to it. On the *right side* it descends behind the common carotid artery, in front of or behind the subclavian, to the trachea where it receives a few filaments from the recurrent laryngeal nerve before joining the right half of the deep (dorsal) part of the cardiac plexus. In the neck, it connects with the superior cardiac and recurrent laryngeal nerves. On the *left side* the cardiac nerve enters the thorax between the left common carotid and subclavian arteries to join the left half of the deep (dorsal) part of the cardiac plexus. Fine branches from the middle cervical ganglion also pass to the trachea and oesophagus.

The cervicothoracic (stellate) ganglion, irregular in shape and much larger than the middle cervical ganglion, is probably formed by a fusion of the lower two cervical and first thoracic segmental ganglia, sometimes including the second and even third and fourth thoracic ganglia. The first thoracic ganglion may be separate, leaving an *inferior cervical ganglion* above it (7.270, 272). The sympathetic trunk turns backwards at the junction of the neck and thorax and so the long axis of the cervicothoracic ganglion becomes almost anteroposterior. The ganglion lies on or just lateral to the lateral border of the longus colli between the base of the seventh cervical transverse process and the neck of the first rib (which are posterior to it), the vertebral vessels being anterior. Below it is separated from the posterior aspect of the cervical pleura by the suprapleural membrane; the costocervical

7.272 The middle and inferior cervical ganglia of the right side, viewed from the right. Note the proximity of the inferior cervical and first thoracic ganglia, usually fused to form a cervicothoracic (stellate) ganglion.

trunk branches near its lower pole. Lateral is the superior intercostal artery.



A small *vertebral ganglion* may be present on the sympathetic trunk anterior or anteromedial to the origin of the vertebral artery and directly above the subclavian. When present, it may provide the ansa subclavia and is also joined to the cervicothoracic ganglion by fibres enclosing the vertebral artery. It is usually regarded as a detached part of the middle cervical or cervicothoracic ganglion. Like the middle cervical ganglion it may supply grey rami communicantes to the fourth and fifth cervical spinal nerves. The cervicothoracic ganglion sends grey rami communicantes to the seventh and eighth cervical and first thoracic spinal nerves and gives off a cardiac branch, branches to nearby vessels and sometimes a branch to the vagus nerve.

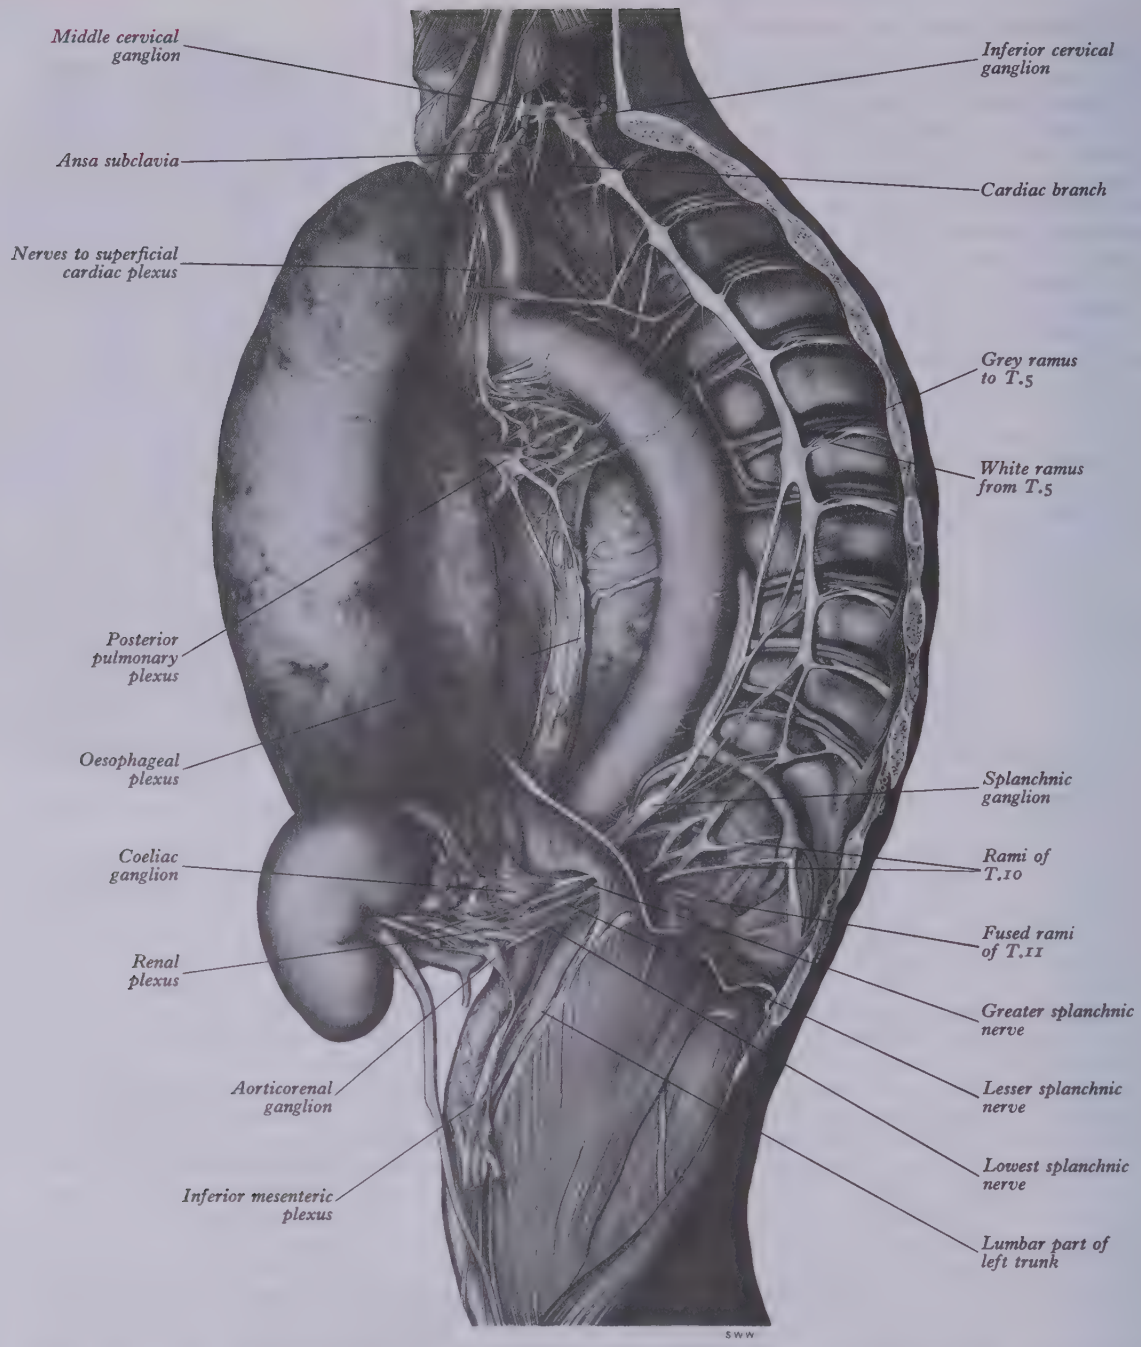
The *grey rami communicantes* to the seventh cervical spinal nerve vary from one to five; two, the usual number, are shown in 7.272, 273. A third often ascends medial to the vertebral artery in front of the seventh cervical transverse process, connects with the seventh cervical nerve and sends a filament upwards through the sixth cervical transverse foramen in company with the vertebral vessels to join the sixth cervical spinal nerve as it emerges from the intervertebral foramen. An inconstant ramus may traverse the seventh cervical transverse foramen. Grey rami to the eighth cervical spinal nerve vary from three to six in number.

The *cardiac branch* descends behind the subclavian artery and along the front of the trachea to the deep cardiac plexus. Behind the artery it connects with the recurrent laryngeal nerve and the cardiac branch of the middle cervical ganglion, the latter often being replaced by fine branches of the cervicothoracic ganglion and ansa subclavia.

Branches to blood vessels form plexuses on the subclavian artery and its branches. The subclavian supply is derived from the cervicothoracic ganglion and ansa subclavia, extending to the first part of the axillary artery; a few fibres may extend further. According to Pearson & Sauter (1971) an extension of the subclavian plexus to the internal thoracic artery is joined by a branch of the phrenic nerve (p. 1128). The vertebral plexus is derived mainly from a large branch of the cervicothoracic ganglion which ascends behind the vertebral artery to the sixth transverse foramen, reinforced by branches of the vertebral ganglion or the cervical sympathetic trunk which pass cranially on the ventral aspect of the artery; from this plexus *deep rami communicantes* join the ventral rami of the upper five or six cervical spinal nerves. The plexus contains some neuronal cell bodies and continues into the skull along the vertebral and basilar arteries and their branches as far as the posterior cerebral artery, where it meets a plexus from the internal carotid. Some consider the vertebral plexus to be the main intracranial extension of the sympathetic system (Lazorthes 1949, Mitchell 1952). The plexus on the inferior thyroid artery reaches the thyroid gland, connecting with recurrent and external laryngeal nerves, the cardiac branch of the superior cervical ganglion, and the common carotid plexus.

The preganglionic fibres for the head and neck emerge from the spinal cord in the upper five thoracic spinal nerves (mainly the upper three), ascending in the sympathetic trunk to synapse in the cervical ganglia. The preganglionic fibres supplying the upper limb stem from upper thoracic segments, probably T2–6 (or 7), ascending via the sympathetic trunk to synapse mainly in its cervicothoracic ganglion, whence postganglionic fibres pass to the brachial plexus (mainly its lower trunk). Most of the vasoconstrictor fibres for the upper limb emerge in the second and third thoracic ventral roots; the arteries can thus be denervated by cutting the sympathetic trunk below the third thoracic ganglion, severing the rami communicantes connected with the second and third thoracic ganglia or by cutting the ventral roots of the second and third thoracic spinal nerves (intradurally). The white ramus to the cervicothoracic ganglion is not cut, partly because it does not convey many vasomotor or sudomotor fibres to the upper limb but mainly because it contains most of the preganglionic fibres; these ascend the trunk to the superior cervical ganglion, from which postganglionic branches supply vasoconstrictor and sudomotor nerves to the face and neck, secretory fibres to the salivary glands, dilatator pupillae (and probably ciliaris oculi), non-striated muscle in the eyelids and the orbitalis. Destruction

7.273 Anterior view of the same structures illustrated in 7.272. Part of the vertebral artery has been excised to show the inferior cervical ganglion.



of this nerve would thus lead to meiosis, ptosis, enophthalmos and loss of sweating on the face and neck (*Horner's syndrome*) and possibly some disturbance of accommodation. For a review consult Haxton (1954).

Blood vessels of the upper limb beyond the first part of the axillary artery receive their sympathetic supply via branches of the brachial plexus adjacent to them, e.g. the median nerve supplies branches to the brachial artery and palmar arches, the ulnar nerve supplies the ulnar artery and palmar arches and the radial nerve supplies the radial artery.

The first and second (and occasionally the third) intercostal nerves may be interconnected anterior to the necks of the ribs by filaments containing postganglionic fibres from their grey rami; these fibres provide another path by which postganglionic nerves can pass from the upper thoracic ganglia to the brachial plexus.

THORACIC PART OF THE SYMPATHETIC SYSTEM

The thoracic sympathetic trunk (7.270, 274) contains ganglia almost equal in number to those of the thoracic spinal nerves (11 in more than 70%, occasionally 12, rarely 10 or 13). The first thoracic ganglion is usually fused with the inferior cervical, forming the cervicothoracic ganglion; Jit & Mukerjee (1960) found a fused ganglion in 80 out of 100 dissections. Rarely the middle cervical or second thoracic ganglion may be included. The succeeding ganglion is counted as the second in order to make the other ganglia correspond numerically with other segmental structures. Except for the lowest two or three, the thoracic ganglia lie against the costal heads, posterior to the costal pleura; the lowest two or three are lateral to the bodies of the corresponding vertebrae. Caudally, the thoracic sympathetic trunk passes dorsal to the medial arcuate ligament (or through the crus of the diaphragm) to become the lumbar sympathetic trunk. The ganglia are small and interconnected by intervening segments of the trunk. Two or more rami communicantes, white and grey, connect each ganglion with its corresponding spinal nerve, white rami joining the nerve distal to the grey. Sometimes a grey and a white ramus fuse to form a 'mixed' ramus (p. 1156).

7.274 The thoracic part of the sympathetic system of the left side. Drawn from a dissection by the late G D Channell, Guy's Hospital Medical School, London. Note that the diaphragm has been divided to its posterior attachment and the left lung and the left kidney have been drawn forwards and rotated to the right, so as to expose the posterior surface of the left kidney and suprarenal gland.

The *medial branches from the upper five ganglia* are very small, supplying filaments to the thoracic aorta and its branches. On the aorta they form a fine *thoracic aortic plexus* with filaments from the greater splanchnic nerve. Rami of the second to fifth or sixth ganglia enter the posterior pulmonary plexus; others, from the second to fifth ganglia, pass to the deep (dorsal) part of the cardiac plexus. Small branches of these pulmonary and cardiac nerves pass to the oesophagus and trachea. The *medial branches from the lower seven ganglia* are large, supplying the aorta and uniting to form the greater, lesser and lowest splanchnic nerves, the last not always being identifiable.

The *greater splanchnic nerve*, consisting mainly of myelinated preganglionic efferent and visceral afferent fibres, is formed by branches from the fifth to ninth or tenth thoracic ganglia; but fibres in the upper branches may be traced to the first or second thoracic ganglion. Its roots vary from one to eight, four being the most usual number. It descends obliquely on the vertebral bodies, supplies branches to the descending thoracic aorta and perforates the ipsilateral crus of the diaphragm to end mainly in the coeliac ganglion but partly in the aorticorenal ganglion and suprarenal gland. A *splanchnic ganglion* exists on the nerve opposite the eleventh or twelfth thoracic vertebra in 17–68% of *dissections* (Jit & Mukerjee 1960); but Mitchell (1953) reported microscopic evidence that it is always present.

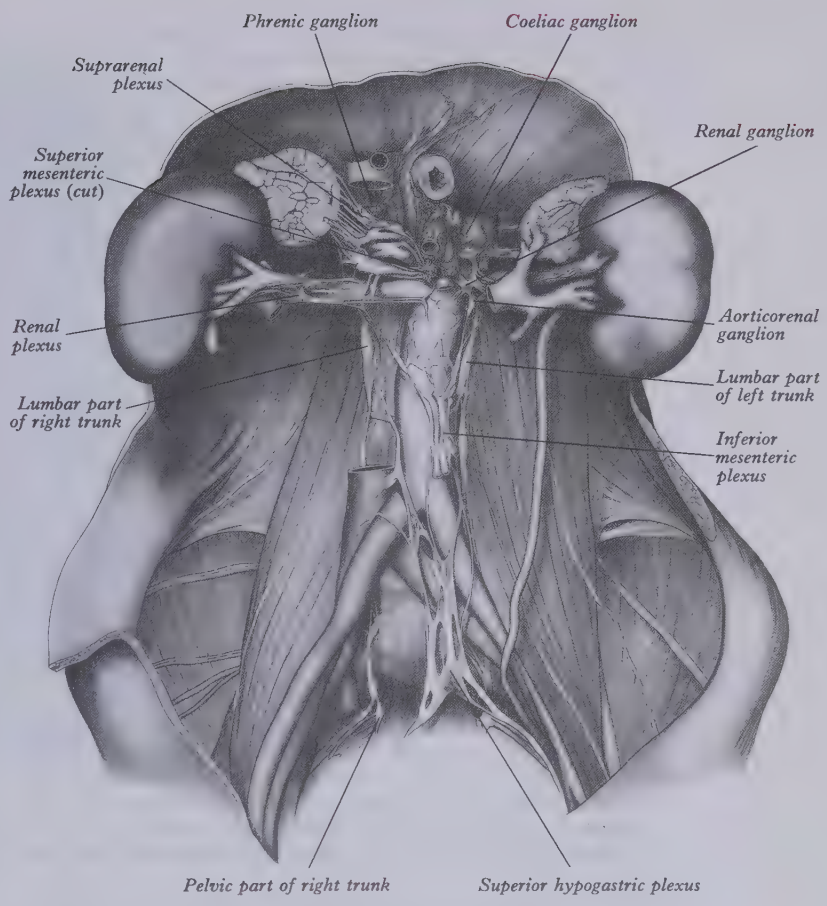
The *lesser splanchnic nerve*, formed by rami of the ninth and tenth (sometimes the tenth and eleventh) thoracic ganglia and the trunk between them, pierces the diaphragm with the greater splanchnic to join the aorticorenal ganglion.

The *lowest (least) splanchnic nerve* (or renal nerve) from the lowest thoracic ganglion enters the abdomen with the sympathetic trunk to end in the renal plexus.

Jit & Mukerjee (1960) described in great detail dissections of the thoracic sympathetic nerves in 50 cadavers and surveyed the previous findings. The incidence of the splanchnic nerves, according to seven observers, is as follows: greater—always present, lesser—94% (86–100%), least—56% (16–98%). A fourth (accessory) splanchnic nerve has been described by de Sousa (1955) but has not been confirmed.

LUMBAR PART OF THE SYMPATHETIC SYSTEM

The lumbar part of each sympathetic trunk (7.274, 275), usually containing four interconnected ganglia, runs in the extraperitoneal connective tissue anterior to the vertebral column and along the medial margin of the psoas major. Superiorly it is continuous with the thoracic trunk posterior to the medial arcuate ligament; inferiorly, passing posterior to the common iliac artery, it becomes the pelvic trunk. On the right side it is overlapped by the inferior vena cava and on the left by the lateral aortic lymph nodes. It is anterior to most of the lumbar vessels but may pass behind some lumbar veins.



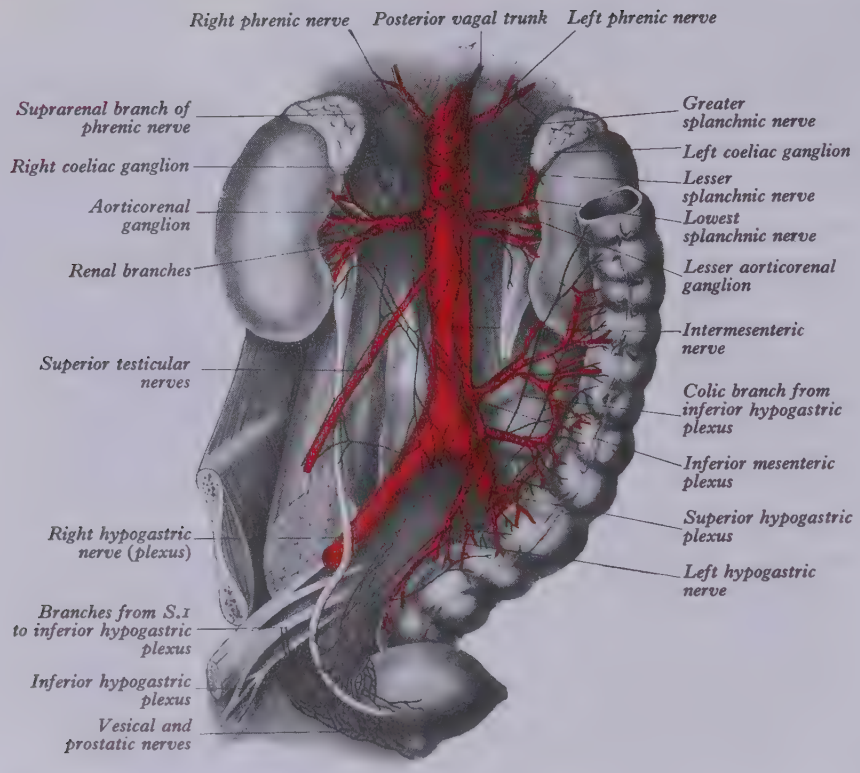
The first, second and sometimes third lumbar ventral spinal rami send *white rami communicantes* to the corresponding ganglia. *Grey rami communicantes*, passing from all ganglia to the lumbar spinal nerves, are long and accompany the lumbar arteries round the sides of the vertebral bodies, medial to the fibrous arches to which the psoas major is attached.

Usually four *lumbar splanchnic nerves* pass from the ganglia to join the coeliac, intermesenteric (abdominal aortic) and superior hypogastric plexuses. The first lumbar splanchnic nerve, from the first ganglion, joins the coeliac, renal and intermesenteric plexuses. The second nerve, from the second and sometimes the third ganglion, joins the inferior part of the intermesenteric plexus; the third nerve issues from the third or fourth ganglion, passing anterior to the common iliac vessels to join the superior hypogastric plexus. The fourth lumbar splanchnic, from the lowest ganglion, passes dorsal to the common iliac vessels to join the lower part of the superior hypogastric plexus or the hypogastric 'nerve'.

Vascular branches from all lumbar ganglia join the intermesenteric (aortic) plexus. Fibres of the lower lumbar splanchnic nerves pass to the common iliac arteries, forming a plexus continued along the internal and external iliac arteries as far as the proximal part of the femoral artery. Many postganglionic fibres in the grey rami, connecting the lumbar ganglia to the spinal nerves, travel in the femoral nerve to its muscular, cutaneous and saphenous branches, supplying vasoconstrictor nerves to the femoral artery and its branches in the thigh. Other postganglionic fibres travel via the obturator nerve to the obturator artery. Considerable uncertainties persist regarding sympathetic supplies to the lower limb (Wilde 1951, Wyburn 1956, Pick 1970).

PELVIC PART OF THE SYMPATHETIC SYSTEM

The pelvic sympathetic trunk (7.275) lies in the extraperitoneal tissue anterior to the sacrum, medial or anterior to the anterior sacral foramina, and has four or five interconnected ganglia. Above it continues into the lumbar trunk; below, the two trunks converge to unite in the small *ganglion impar* anterior to the coccyx. *Grey rami communicantes* pass from the ganglia to sacral and coccygeal spinal nerves but white rami communicantes are absent. *Medial branches of distribution* connect across the midline; twigs from the first two ganglia join the inferior hypogastric plexus (pelvic plexus) or the hypogastric 'nerve'; others form a plexus on the median sacral artery. The glomus coccygeum is supplied from the loop between the two trunks. The hypogastric 'nerve', which is usually plexiform, is a redundant term for the right and left connections, between the superior and inferior hypogastric plexuses (p. 1166).



7.275 The abdominal part of the sympathetic system (drawn from a dissection by the late G D Channell, Guy's Hospital Medical School, London).

Vascular branches. Through the grey rami many postganglionic fibres pass to the roots of the sacral plexus, especially those forming the tibial nerve, to be conveyed to the popliteal artery and its branches in the leg and foot. Others are carried in the pudendal and superior and inferior gluteal nerves to the accompanying arteries. Branches to lymph nodes are also described (Woźniak 1967).

Preganglionic fibres for the lower limb are derived from the lower three thoracic and upper two or three lumbar spinal segments. They reach the lower thoracic and upper lumbar ganglia through white rami; some descend through the sympathetic trunk to synapse in the lumbar ganglia, whence postganglionic fibres join the femoral nerve to supply the femoral artery and its branches; other fibres descend to synapse in the upper two or three sacral ganglia, from which postganglionic axons join the tibial nerve to supply the popliteal artery and its branches in the leg and foot. Sympathetic denervation of vessels in the lower limb can thus be effected by removing the upper three lumbar ganglia and the intervening parts of the sympathetic trunk, all the preganglionic fibres to the lower limb thus being divided.

PLEXUSES OF THE AUTONOMIC NERVOUS SYSTEM

The larger autonomic plexuses are aggregations of nerves and ganglia situated in the thoracic, abdominal and pelvic cavities. They are the cardiac, pulmonary, coeliac and hypogastric plexuses, supplying the thoracic, abdominal and pelvic viscera. Extensions of these major plexuses pass along most branches of the large vessels which they surround and are usually named after the artery along which they are distributed. This leads to a plethora of named plexuses, often separately described in detail which may overshadow their essential continuity.

7.276 Autonomic nerves and plexuses in the abdomen and pelvis (after Mitchell 1953, by courtesy of the author and the publishers). Note the ascending branches of the inferior hypogastric plexus passing up to supply the descending colon. The sympathetic trunks are not shown on the right side; note the upper, middle and lower ureteric nerves.

CARDIAC PLEXUSES

The cardiac plexus (7.270, 274) at the base of the heart is divided into *superficial* (ventral) and *deep* (dorsal) *parts* which are closely connected. Several small ganglia lie within it, the most constant being the *cardiac ganglion* described below. Mizeres (1963) has emphasized the unity of the cardiac plexus, considering its division into two parts as an artefact of dissection; he was, however, prepared to allow regional names for its coronary, pulmonary, atrial and aortic extensions. Since major concentrations of the plexus are situated as described here, the terms superficial and deep have been retained.

The superficial (ventral) part of the cardiac plexus lies below the aortic arch and anterior to the right pulmonary artery. It is formed by the cardiac branch of the left superior cervical sympathetic ganglion and the lower of the two cervical cardiac branches of the left vagus. A small *cardiac ganglion* is usually present in this plexus immediately below the aortic arch, to the right of the ligamentum arteriosum. This part of the cardiac plexus connects with (1) the deep part, (2) the right coronary plexus, (3) the left anterior pulmonary plexus.

The deep (dorsal) part of the cardiac plexus is anterior to the tracheal bifurcation, above the point of division of the pulmonary trunk and posterior to the aortic arch. It is formed by the cardiac branches of the cervical and upper thoracic sympathetic ganglia and of the vagus and recurrent laryngeal nerves. The only cardiac nerves which do not join it are those joining the superficial part of the plexus.

Branches from the *right half* of the deep part of the cardiac plexus pass in front of and behind the right pulmonary artery; those anterior to it, the more numerous, supply a few filaments to the right anterior pulmonary plexus and continue on to form part of the right coronary plexus; those behind the pulmonary artery supply a few filaments to the right atrium and then continue into the left coronary plexus. The *left half* of the deep part of the cardiac plexus is connected with the superficial, supplying filaments to the left atrium and left anterior pulmonary plexus and then continuing to form much of the left coronary plexus.

The left coronary plexus, larger than the right, is formed chiefly by the prolongation of the left half of the deep part of the cardiac plexus and a few fibres from the right; it accompanies the left coronary artery to supply the left atrium and ventricle.

The right coronary plexus, formed from both superficial and deep parts of the cardiac plexus, accompanies the right coronary artery to supply the right atrium and ventricle.

The atrial plexuses, described by Mizeres (1963), are derivatives of the right and left continuations of the cardiac plexus along the coronary arteries. Their fibres are distributed to the corresponding atria, overlapping those from the coronary plexuses.

All the cardiac branches of the vagus and sympathetic contain both afferent and efferent fibres, except the cardiac branch of the superior cervical sympathetic ganglion, which is purely efferent. The *efferent* preganglionic cardiac *sympathetic* fibres arise in the upper four or five thoracic spinal segments; they pass by white rami communicantes to synapse in the upper thoracic sympathetic ganglia, though many ascend to synapse in the cervical ganglia. Postganglionic fibres from the thoracic and cervical ganglia form the sympathetic cardiac nerves, which accelerate the heart and dilate the coronary arteries. Of the sympathetic fibres from the first four or five spinal segments, the upper pass to the ascending aorta, pulmonary trunk and ventricles, the lower to the atria.

The *efferent* cardiac *parasympathetic* fibres from the dorsal vagal nucleus and neurons near the nucleus ambiguus run in vagal cardiac branches to synapse in the cardiac plexuses and atrial walls. These vagal fibres slow the heart and cause constriction of the coronary arteries (p. 723). In man (like most mammals) intrinsic cardiac neurons are limited to the atria and interatrial septum (Davies et al 1952, King & Coakley 1958); they are most numerous in the subepicardial connective tissue (**6.57**) near the sinuatrial and atrioventricular nodes. For variations in human sympathetic cardiac innervation consult Ellison & Williams (1969).

PULMONARY PLEXUSES

These are anterior and posterior to the other hilar structures of the lungs, the anterior plexus being much smaller. According to Mizeres (1963) they are extensions from the cardiac plexus along the right and left pulmonary arteries. They are formed by vagal and sympathetic branches. Efferent parasympathetic fibres arise from the dorsal vagal nucleus; efferent sympathetic fibres are postganglionic branches of the second to fifth thoracic sympathetic ganglia.

The *anterior pulmonary plexus* is formed by rami from vagal and cervical sympathetic cardiac nerves as well as direct branches from both sources; the *posterior pulmonary plexus* is formed by the rami of vagal cardiac branches from the second to fifth or sixth thoracic sympathetic ganglia, the left plexus also receiving branches from the left recurrent laryngeal nerve. The two plexuses are interconnected; from them nerves enter the lung as networks along branches of the bronchi and pulmonary and bronchial vessels extending as far as the visceral pleura. Near the hila they contain minute groups of postganglionic neurons, with which efferent vagal preganglionic fibres synapse. In the small intestine *interstitial cells* have been described in terminal autonomic networks, but have not been seen in thoracic organs, apart perhaps from the oesophagus (Dijkstra 1969). Efferent vagal fibres are bronchoconstrictor, secretomotor to bronchial glands and vasodilator. Efferent sympathetic fibres are bronchodilator and vasoconstrictor.

COELIAC PLEXUS

The coeliac (7.270, 275), the largest major autonomic plexus, sited at the level of the last thoracic and first lumbar vertebrae, is a dense network uniting two large *coeliac ganglia*. It surrounds the coeliac artery and the root of the superior mesenteric artery. It is posterior to the stomach and omental bursa, anterior to the crura of the diaphragm and the commencement of the abdominal aorta and between the suprarenal glands. The plexus and ganglia are joined by the greater and lesser splanchnic nerves of both sides and branches from both the vagus and phrenic nerves. They extend as numerous secondary plexuses along adjacent arteries.

The *coeliac ganglia* are irregular masses, one on each side, between the suprarenal gland and the coeliac origin and in front of the crura; the right one is behind the inferior vena cava, the left behind the splenic vessels. The upper part of each is joined by a greater splanchnic nerve; the lower part, more or less detached as the *aorticorenal* ganglion, receives the lesser splanchnic nerve and forms most of the renal plexus; its position is variable but near the origin of the renal artery from the aorta. (For details consult Norvell 1968.) Secondary plexuses from or connected with the coeliac are: the phrenic, splenic, hepatic, left gastric, intermesenteric, suprarenal, renal, testicular or ovarian, superior mesenteric and inferior mesenteric.

The phrenic plexus accompanies the inferior phrenic artery to the diaphragm, with branches to the suprarenal gland. It arises near the upper end of the coeliac ganglion and is larger on the right. It receives one or two phrenic branches. At the junction of the right phrenic plexus with the phrenic nerve is a small *phrenic ganglion*, distributing branches to the inferior vena cava, suprarenal and hepatic plexuses.

The hepatic plexus, the largest coeliac derivative, also receives filaments from the left and right vagi and right phrenic nerve. It accompanies the hepatic artery and portal vein and their branches into the liver, where its fibres are confined to the vicinity of the blood vessels. It follows all branches of the hepatic artery. Branches to the gallbladder form a thin *cystic plexus*; bile ducts are also supplied. Branches accompanying the right gastric artery supply the pylorus. From the gastroduodenal extension of the plexus branches reach the pylorus and the first part of the duodenum. Many follow the right gastro-epiploic artery to supply the right side of the stomach and the greater curvature. The superior pancreaticoduodenal extension of the plexus supplies the duodenum's descending part, the pancreatic head and the lower part of the bile duct. The hepatic plexus contains afferent and efferent sympathetic and parasympathetic fibres; the vagal constituents are said to be motor to the musculature of the gallbladder and bile ducts and inhibitory to the sphincter of the bile duct. Petkov (1968) identified a distinct nerve to the sphincter in 23 out of 25 human dissections.

The left gastric plexus accompanies its artery along the lesser curvature of the stomach, joining with the vagal gastric branches. Gastric sympathetic nerves are motor to the pyloric sphincter but inhibitory to the gastric mural musculature.

The splenic plexus, formed by branches of the coeliac plexus, left coeliac ganglion and right vagus, accompanies its artery to the spleen, giving off subsidiary plexuses along arterial branches. The fibres are mainly, perhaps wholly, sympathetic and terminate in blood vessels and non-striated muscle of the splenic capsule and trabeculae.

The suprarenal plexus is formed by branches from the coeliac ganglion and plexus and greater splanchnic nerve. Relative to its size, the suprarenal gland has a larger autonomic supply than any other organ. Its fibres are commonly described as myelinated and preganglionic. In rats, however, non-myelinated fibres are ten times as numerous and are considered preganglionic; they end in synapses, often deeply invaginated, with large chromaffin cells, the phaeochromocytes, which are thus homologous with the postganglionic sympathetic neurons (p. 1469). A space of 150–200 nm separates the synaptic membranes, which often have electron-dense zones. Small and large vesicles with electron-dense granular contents occur in these endings. Only non-myelinated fibres appear to innervate chromaffin cells, all of which are related to one or more such terminals. Multipolar neurons also occur in the adrenal medulla; some preganglionic non-myelinated fibres form axodendritic synapses with them. The destination of their axons is not known (Coupland 1965a). A preponderance of non-myelinated fibres has also been described in the human suprarenal plexus (Coupland 1965a,b, Grottel 1968).

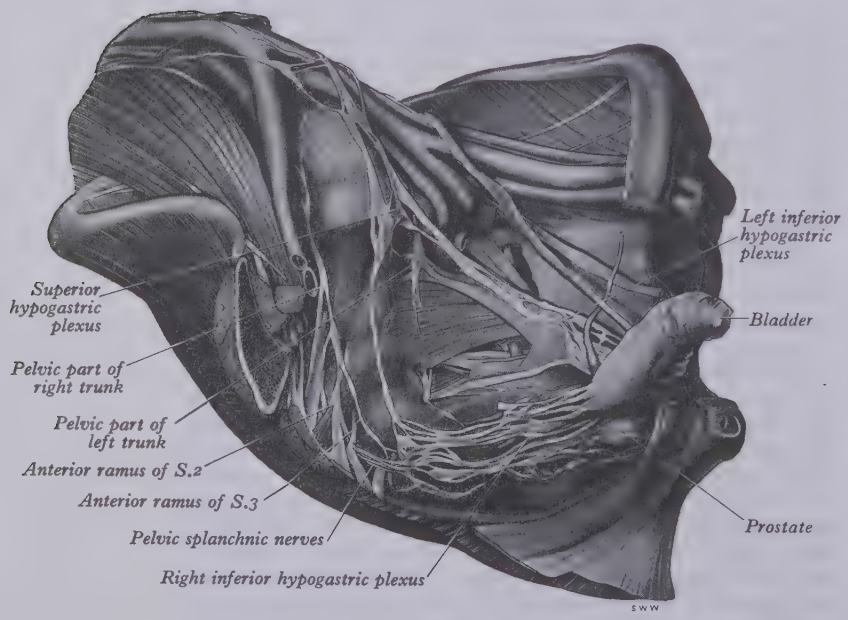
The renal plexus is dense and formed by rami from the coeliac ganglion and plexus, aorticorenal ganglion, lowest thoracic splanchnic nerve, first lumbar splanchnic nerve and aortic plexus. Small ganglia occur in the renal plexus, the largest usually behind the start of the renal artery. The plexus continues into the kidney around the arterial branches to supply the vessels, renal glomeruli, and tubules, especially the cortical tubules (Norvell 1968). Renal nerves are mostly vasomotor. From the renal plexus branches supply ureteric and testicular (or ovarian) plexuses. The *ureteric plexus* receives, in its upper part, branches from the renal and aortic plexuses, in its intermediate part from the superior hypogastric plexus and hypogastric nerve and in its lower part from the hypogastric nerve and inferior hypogastric plexus. This supply influences the inherent motility of the ureter.

The testicular plexus accompanies the gonadal artery to the testis. Its upper part receives branches from the renal and aortic plexuses. Distally it is reinforced from the superior and inferior hypogastric plexuses. Its rami pass to the epididymis and ductus deferens.

The ovarian plexus accompanies the ovarian artery to the ovary and uterine tube. The upper part is formed by branches from the renal and aortic plexuses; its lower part is reinforced from the superior and inferior hypogastric plexuses.

The nerves in the testicular and ovarian plexuses contain efferent and afferent sympathetic fibres; the efferents are vasomotor and derived from the tenth and eleventh thoracic spinal segments; the parasympathetic fibres, from the inferior hypogastric plexuses, are probably vasodilator.

The superior mesenteric plexus, a downward continuation of the coeliac, receives a branch from the junction of the right vagus and coeliac plexus. It accompanies the superior mesenteric artery into the mesentery, dividing into secondary plexuses distributed to parts supplied by the artery: pancreatic, jejunal and ileal, ileocolic, right colic and middle colic. The *superior mesenteric ganglion* lies superior in the plexus, usually above the superior mesenteric artery's origin. Intestinal sympathetic nerves are motor to the ileocaecal sphincter but inhibitory to the mural musculature; some are vasoconstrictor.



The abdominal aortic plexus (intermesenteric plexus) is formed by branches from the coeliac plexus and ganglia and

receives rami from the first and second lumbar splanchnic nerves. It is on the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. It consists of four to 12 intermesenteric nerves, connected by oblique branches. It is continuous above with the coeliac plexus and coeliac and aorticorenal ganglia, below with the superior hypogastric plexus. From it parts of testicular, inferior mesenteric, iliac and superior hypogastric plexuses arise; it also supplies the inferior vena cava.

The inferior mesenteric plexus, chiefly from the aortic plexus but also from the second and third lumbar splanchnic nerves, surrounds the inferior mesenteric artery and is distributed along its branches; thus a left colic plexus supplies the transverse colon's left part, the descending and the sigmoid colon; a superior rectal plexus supplies the rectum. Near the origin of the inferior mesenteric artery an *inferior mesenteric ganglion* may occur but more often small ganglia are scattered around the origin of the artery in the proximal part of the plexus. In one study (Southam 1959) an inferior mesenteric ganglion occurred in all of 22 human stillborn infants. The colic sympathetic nerves are inhibitory to mural muscle in the colon and rectum. Branches from parasympathetic pelvic splanchnic nerves ascend occasionally through but usually near the superior hypogastric and inferior mesenteric plexuses to supply the large intestine from the left half of the transverse colon to the rectum (p. 1375 and vide infra); they are motor to the colic musculature. It is to be emphasized that the parasympathetic supply to the distal colon is largely by these direct branches of the pelvic splanchnic nerves, *not* via the hypogastric and inferior mesenteric plexuses (Mitchell 1935, Woodburne 1956).

SUPERIOR HYPOGASTRIC PLEXUS

The superior hypogastric plexus (7.275–277) is anterior to the aortic bifurcation, the left common iliac vein, median sacral vessels, fifth lumbar vertebral body and sacral promontory and between the common iliac arteries. Often termed the *presacral nerve*, it is seldom a single nerve and is prelumbar rather than presacral. It lies in extraperitoneal connective tissue; the parietal peritoneum can easily be stripped off its anterior aspect. It varies in breadth and condensation of its constituent nerves and is often a little to one side of the midline (more often to the left); the attachment of the sigmoid mesocolon, containing superior rectal vessels, is to the left of the lower part of the plexus. Scattered neurons occur in it. The plexus is formed by branches from the aortic plexus and third and fourth lumbar splanchnic nerves. It divides into right and left hypogastric 'nerves' which descend to the two inferior hypogastric plexuses. The superior plexus supplies branches to the ureteric, testicular, ovarian and common iliac plexuses. In addition to sympathetic fibres, it may also contain parasympathetic fibres (from pelvic splanchnic nerves) which ascend from the inferior hypogastric plexus; but these fibres usually ascend to the left of the superior hypogastric plexus and across the sigmoid branches of left colic vessels. These parasympathetic fibres are distributed partly along the inferior mesenteric arterial branches and also as independent retroperitoneal nerves, to supply the left part of the transverse colon, left colic flexure, descending and sigmoid colon (p. 1156 and 7.275).

7.277 The pelvic part of the sympathetic system, viewed from in front and from the right side, a large part of the right hip bone having been removed. The superior hypogastric plexus is seen to divide below into the right and left hypogastric nerves (which are not labelled), which run down to the inferior hypogastric plexuses. Drawn from a dissection by the late G D Channell, Guy's Hospital Medical School, London.

INFERIOR HYPOGASTRIC PLEXUSES

The *superior hypogastric plexus* divides caudally into right and left *hypogastric 'nerves'*, each descending in extraperitoneal connective tissue into the pelvis, medial to each internal iliac artery and its branches to become the *inferior hypogastric plexus* (7.277). Each nerve may be single or an elongated plexus of anastomosing filaments. (Hypogastric nerves can scarcely be distinguished from their continuations, the inferior hypogastric plexuses. The latter are joined by pelvic splanchnic nerves, a distinction minimized by the fact that both nerves and plexuses contain sympathetic and parasympatheric fibres. Some authorities prefer to describe a superior hypogastric plexus dividing into two inferior plexuses.) From each hypogastric nerve branches may pass to the testicular, ovarian and ureteric plexus or to the internal iliac plexuses and to the sigmoid colon; each nerve may be joined initially by the lowest lumbar splanchnic nerve from last lumbar sympathetic ganglion.

The inferior hypogastric (pelvic) plexus is in the extraperitoneal connective tissue. In males it is lateral to: the rectum, seminal vesicle, prostate and the posterior part of the urinary bladder; in females each plexus is lateral to: the rectum, uterine cervix, vaginal fornix and the posterior part of the urinary bladder, extending into the broad uterine ligament. Lateral to it are the internal iliac vessels and their branches and tributaries, the levator ani, coccygeus and obturator internus. Posterior are the sacral and coccygeal plexuses and above are the superior vesical and obliterated umbilical arteries. The plexuses contain numerous small ganglia. Each is formed by a hypogastric nerve, conveying most of the sympathetic fibres of the plexus, the remaining few arriving via branches from the ganglia. Parasympathetic fibres are derived from pelvic splanchnic nerves. Preganglionic efferent sympathetic fibres originate in the lower three thoracic and upper two lumbar spinal segments, some relaying in ganglia of the lumbar and sacral parts of the sympathetic trunk, others synapsing in the lower part of the aortic plexus and in the superior and inferior hypogastric plexuses. Preganglionic parasympathetic fibres originate in the second to fourth sacral spinal segments, reach the plexus in the pelvic splanchnic nerves and synapse in it or in walls of viscera supplied by its branches. Numerous branches are distributed to the pelvic and some abdominal viscera, either directly or along their arteries.

Parasympathetic fibres ascend in the hypogastric plexuses or as separate filaments to reach the inferior mesenteric plexus by way of the aortic plexus. By this route the descending and sigmoid parts of the colon receive parasympathetic innervation.

The middle rectal plexus, formed by fibres from the upper part of the inferior hypogastric plexus to the rectum passing directly or along the middle rectal artery, connects above with the superior rectal plexus and extends below to the internal anal sphincter. The rectal and anal nerve supply is from: (1) the superior rectal plexus, (2) the middle rectal plexus and (3) the inferior rectal (haemorrhoidal) nerves, branches of the pudendal nerve. The parasympathetic preganglionic fibres from the rectal plexuses synapse with postganglionic neurons in the well-developed myenteric plexus, while sympathetic afferents pass through it without interruption. Efferent sympathetic fibres in

the rectal plexuses inhibit the expulsive musculature and stimulate the sphincter. Pain impulses traverse the sympathetic and parasympathetic fibres but the parasympathetic afferent and efferent fibres are more active in normal defaecation. Inferior rectal nerves supply motor fibres to the striated external anal sphincter and sensory (somatic) fibres to the lower (ectodermal) part of the anal canal (p. 233).

The vesical plexus, from the anterior part of the inferior hypogastric plexus, comprises many filaments which pass along vesical arteries to the bladder. Branches supply the seminal vesicles and deferent ducts. Many small groups of neurons exist among the nerve fibres in the vesical muscular wall. Sympathetic preganglionic fibres in the plexus are from the lower two thoracic and upper two lumbar spinal segments, synapsing with neurons scattered in the superior and inferior hypogastric plexuses and vesical wall. The parasympathetic preganglionic efferent fibres come from the second to fourth sacral spinal segments and synapse near or in the vesical wall with postganglionic neurons which stimulate its detrusor muscle and inhibit its sphincter. Efferent sympathetic nerves are motor to the sphincter and inhibitor to the detrusor muscle; but some maintain that they are mainly vasomotor and that vesical filling and emptying are controlled by parasympathetic nerves.

The prostatic plexus, continued from the lower part of the inferior hypogastric plexus, is composed of large nerves entering the base and sides of the prostate and contains neurons. It supplies: the prostate, seminal vesicles, prostatic urethra, ejaculatory ducts, corpora cavernosa, corpus spongiosum, membranous and penile urethra and bulbo-urethral glands. The nerves to the corpora cavernosa form two sets, the lesser and greater cavernous nerves, arising from the front of the plexus to join branches from the pudendal nerve and then passing forwards below the pubic arch. The precise localization of the autonomic nerves from the pelvic plexus to the corpora cavernosa has been described by Lepor et al (1985) in the adult male pelvis. *Lesser cavernous nerves* pierce the fibrous penile sheath proximally to supply the erectile tissue of the corpus spongiosum and penile urethra. *Greater cavernous nerves* proceed on the dorsum penis, connect with the dorsal nerve and supply the erectile tissue, some filaments reaching the erectile tissue of the corpus spongiosum. Sympathetic supplies to the male genital organs produce vasoconstriction, the parasympathetic being vasodilator. Seminal vesicles are supplied from the vesical and prostatic plexuses and inferior hypogastric nerves; extensions pass to the ejaculatory and deferent ducts. Contraction of the seminal vesicles and ejaculation are considered to be due to the sympathetic supply, which also inhibits the vesical musculature and stimulates the sphincter during ejaculation, preventing reflux into the bladder. Others have suggested that contraction of the seminal vesicles is under parasympathetic control (Matthews & Raisman 1969).

Uterine nerves arise from the inferior hypogastric plexus, mainly the part in the broad ligament, the **uterovaginal plexus**, from which branches descend with the vaginal arteries, while others pass directly to the cervix uteri or ascend with or near uterine arteries in the broad ligament. Nerves to the cervix form a plexus in which are small *paracervical* ganglia, one ganglion sometimes being larger and termed the *uterine cervical ganglion*. Nerves ascending with the uterine arteries supply the uterine body and tube, connecting with *tubal nerves* from the inferior hypogastric plexus and with the ovarian plexus. The uterine nerves ramify in the myometrium and endometrium, generally accompanying the vessels. Efferent preganglionic sympathetic fibres are from the last thoracic and first lumbar spinal segments; the sites of their postganglionic neurons are unknown. Preganglionic parasympathetic fibres arise in the second to fourth sacral spinal segments and relay in the paracervical ganglia. Sympathetic activity may produce uterine contraction and vasoconstriction and parasympathetic activity may produce uterine inhibition and vasodilatation, but these activities are complicated by hormonal control of uterine functions.

Vaginal nerves from the lower parts of the inferior hypogastric and uterovaginal plexuses follow the vaginal arteries to supply the vaginal walls, the erectile tissue of the vestibular bulbs and clitoris (cavernous nerves of the clitoris), the urethra and the greater vestibular glands. The nerves contain many parasympathetic fibres which are vasodilator to the erectile tissue.

Afferent Autonomic Pathways

Efferent autonomic fibres to the viscera and blood vessels are accompanied by their sensory counterparts, the *general visceral afferent* or *autonomic afferent* fibres. These are the peripheral processes of unipolar neurons in some cranial and spinal ganglia. Their central axons enter the central nervous system in the nerves concerned; their peripheral dendrites, myelinated or non-myelinated fibres of varying calibre, are distributed with pre- and postganglionic fibres of both autonomic divisions but do not synapse in their ganglia. Their terminals are described as knobs, loops, rings, tendrils and more elaborate encapsulated endings in the visceral and vascular walls, including the epithelia and serosae. Afferent impulses conducted by these neurons evoke visceral reflexes but usually do not obtrude on consciousness. They also probably mediate organic visceral sensations such as hunger, nausea, sexual excitement, vesical distension, etc. and visceral pain fibres may follow these routes. Although viscera are insensitive to cutting, crushing or burning, excessive tension in non-striated muscle and some pathological conditions produce visceral pain. It is not always easy to distinguish between what is pathological and mere exaggeration of normal activity. 'Abdominal' pain due to strong intestinal contraction is commonplace. In visceral disease vague pain may be felt near the viscus itself (visceral pain) or in a cutaneous area or other tissue whose somatic efferents enter spinal segments receiving afferents from the viscus; this is *referred pain*. If inflammation spreads from a diseased viscus to the adjacent parietal serosa (e.g. the peritoneum), somatic afferents will be stimulated, causing local somatic, commonly spasmodic, pain in this region. Referred pain is often associated with local cutaneous tenderness.

General visceral afferent fibres exist in vagal, glossopharyngeal and possibly other cranial nerves in the second to fourth sacral nerves distributed with pelvic splanchnic nerves and in thoracic and upper lumbar spinal nerves, distributed through rami communicantes and alongside the efferent sympathetic innervation of viscera and blood vessels.

The large vagal general visceral afferent components have their somata in the superior and inferior vagal ganglia, which appear predominantly sensory, despite contrary views regarding the inferior ganglion. Their central processes end in the dorsal vagal nucleus in the medulla oblongata or, according to some, the nucleus solitarius. Their peripheral processes are distributed to terminals in the pharyngeal and oesophageal walls, where with glossopharyngeal visceral afferents in the pharynx, they are concerned in swallowing reflexes. Vagal afferents are also ascribed to the thyroid and parathyroid glands. In the thorax some end in the heart, the walls of the great vessels, the aortic bodies and pressor receptors; in the last they are stimulated by raised intravascular pressure. Some reach the lungs through the pulmonary plexuses, being distributed to: (1) bronchial mucosa, probably involved in cough reflexes, (2) bronchial muscle, where they encircle myocytes and end in tendrils sometimes regarded as 'muscle spindles', believed to be stimulated by change in the length of myocytes, (3) interalveolar connective tissue, where their knob-like endings, together with terminals on myocytes, may evoke Herring–Breuer reflexes, (4) adventitia of pulmonary arteries, where they may be pressor receptors, and the intima of pulmonary veins, where they may be chemoreceptors. Afferent fibres from visceral pleura and bronchi may also travel with the pulmonary sympathetic supply, mediating nociceptive responses.

Vagal visceral afferent fibres also end in the gastric and intestinal walls, in digestive glands, and the kidney. Fibres ending in the gut and its ducts respond to stretch or contraction. Gastric impulses may evoke sensations of hunger and nausea.

Glossopharyngeal general visceral afferents innervate the posterior lingual region, tonsils and pharynx, whose epithelia are endodermal. Innervation of taste buds is not included; these have *special* visceral afferents (p. 1170). Glossopharyngeal afferents also innervate the carotid sinus and body, receptors sensitive to

tension and changes in chemical composition of the blood; impulses from these receptors are essential to circulatory and respiratory reflexes. Somata of the glossopharyngeal general visceral afferents are in the nerve's ganglia, their terminations in the medulla oblongata being probably like those of the vagal visceral afferents.

Sensory fibres in pelvic splanchnic nerves innervate pelvic viscera and the distal part of the colon. Vesical receptors are widespread; those in muscle strata are connected with thickly myelinated fibres reaching the spinal cord via pelvic splanchnic nerves and are believed to be stretch receptors, possibly activated by contraction. Pain fibres from the bladder and proximal urethra traverse both pelvic splanchnic nerves and the inferior hypogastric plexus, hypogastric nerves, superior hypogastric plexus and lumbar splanchnic nerves to reach their somata in ganglia on the lower thoracic and upper lumbar dorsal spinal roots. The significance of this dual sensory pathway is uncertain; lesions of the cauda equina abolish pain from vesical overdistension but hypogastric section is ineffective.

Though the fibres of pelvic splanchnic nerves, possibly afferent, are described in the ovary, no supply from this source to the testis is known.

Pain fibres from the uterine body traverse the hypogastric plexus and lumbar splanchnic nerves to reach somata in the lowest thoracic and upper lumbar spinal ganglia; hypogastric division may relieve dysmenorrhoea. Afferents from the cervix, however, traverse the pelvic splanchnic nerves to somata in the upper sacral spinal ganglia. Stretch of the cervix uteri causes pain but cauterization and biopsy excisions do not.

Afferent fibres accompanying pre- and postganglionic sympathetic fibres have a generally segmental arrangement. They end in spinal cord segments from which preganglionic fibres innervate the region or viscus concerned (vide infra). General visceral afferents entering thoracic and upper lumbar spinal segments are largely concerned with pain. Nociceptive impulses from the pharynx, oesophagus, stomach, intestines, kidney, ureter, gallbladder and bile ducts seem to be carried in sympathetic pathways. Cardiac nociceptive impulses enter the spinal cord via the first to fifth thoracic spinal nerves, carried mainly in the middle and inferior cardiac nerves, but a few pass directly to the spinal nerves. There are no general visceral afferents in the superior cardiac nerves. Peripherally the fibres pass through the cardiac plexuses and along the coronary arteries. Myocardial anoxia may evoke symptoms of angina pectoris in which there is typically presternal pain, pain referred to much of the left chest, radiating to the left shoulder and the left arm's medial aspect, along the left side of the neck to the jaw and occiput and down to the epigastrium; pain may be bilateral or even confined to the right. Cardiac afferents are also carried in vagal cardiac branches and are concerned with the reflex depression of cardiac activity. In some animals (e.g. rabbit) a separate depressor cardiac nerve is a branch of the vagus or superior laryngeal nerve. Human depressor fibres, however, run in branches of the superior or internal laryngeal nerves, cardiac branches of the vagus or the sympathetic. Ureteric pain fibres, also running with sympathetic fibres, are presumably concerned in the agonizing renal colic of obstruction by calculi. Afferent fibres from the testis and ovary run through the corresponding plexuses; their somata are in the tenth and eleventh thoracic dorsal spinal root ganglia.

It must be emphasized that autonomic reflexes are not initiated solely by general visceral afferent pathways, nor do impulses in these necessarily activate general visceral efferents. In most situations demanding general sympathetic activity for effort, the afferent element is usually somatic, either from special senses or the skin. Rises in blood pressure and pupillodilatation may result from the stimulation of somatic receptors in the skin and other tissues. Conversely, contraction of the rectus abdominis, a somatic structure, may result from irritation of abdominal viscera. There is also evidence that axon reflexes may be evoked at the terminals of autonomic postganglionic fibres.

Denervation often has no obvious effect on the effector organs, non-striated muscle or glands innervated by autonomic fibres. Contraction may be unaffected by denervation and no structural changes ensue. This is variously attributed to the continued activity of local plexuses or the intrinsic activity of visceral muscle. The severance of preganglionic efferent fibres may result in the hypersensitivity of postganglionic neurons. Denervation does sometimes result in cessation of activity, e.g. in sweat glands, pilomotor muscle, orbital non-striated muscle and the suprarenal medulla (Pick 1970).

DEGENERATION AND REGENERATION IN AUTONOMIC NERVES

Degeneration in the autonomic nervous system resembles that in cerebrospinal nerves. Some evidence suggests that the rate of degeneration differs in different regions or different types of fibre. Regeneration of preganglionic fibres may vary with the site of lesion and, in postganglionic neurons, regeneration may be followed by reinnervation from neighbouring intact nerve fibres. As far as experimental evidence goes, the integrity of Schwann cell sheaths is essential in the regeneration of autonomic nerve fibres (Evans & Murray 1954, Kapeller & Mayor 1967, Williams 1971, King & Thomas 1971, Landon 1976). Some observations suggest that proximity of myelinated fibres is necessary to regeneration in non-myelinated fibres (Evans & Murray 1954, Williams 1971). It is pertinent to mention earlier experiments in which large experimental gaps in the sympathetic trunk, in monkeys and other mammals, have been filled by the growth of fibres, pre- or postganglionic (Tower & Richter 1931, Haxton 1954). Conflicting evidence comes from the human sympathectomies; functional recoveries sometimes observed may be otherwise explained, such as by incomplete interruption of the sympathetic supply or by alternative routes being overlooked. On the whole the experience of surgeons corroborates the experimental findings (Pick 1970).

SEGMENTAL SYMPATHETIC SUPPLIES

Head and neck	T1–5
Upper limb	T2–5
Lower limb	T10–L2
Heart	T1–5
Bronchi and lung	T2–4
Oesophagus (caudal part)	T5–6
Stomach	T6–10
Small intestine	T9–10
Large intestine to splenic flexure	T11–L1
Splenic flexure to rectum	L1–2
Liver and gallbladder	T7–9
Spleen	T6–10
Pancreas	T6–10
Kidney	T10–L1
Ureter	T11–L2
Suprarenal	T8–L1
Testis and ovary	T10–11
Epididymis, ductus deferens, seminal vesicles	T11–12
Urinary bladder	T11–L2
Prostate and prostatic urethra	T11–L1
Uterus	T12–L1
Uterine tube	T10–L1

Applied Anatomy. Various autonomic nervous structures are divided or removed in treating several pathological conditions. In operations on the efferent sympathetic paths, ganglia on the sympathetic trunk are removed or preganglionic fibres cut, rather than postganglionic fibres, since the latter may regenerate. For example, the arteries of limbs may be denervated to alleviate vascular spasm (Raynaud's disease) and the parts removed are as described above (pp. 1160, 1123). In the treatment of hypertension, more extensive sympathectomy has been performed, involving bilateral removal of the sympathetic trunks from the eighth thoracic to the first lumbar ganglia, including the greater and lesser thoracic splanchnic nerves. Sympathectomy is also performed to relieve pain, e.g. in severe angina pectoris (p. 1167). Division of the superior hypogastric plexus (presacral neurectomy) does not relieve all pain in disease of the pelvic organs,

because many pain fibres traverse the pelvic splanchnic nerves. But uterine pain fibres pass in sympathetic nerves via the superior hypogastric plexus so that this division does relieve dysmenorrhoea. In males resection of the superior hypogastric plexus leads to loss of ejaculation and sterility, due to interruption of the sympathetic paths to the seminal vesicles, deferent ducts and prostate. The routes of these nerves between the sympathetic ganglia and the superior hypogastric plexus are uncertain and may vary; but in some individuals an outflow from the first lumbar and possibly the twelfth thoracic ganglia is concerned and in others fibres from the third lumbar ganglion (White et al 1952). For the surgical anatomy of the autonomic nervous system consult Pick (1970).

THE PERIPHERAL APPARATUS OF THE SPECIAL SENSES

In this section the detailed anatomy of the taste buds, the olfactory epithelium and nasal cavity and the eye and ear is considered. The general development of these structures is described in Embryology (pp. 201-206), while their connections with the central nervous system and cranial nerves are detailed on pp. 949-1092 and pp. 1094-1123 respectively.

The Gustatory Apparatus

The peripheral organs of gustation are the *taste buds* (*gustatory caliculi*), composed of modified epithelial cells set in piriform groups (7.278–281) within the epithelia of the tongue, soft palate, palatoglossal arches, posterior epiglottic surface and posterior wall of the oropharynx. They are most numerous in the vallate papillae of the tongue (7.279, 280), although fewer in the walls of the groove surrounding each of these structures. They are also abundant over the foliate papillae and on the posterior third of the tongue, but only sparsely scattered on the lingual fungiform papillae, the soft palate, epiglottis and pharynx. Taste buds occur in greater numbers in infants but gradually atrophy with age; those located most posterior in the tongue and in the epiglottis disappear early in development. There are no taste buds in the central region of the dorsum of the tongue.

MICROSCOPIC STRUCTURE OF TASTE BUDS

Each taste bud (7.280, 281) is separated by a basement membrane from the subjacent lamina propria and opens on to the epithelial surface by a *gustatory pore*. In longitudinal section the cells of taste buds are crescentic, their apices converging to a small cavity connected to the gustatory pore (7.280, 281); some cells have so-called gustatory hairs, which are groups of microvilli. The base of each bud is penetrated by a small fasciculus of afferent nerve fibres which ramify and spiral around certain of its cells.

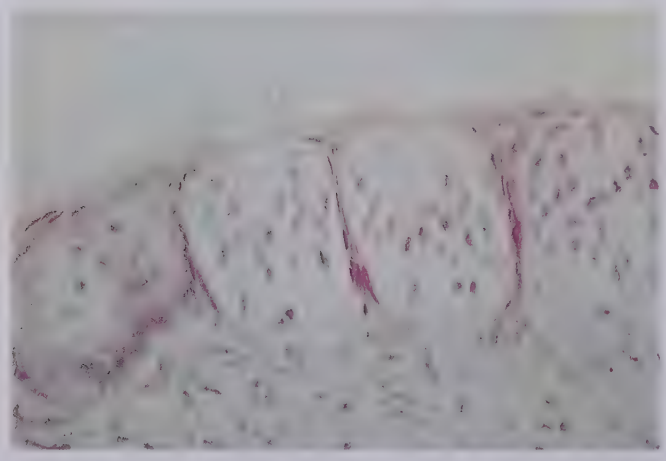
Gustatory sensory cells have long been recognized as modified epitheliocytes with synaptic contacts with the terminals of afferent fibres. Reconstructions of taste buds from serial electron micrographs (Murray & Murray 1970) have shown at least five distinct types of epithelial cell, two (or three, see Kinnamon et al 1985) apparently receptors and the others supportive or generative in function (7.281). The receptor cells are typified by the presence of synaptic contacts with the afferent terminals at various points on their surfaces; these show a characteristic asymmetical thickening and presynaptic small (50 nm), clear synaptic vesicles in the receptor cell, although these are less abundant than in many other synapses (p. 884). Also, one epithelial type contains dense-cored vesicles about 70 nm in diameter, identified in other sites as catecholamine vesicles (p. 884); in the other receptor these are absent. These two cell types may be different stages of receptor maturation, as they are continually lost and replaced (vide infra). At their apices few microvilli appear; the 'gustatory hairs' of light microscopy mainly occur on supporting cells enclosing the receptors, except at their apices (Miller & Chaudry 1976). One type of these supportive cells appears to form an encapsulating sheath for the bud, separating it from the adjacent epithelium; another type is located basally and is probably a blastemal cell giving rise to new cells. A third type insulates each receptor from its neighbours and also ensheathes the afferent nerve fibres, which lose their Schwann cells as they enter the taste buds. Ultrastructurally, supporting cells are seen to contain dense secretory bodies, probably the source of polysaccharide material in the bud's apical cavity, into which the sensory terminals project. Gustatory molecules must traverse this to reach the receptor surface; its role in gustation is otherwise unknown. Occluding junctions between the apices of various cells in the bud prevent the access of chemical stimuli to non-apical regions of the receptors (Akisaka & Oda 1978).

7.278 A low-power light micrograph of a sagittal section through the tip and anterior part of a human tongue, showing: muscle fibres orientated in three different directions; a delicate non-keratinized stratified squamous epithelium on the ventral surface; and a partly keratinized stratified epithelium on the dorsum. The latter is convoluted to produce filiform and fungiform papillae. Dermal papillae project into the deep surface of the epidermal irregularities, Haematoxylin and eosin. Magnification × 10.

7.279 A light micrograph of a human vallate lingual papilla showing the numerous taste buds clustered along its lateral surfaces. A connective tissue papilla forms the core of the whole structure and serous glands, situated between the muscle blocks deep to the corium, open into the lateral recesses of the papilla. Haematoxylin and eosin. Magnification × 150.

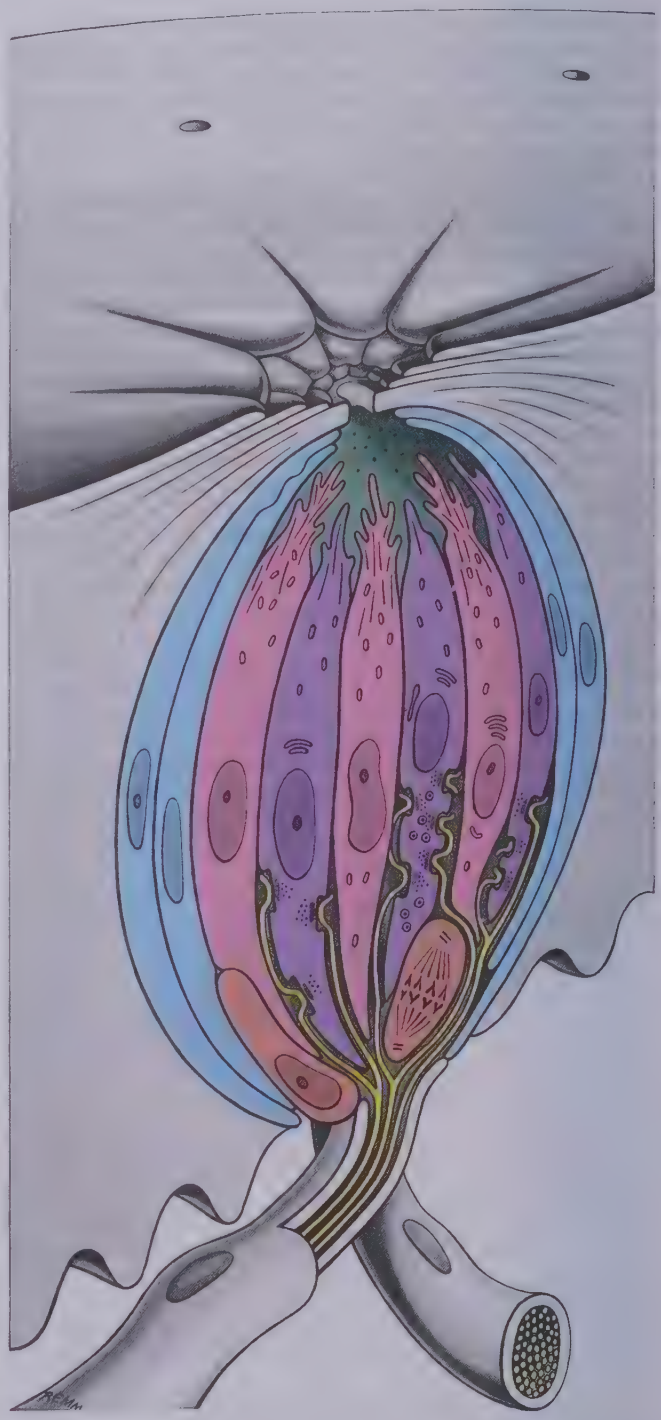
Nerve fibres reaching the taste buds from the subepithelial plexus are complex in their distribution in the tongue, as deduced by recordings from individual nerve fibres in the proximal fasciculi of the chorda tympani and glossopharyngeal nerve. Each fibre may have many terminals, spreading to innervate widely separated taste buds and more than one sensory cell in each bud. Conversely, individual buds may receive the terminals of several nerve fibres. This cross-innervation may be functionally of considerable importance (vide infra and Beidler 1970). No evidence has emerged concerning efferent terminals or inhibitory phenomena in the taste buds.

REPLACEMENT OF CELLS IN TASTE BUDS



The cells of taste buds resemble those in the adjacent epithelium in undergoing continual renewal (Farbman 1980). Isotopic labelling shows that none of the cells of taste buds survive for more than a few days, except the basal, blastemal cells. Newly formed sensory cells must therefore make new synapses with sensory nerve terminals. Experiments indicate that the sensitivity of sensory cells to particular chemicals is determined by the trophic influence of the nerve fibres and not the reverse (p. 919). The continual degeneration and replacement in taste buds implies that their different cells show a scale of structural appearances due to maturation, adding to the difficulties of their classification.

FUNCTION OF GUSTATORY RECEPTORS



In many aquatic vertebrates gustatory receptors are widely distributed over the surface of the body as well as in the alimentrary tract; in terrestrial vertebrates this sense is largely confined to the oral cavity and adjoining pharynx. Human gustation, as commonly understood, is largely mediated by the activity of lingual receptors, though others may participate (vide supra). Four subjective qualities have been classically distinguished, each associated with a region of the tongue, e.g. sweet and salty at the apex, sour (acid) at the sides and bitter at its pharyngeal end. Though these are subjective sensations, it seemed at one time possible that their localization to particular areas might reflect the existence of specific receptors. Electrophysiological evidence suggests that this is, as usual, an over-simplification, since each afferent fibre is connected to widely separated taste buds and may respond to several different chemical stimuli. Some respond to all four classic categories, others to less or only one. Within a particular class of tastes, receptors are also differentially sensitive to a wide range of similar chemicals. It therefore seems that perceived sensations of taste are the results of analysis (presumably central) of a complex pattern of responses from particular areas of the tongue, so that even if there are only a few specific types of taste receptor, much more information about the chemical nature and intensity of a taste may be gained than if the innervation were simpler (Beidler 1970, Beidler & Smallman 1965, Pfaffman 1970).

GUSTATORY NERVES

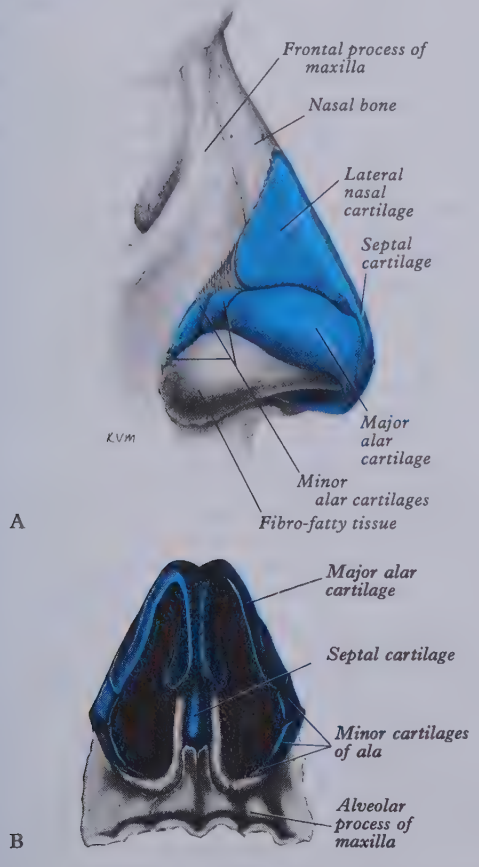
Gustatory nerve fibres are the peripheral processes of unipolar neurons in the genicular ganglion of the facial nerve and the inferior ganglia of the glossopharyngeal and vagal nerves. Their central axons form the tractus solitarius (p. 954), their terminals synapsing with neurons in the rostral third of the nucleus of that tract. Secondary gustatory axons cross the midline, many to

7.280 A light micrograph of a group of taste buds in a vallate lingual papilla, showing the apical cavity and various fusiform cells within the epithelial capsule. Haematoxylin and eosin. Magnification × 400.

7.281 A schematic reconstruction of the structure of a taste bud, cut away to expose the various cell types. Presumed sensory cells of two types (one with dense-cored vesicles, the other without) are indicated in purple and their innervation in yellow. The supporting cells are indicated in magenta and basal cells in brick red. A dense mucosubstance is present in the apical cavity beneath the apical aperture.

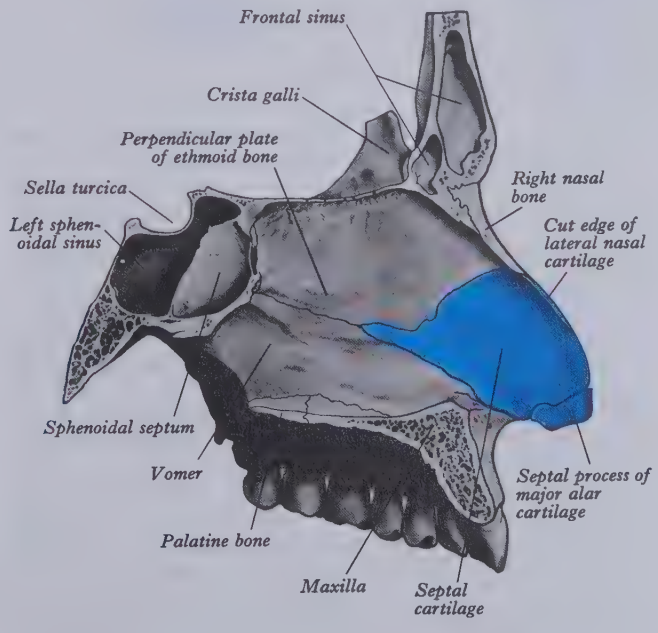
ascend the brain stem in the dorsomedial medial lemniscus to synapse with the most medial neurons of the thalamic *nucleus ventralis posterior medialis* (VPM) (in a region sometimes termed the *accessory arcuate nucleus*). From the VPM axons radiate through the internal capsule to the anterio-inferior area of the sensorimotor cortex and the limen insulae. Electrophysiological recording from the VPM and cortex largely confirms these anatomical pathways; some units react to one type of stimulus, others to several different stimuli. Other ascending paths have been described, ending in a number of the hypothalamic nuclei by which gustatory information may reach the limbic system (p. 1028) and allowing appropriate autonomic reactions to be made (p. 1124) (see Stewart & Shepherd 1985).

The gustatory nerve for the anterior part of the tongue, excluding the vallate papillae, is the chorda tympani (via the lingual nerve); in most individuals these fibres traverse the chorda tympani to the facial ganglion but in a few they diverge through connecting branches to the otic ganglion, proceeding thence in the greater petrosal nerve to the facial ganglion (Schwartz & Weddell 1938). The anterior or *oral* part of the tongue is derived from the mandibular branchial arch and is limited posteriorly by the *sulcus terminalis*. Taste buds in the soft palate's inferior surface are also supplied mainly by the facial fibres, through the greater petrosal nerve distributing via the nerve of the pterygoid canal and middle and posterior palatine nerves; the glossopharyngeal also contributes to this region. Taste buds in the vallate papillae and the *pharyngeal* (postsulcal) part of the tongue and in the palatoglossal arches and the oropharynx are innervated by glossopharyngeal fibres, while those in the extreme pharyngeal part of the tongue and epiglottis receive fibres from the internal laryngeal branch of the vagus. (For literature concerning gustatory paths consult Rollin 1979.) These supplies accord with the embryological development of the tongue (p. 228), see also p. 1322).



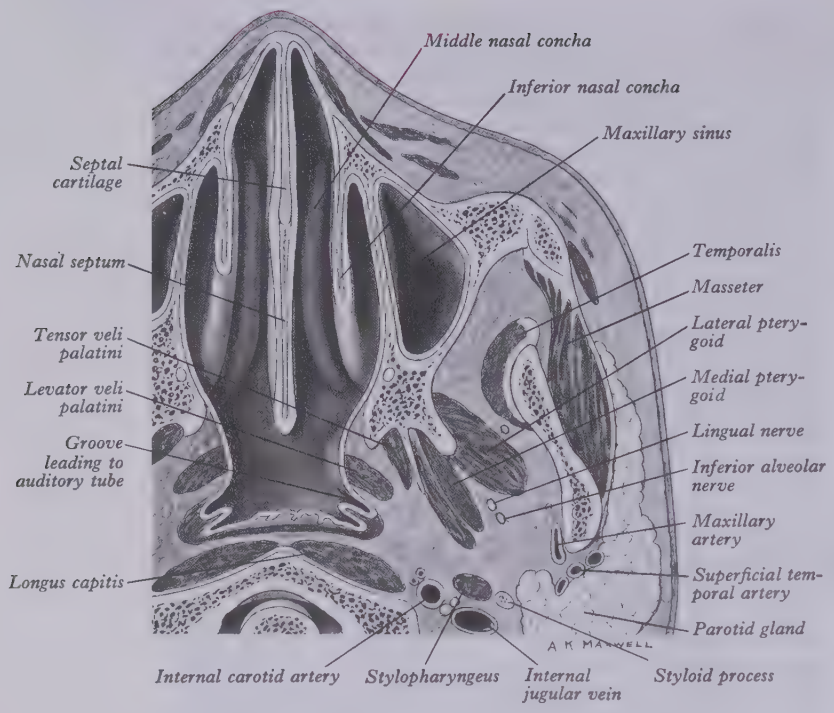
THE OLFACTORY APPARATUS

The peripheral olfactory organs include the *external nose* and *nasal cavity* which are divided sagitally by a septum into right and left parts. However, these are in reality only accessory organs, the essential olfactory structures being the olfactory epithelium and its nervous connections.



THE EXTERNAL NOSE

Externally the nose is pyramidal, its upper angle or *root* being continuous with the forehead, and its free tip is the *apex*. Inferiorly are two ellipsoidal apertures, the nostrils or external *nares*, separated by the *nasal septum*. The lateral surfaces of the nose are continuous at the median *dorsum nasi*, the shape of which varies greatly between individuals; the upper nose is kept patent by the nasal bones and the frontal processes of the maxillae and below this by cartilages. The lateral surfaces end in rounded *alae nasi*. The supporting framework (7.282) is composed of bone and hyaline cartilages. The *osseus skeleton*, supporting its upper part, consists of the nasal bones, the frontal processes of the maxillae and the nasal part of the frontal bone; the *cartilaginous skeleton* consists of the septal, lateral and major and minor alar cartilages (7.282, 283), all connected to each other and to nearby bones by the continuity of their perichondrium and periosteum. These junctions, though of much interest, have attracted little attention; the cartilages and intervening connective tissue which surround the nares may be regarded as forming a valve, controlling the intake of air (Cottle 1960, Galindo et al 1977).



The *septal cartilage* (7.282B, 283), almost quadrilateral in shape and thicker at its margins than its centre, forms almost the whole of the septum between the anterior parts of the nasal cavity. Its anterosuperior margin is connected above to the posterior border of the internasal suture; the middle part is continuous with the lateral cartilages, and its lowest part is attached to these cartilages by perichondrium. Its antero-inferior border is connected on

7.282 A. The cartilages of the right side of the nose: lateral aspect. B. The cartilages of the nose: inferior aspect. Note changes in terminology.

7.283 The right side of the septum of the nose, showing its constituent bones and cartilages. Note the changes in terminology.

7.284 A transverse section through the anterior part of the head at a level just inferior to the apex of the odontoid process: inferior aspect.

each side with the septal process of the major alar cartilage. (Galindo et al 1977 suggest that the two lateral and septal cartilages should be regarded as a unit, the *septodorsal cartilage*, an older term used in the Jena Nomina Antomica.) Its posterosuperior border joins the perpendicular plate of the ethmoid; its postero-inferior border is attached to the vomer and to the maxillary nasal crest and anterior nasal spine. The septal cartilage may extend back (especially in children) as a narrow *sphenoidal process* for some distance between the vomer and the perpendicular plate of the ethmoid. The antero-inferior part of the nasal septum, between the nares, is named the *septum mobile nasi* because of its mobility; it is formed by the septal processes of the major alar cartilages and skin and not by the main septal cartilage.

The *lateral* (superior) *nasal cartilage* (7.282A) is triangular, its anterior margin thicker than the posterior and its upper part continuous with the septal cartilage, but separated from it below by a narrow fissure; its superior margin is attached to the nasal bone and frontal process of the maxilla and its inferior margin is connected by fibrous tissue to the major alar cartilage.

The *major alar* (inferior) *cartilage* (7.282A,B), a thin flexible plate lying below the lateral cartilage, is curved acutely around the anterior part of its naris; its medial part, the narrow *medial crus* (septal process), is loosely connected by fibrous tissue to its contralateral fellow and to the antero-inferior part of the septal cartilage, thus forming part of the septum mobile nasi. The *lateral crus*, lateral to the naris, is little more than the inferior border of the major alar cartilage. The upper border of the lateral part of the major alar cartilage is attached by fibrous tissue to the lower border of the lateral nasal cartilage. Its narrow posterior end is connected to the frontal process of the maxilla by a tough membrane containing three or four *minor alar cartilages* (7.282A). According to Drumheller (1969) the junction between the major alar and the lateral cartilages is variable; the two edges may abut or overlap, the lateral cartilage being then the more lateral at the junction. The lower edge (lateral crus) of the major cartilage is shorter than the lateral narial margin, the lower part of the ala nasi being fibro-adipose tissue covered by skin. In front, the major alar cartilages are separated by a notch palpable at the tip of the nose. The *muscles* acting on the external nose are described on p. 572.

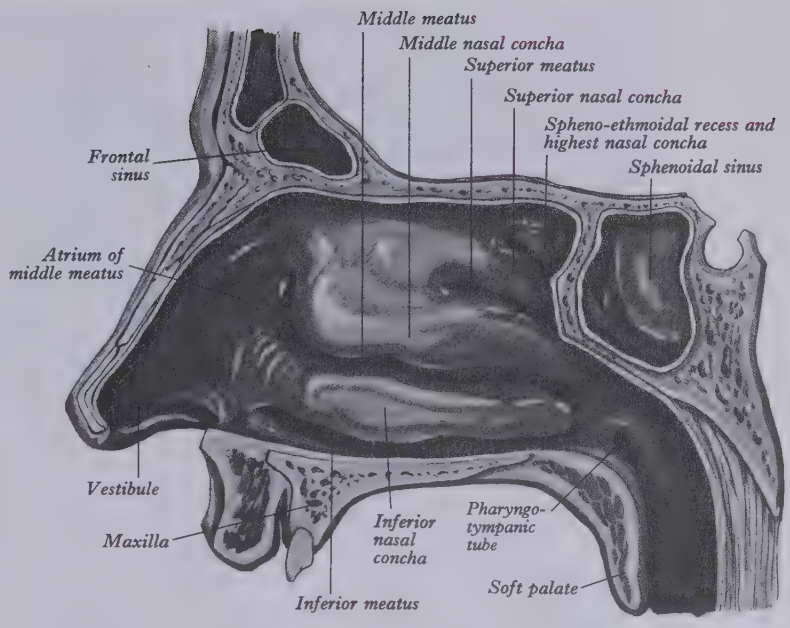
Nasal skin is thin and loosely connected to the underlying structures. Over the apex and alae it is thicker and more adherent and bears numerous large sebaceous glands, their orifices usually being obvious. The *arteries* of the external nose are the alar and septal branches of the facial artery supplying the alae and lower septum; the dorsal nasal branch of the ophthalmic and infraorbital branch of the maxillary artery supply the lateral aspects and the dorsum. The *veins* end in the facial and ophthalmic veins. The *nerves* for the nasal muscles are from the facial; the skin receives branches from the ophthalmic nerve through its infratrochlear branch and external nasal nerve (p. 1100) and from the infraorbital branch of the maxillary nerve.

THE NASAL CAVITY

This is divided sagittally by the nasal septum (7.284), its two halves opening on the face through the nares and being continuous posteriorly with the nasopharynx through the posterior nasal apertures. The *nares* are ellipsoid or piriform, narrower in front; each one measures 1·5 cm–2 cm anteroposteriorly and 0·5 cm–1 cm transversely. The *posterior nasal apertures* (*choanae*) are oval openings, each about 2·5 cm in vertical and 1·25 cm in transverse dimension.

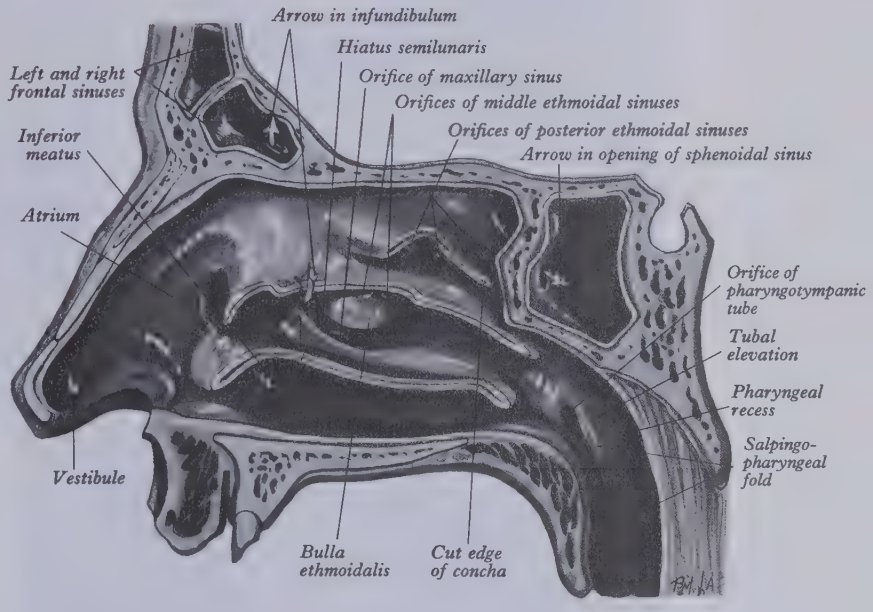
For details of nasal skeletal structures, see p. 365.

Each half of the nasal cavity has a floor, roof and a lateral and medial (septal) wall. It has three regions: vestibular, olfactory and respiratory. The *nasal vestibule* is a slight dilatation just inside the naris (7.285), bounded laterally by the ala and lateral part of lower nasal cartilage and medially by the septal process of this cartilage; it extends as a small recess towards the nasal apex. It is lined with skin bearing coarse hairs (*vibrissae*) curving towards the naris to arrest the passage of particles in inspired air. In males, after middle age, these hairs increase considerably in size. The vestibule is limited above and behind by a curved elevation, the *limen nasi*, corresponding to the upper margin of the major alar cartilage; along this, vestibular skin is continuous with the nasal mucosa. The *olfactory region* is limited to the superior nasal concha, the opposing septum and the intervening roof. The *respiratory region* is the rest of the cavity.



The lateral wall (7.285, 286) shows three elevations: the *superior*, *middle* and *inferior nasal conchae*, inferolateral to each being a corresponding *meatus*. Above the superior concha a triangular *spheno-ethmoidal recess* bears the opening of the sphenoidal sinus; sometimes a fourth, *highest nasal concha* appears on the recess's lateral wall (7.285); the *supreme nasal meatus* inferior to it may display an opening of a posterior ethmoidal sinus. The *superior meatus* is a short oblique passage extending about halfway along the upper border of the middle concha; the posterior ethmoidal sinuses open, usually by one aperture, into its anterior part. The *middle meatus*, deeper in front than behind, is inferolateral to the middle concha and continues anteriorly into a shallow fossa above the vestibule, termed the *atrium* of the middle meatus. Above the atrium an ill-defined curved ridge, the *agger nasi* (p. 389), slopes down and forwards from the upper end of the anterior free border of the middle concha; it is better developed in the newborn than in adults. The middle concha must be displaced to display the lateral wall of the middle meatus fully. The main features of this wall are a rounded elevation, the bulla ethmoidalis, and below it and extending up in front of it, a curved cleft, the hiatus semilunaris. The *bulla ethmoidalis* is formed by the bulging of the middle ethmoidal sinuses, which open on or just above it, its size varying with the contained sinuses. The *hiatus semilunaris*, bounded inferiorly by a sharp concave ridge produced by the ethmoid's uncinate process, leads forwards and up into a curved channel, the *ethmoidal infundibulum*; the anterior ethmoidal sinuses open into it and in 50% or more of subjects it is continuous with the *frontonasal duct* from the frontal sinus; otherwise the infundibulum ends blindly in front in one or more anterior ethmoidal sinuses (*infundibular sinuses*) and the frontonasal duct then opens directly into the anterior end of the middle meatus. The opening of the maxillary sinus lies below the bulla, usually hidden by the flange-like lower edge of the hiatus; this opening is near the roof of the sinus (7.291); an accessory opening frequently exists inferoposterior to the hiatus. The *inferior meatus*, below and lateral to the inferior concha, contains the opening of the nasolacrimal duct under the cover of the anterior end of the inferior concha.

The medial wall or nasal septum (7.283B) is often deflected from the midline, making the nasal chambers unequal in size; ridges or spurs of bone sometimes project from the septum on either side. Above the incisive canal at the lower edge of the septal cartilage there is sometimes a depression which points down and forwards, occupying the position of a canal connecting the nasal and buccal cavities in early fetal life. On each side of the septum near this recess a minute orifice may be seen leading back into a blind tubule, 2–6 mm long, the vestigial *vomeronasal organ*, supported by a *vomeronasal cartilage*; it is lined by a single layer of tall columnar cells and contains many glands. It is prominent in amphibians and reptiles, moderately developed in most mammals including New World monkeys but vestigial in adult primates (Graziadei 1974); in species having a functional vomeronasal organ, it is a chemosensory structure similar to the olfactory epithelium, being connected to the olfactory bulb by the vomeronasal nerve (see p. 1032). **The nasal roof** is narrow transversely, except posteriorly; from behind forwards it can be divided into sphenoidal, ethmoidal and frontonasal regions (pp. 167, 343), according to the bones helping to form it. The ethmoidal part is almost horizontal, the frontonasal part slopes down and forwards and the sphenoidal is inclined downwards and backwards. The cavity is therefore deepest under the cribriform plate of the ethmoid.



The nasal floor is transversely concave, anteroposteriorly flat and almost horizontal, its anterior three-quarters being formed by the palatine process of the maxilla and the rest by the horizontal part of the palatine bone. About 2 cm behind its anterior end a slight depression in the mucosa overlies the incisive canal (p. 389).

The nasal conchae add greatly to the surface area of the nasal cavity. This increases turbulence, perhaps improving olfaction by slowing the passage of air past the olfactoria area. Humidification and warming of the inhaled air are also augmented by the increased mucosal area and turbulence, even in a microsomatic mammal such as man (Cole 1954). Swirling currents also aid the trapping of particles by mucous secretion. In many mammals the conchae are large and highly elaborate structures and the olfactory area spreads over much of their superior and medial surfaces, producing a highly developed olfactory system (Negus 1958; see also p. 1177).

Nasal mucosa lines the nasal cavities, except its vestibules; it is adherent to the periosteum or perichondrium and continuous: with the nasopharyngeal mucosa through posterior nasal apertures, with the conjunctiva through the nasolacrimal duct and lacrimal canaliculi and with the mucosae of the sphenoidal, ethmoidal, frontal and maxillary sinuses through their openings. The mucosa is thickest and most vascular over the conchae, especially at their extremities and also on the nasal septum, but is very thin in the meatuses, on the floor and in the sinuses. Its thickness reduces materially the volume of the nasal cavity and its apertures. The epithelium differs according to local functions; in the *olfactory region*, over the upper 10 mm or so of the septum and over the superior concha and the lateral wall above it, the mucosa is yellowish and the epithelium distinctive in structure.

7.286 The lateral wall of the right half of the nasal cavity; the three nasal conchae have been partially removed.

STRUCTURE OF THE OLFACTORY EPITHELIUM

The olfactory epithelium is considerably thicker (up to 100 μm) than the adjacent nasal epithelium and is pseudostratified sensory in type. It contains three principal types of cell (7.287, 288): olfactory receptors, supporting cells (sustentaculocytes) and basal cells (Moulton & Beidler 1967).

Olfactory receptor cells are of much phylogenetic interest, as they are *primary sensory neurons*, with somata situated near the sensory surface, an arrangement common in invertebrates but unique in vertebrates. They are *bipolar* neurons, orientated vertically within the olfactory epithelium, their somata restricted to its basal two-thirds. A basal non-myelinated axon extends from each receptor to run with other axons in small intra-epithelial fascicles among the processes of supporting and basal cells to penetrate the basal lamina, where each fascicle is ensheathed by a Schwann cell (Frisch 1967). Such *fila olfactoria* join to form *olfactory fasciculi* which enter the olfactory bulb to synapse with secondary sensory neurons (mitral cells, basket cells, periglomerular cells, p. 1031). Olfactory axons are amongst the most slender of nerve fibres, about 0·2 μm in diameter. Within the olfactory fila the axons are grouped in bundles of up to 50 or more by invagination into Schwann cells (Gasser 1956), perhaps permitting electrical interaction between adjacent axons.

From the apical pole of each receptor cell (7.290A,B) a single unbranched dendrite extends to the surface, expanding into a bulbous olfactory ending (*rod*, *knob* or *vesicle*) which projects above it (Frisch 1967, Reese 1965, Graziadei 1971, 1974, Naessen 1971). The endings have numerous *olfactory cilia* projecting into a fluid layer on the epithelium. The cilia have an internal '9 plus 2' pattern of microtubules, as in motile, non-sensory cilia elsewhere (p. 31). Amongst different groups of vertebrates the length and form of olfactory cilia vary. In mammals they have short, thick proximal 'shafts' tapering rapidly to a long, thin, distal tip, with fewer microtubules, thus forming a considerable

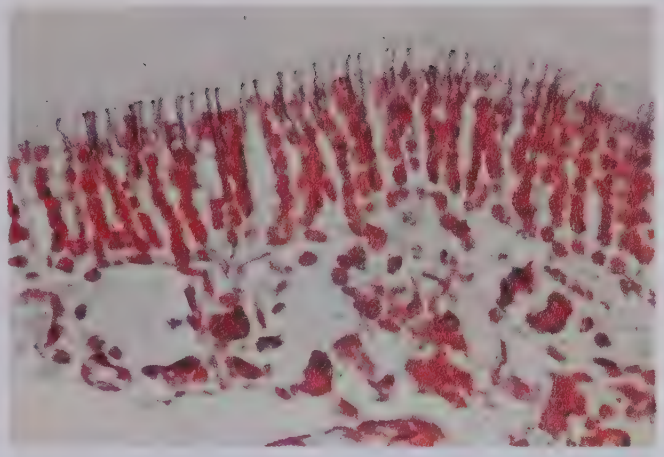
7.287 A schematic reconstruction showing the chief cytological features of the olfactory epithelium. Receptor cells (yellow) are situated among columnar supporting cells. The axons of the receptor cells emerge from the epithelium in groups ensheathed in Schwann cells. Observe the rounded basal epithelial cells and the subepithelial glands of Bowman with their intra-epithelial ducts. One of the basal cells is in process of differentiating into a receptor cell. At the surface are cilia of the receptor cells and microvilli of the supporting cells.

area of receptor surface. The dendrite contains numerous mitochondria, indicative of high energy consumption, and other organelles typical of dendrites: microtubules, smooth and coated vesicles, agranular endoplasmic reticulum and ribosomes; centrioles also often appear, especially in young animals. The *perikaryon* contains abundant granular and agranular endoplasmic reticulum, Golgi bodies and lysosomes, all indicating a high metabolic rate. The nucleus is elliptical and heterochromatic. The exposed regions of olfactory dendrites and cilia are covered by plasma membrane containing high concentrations of intramembranous particles (7.290A) demonstrable by freeze-fracturing (Kerjaschki & Horandner 1976, Menco et al 1975, Menco 1984). These particles are probably the sites of olfactory reception and the ionic movements concerned in sensory activity; their large numbers accord with the extreme sensitivity of olfactory receptors to low concentrations of chemicals (Menco 1976).

Supporting cells are irregular columnar elements separating and partially enclosing the receptors. Their large, elongate, euchromatic nuclei form a layer superficial to the receptor perikarya. Their surfaces are marked by numerous, long, irregular microvilli which, with the olfactory cilia, form a complex meshwork of processes in the mucus at the epithelial surface. Their cytoplasm contains many mitochondria, granular and agranular endoplasmic reticulum and, basally, lamellated dense bodies resembling the lipofuscin granules of neurons (p. 881), representing the remains of autophagic lysosomes and making the whole olfactory area yellowish-brown. A prominent Golgi apparatus and lysosomes also exist in their apical parts. Near the epithelial surface fine microfilaments attached to desmosomes probably give mechanical coherence to the epithelium. Tight junctions also occur between the supporting cells and olfactory receptors at the level of the epithelial surface (Reese & Brightman 1970).

Basal cells are of two types: one probably supportive and the other *blastemal*, able to give rise to new cells by mitotic division (Andres 1966). The first is confined to the vicinity of the epithelial basal lamina, composed of irregular polygonal cells with irregular heterochromatic nuclei and sparse cytoplasm containing numerous tonofibrils attached to desmosomal contacts with adjacent cells. It is likely that they strengthen the epithelial base.

The blastemal cells are confined to a zone at the epithelial base; they are particularly prominent in young animals. Mitotic figures often appear among them and their nuclei can be labelled with tritiated thymidine and examined by autoradiography. Structurally they have many of the features of embryonic neuroblasts, being rounded, with a large euchromatic nucleus and basophilic cytoplasm containing numerous free ribosomes, scattered mitochondria and occasional clusters of centrioles. Some basal cells show an early differentiation into olfactory receptors by developing dendrites and receptor organelles. Various studies have shown that blastemal cells constantly contribute new receptor cells by migrating upwards in the epithelium. During the early development and postnatal period this recruitment is needed for epithelial expansion in both its thickness and area; but a slower, continuous addition to the receptor population appears to occur throughout life, balanced by the degeneration of existing cells, which (in rodents) may only last for two to three weeks (Moulton et al 1970, Graziadei 1974). Degenerating receptors are phagocytosed by the adjacent supporting cells; their remnants, after hydrolysis in lysosomes, contribute to the olfactory pigment (Bannister & Dodson 1975). A continuous turnover of olfactory receptors is required by the exposed position of the olfactory endings and their liability to damage from inhaled noxious agents or viruses; but in the latter case functional regeneration appears to depend on the absence of scar tissue, which may prevent the regrowth of axons (Douek et al 1975). This ability to regenerate primary sensory neurons is unique in mammalian nervous systems, a phenomenon of much neurobiological interest (Graziadei 1978).



The olfactory glands (of Bowman) (7.287, 288) are branched tubular structures beneath the olfactory epithelium, on to whose surface they secrete through narrow, vertical ducts. Their secretory acini have cells with basal nuclei and granular cytoplasm; ultrastructurally two types appear, both containing dense secretory vesicles but one with denser cytoplasm. Their secretions are reported to contain enzymes in some mammals (acid phosphatase, esterase and, in mice, sulphated acid mucosubstances). Since this fluid forms the environment of the receptor endings, it may aid the diffusion of odoriferous substances from the air to the olfactory receptors and regulate the passage of ions to and from sensory cells during electrical activity. it may also be bactericidal.

A variable number of lymphocytes exists, particularly in basal epithelium, as elsewhere in the upper respiratory tract. During life olfactory receptors and their axons gradually diminish in total number, up to 1% being lost each year; the sensory epithelium may be replaced by ciliated columnar epithelium of the respiratory type lining the adjacent nasal regions. These changes parallel a gradual loss of olfactory sense.

DEVELOPMENT OF THE OLFACTORY EPITHELIUM

Olfactory elements develop from the embryonic olfactory placode, resembling the early ontogeny of the neural tube (p. 178). Cuboidal ectodermal cells of the placode gradually lengthen but remain as a single layer throughout development. Mitosis occurs at first only near the placodal surface, the dividing cells rounding up and then re-extending to the epithelial base; but later mitoses appear deeper in the epithelium and are finally confined to the basal layers, where division persists throughout life (Smart 1971, Cuschieri & Bannister 1975a). Electron microscopy shows that receptor cells differentiate early, sprouting apical dendrites and basal axons with large growth cones, growing back to the olfactory bulb to synapse with the secondary neurons (Hinds & Hinds 1972, Cuschieri & Bannister 1975b, Farbman 1975, Constanzo & Graziadei 1986). On reaching the surface, the dendrites expand to form bulbs into which centrioles migrate from the receptor soma, eventually growing cilia. Later the supporting cells, glands and basal cells differentiate, the olfactory apparatus being functional at birth.

In the **vomeronasal organ** (of Jacobson), which is rudimentary in mankind (p. 1173), the cellular components resemble those of the olfactory epithelium except for an absence of basal cells, a larger size of receptor cells and the existence of microvilli instead of cilia (Kolnberger 1971). The absence of cilia is interesting, for

7.288 A vertical section through the olfactory epithelium of the mouse, stained with Holmes' silver method to show the olfactory dendrites and their terminal expansions (above). The nuclei of the receptor neurons are arranged in columns in this preparation; the fila olfactoria can also be seen emerging from the base of the epithelium (below). Provided by A Cuschieri, University of Malta.

7.289 An electron micrograph showing receptor endings in the olfactory mucosa of a mouse. Note the presence of numerous cilia on the sensory terminals, interspersed by numerous microvilli on the surfaces of the supporting cells. Provided by H C Dodson, Dept. of Anatomy, UMDS, Guy's Campus, London.

they are claimed to be the sites of chemoreception in the olfactory epithelium; however, essentially the exposed plasma membrane is the chemoreceptive area and cilia or microvilli merely increase the receptive surface. Electrical recordings show that vomeronasal receptors respond to odours like the olfactory receptors, but possibly to a narrower range of substances.

Other nasal chemoreceptors include terminals responsive to strong odours and noxious chemicals in aerial solution, e.g. ammonia and sulphur dioxide, even when the olfactory pathway has been destroyed by fracture of the cribriform plate or division of the olfactory tract. The major nerves possibly supplying nasal chemosensory endings include trigeminal fibres from ethmoidal

7.290A An electron micrograph of an olfactory cilium (bovine) attached at its basal end to an olfactory dendrite terminal, freeze-fractured to expose the numerous intramembranous particles which are thought to be sites of odour reception. An extensive ciliary necklace is present at the base of the cilium and microvilli of a supporting cell are visible on the left. Supplied by B Menco, University of Utrecht, Netherlands. branches of the ophthalmic nerve and various maxillary branches (p. 1177); small bundles of myelinated fibres from these have been detected by Graziadei & Gagne (1973) in the basal olfactory epithelium, losing their sheaths as they penetrate amongst the supporting cells. Another possible chemosensory path is the *nervus terminalis*, whose functions are uncertain but which terminates widely in the nasal cavity in some species (Graziadei 1974 and p. 1095).

FUNCTION OF THE OLFACTORY RECEPTORS

The chemical sense served by the olfactory epithelium differs from the gustatory sense in discriminating between different *airborne* molecules even at very low concentrations. Although the human sense of smell is only moderate compared with that of macrosomatic species in whose behaviour odours play a dominant role, human olfaction may be more significant than imagined. In mammals, including primates, specific scents ('pheromones') affecting social or sexual behaviour are recongized as a common phenomenon, and associations between the central olfactory pathways and cerebral areas concerned with emotional behaviour may be important indications of a more general significance of odours (see the limbic system, p. 1028).

The mechanisms of detection and neural signalling of odours have been studied chiefly by recording electrical changes elicited in or at the surface of the olfactory epithelium by odours (Moulton & Beidler 1967). Two types of electrical change can be recorded; a slow negative wave (*electro-olfactogram*) at the surface and just below it, representing summated ionic fluxes from many receptor dendrites; deeper in the epithelium and in the olfactory nerves *action potentials* can be detected.

Precisely how receptors provide information regarding the quality and quantity of odorous stimuli is little understood. Individual receptors might respond specifically to particular odours

7.290B An electron micrograph of a group of non-sensory cilia from the respiratory epithelium of the nasal cavity (bovine), freeze-fractured to show the distribution of intramembranous particles. Note the presence of ciliary necklaces at the bases of cilia and the relative paucity of particles elsewhere on the cilia (compare with 7.290A). Supplied by B Menco, University of Utrecht, Netherlands. Magnification × 80 000.

but a huge variety of odours can be distinguished and an equally wide range of specific receptors would then be required, each able to detect slight differences in molecular structure, if there is a one-to-one relation between receptor types and odours. It has been shown electrophysiologically that single receptors can respond to several odours and conversely that different receptors exhibit diverse responses to the same odour. It seems likely that olfactory discrimination results from a central analysis of complex patterns of activity in many receptors (Gesteland et al 1965), as in gustatory discrimination.

How odoriferous substances actually stimulate the receptors is also uncertain; many theories have been proposed. The most widely accepted is the stereochemical theory, first elaborated by Amoore (1971); this postulates the presence of various receptor molecules, each responsive to particular chemical groups, on odorous molecules dissolved in the nasal mucus, rather as an enzyme recognizes its specific substrate (a 'lock and key' phenomenon). Thus the shape of some part of an odorous molecule would correspond to a complementary site in a receptor molecule. In early studies of correspondences between molecular shape and subjective olfactory perception, it was postulated that there might be a simple basis for quality coding, with as few as perhaps seven or eight 'primary odours', analogous to primary colours (e.g. floral, fruity, minty, pungent, musky, etc.) and corresponding receptor sites. Later studies have indicated a greater complexity than this. Of particular interest have been investigations into specific anosmias, in which one or more specific classes of odour cannot be sensed, although olfaction is generally unaffected. These suggest that there are perhaps 30 or more 'primary odours' in humans. The receptor sites appear to be all on the surfaces of the olfactory receptor cells, embedded in their exposed plasma membrane (probably as transmembrane proteins). Odorants bind transiently to each site to change the ionic permeability of the membrane to calcium ions. Further studies at a cellular level are necessary for a fuller understanding of the general nature of olfaction, which in the past has been a somewhat neglected sense.

THE RESPIRATORY EPITHELIUM

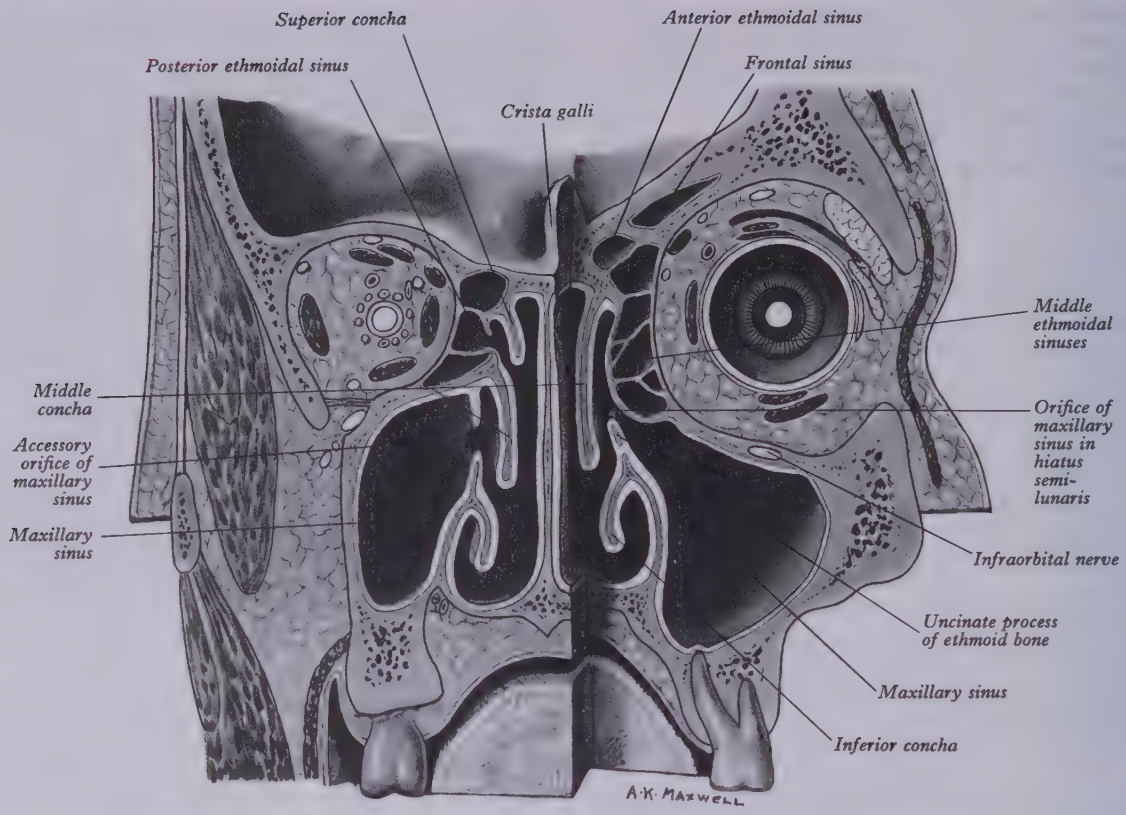
The non-olfactory regions of the nasal and sinus mucosae have columnar or pseudo-stratified ciliated epithelium containing goblet cells, non-ciliated columnar cells with microvilli and basal cells (Mygind 1975, 1978), collectively termed the *respiratory epithelium* (Negus 1958). In some areas cells may be low columnar or cuboidal. Beneath the basal lamina are groups of serous and mucous glands of variable cytological detail and secretory contents, many of them opening by branched ducts on the epithelial surface. *Cavernous tissue* beneath the respiratory mucosa in such areas is extensive (vide infra) and vascular disturbances, e.g. due to vasomotor autonomic innervation, alter epithelial surfaces visibly by swelling or shrinkage. The endothelium in these cavernous regions is particularly interesting in being fenestrated; the muscular walls of their supplying arterioles may also be under endocrine as well as neural control, providing a basis for cyclical fluctuations in their blood pressure and degree of enlargement (Cauna & Hinderer 1969, Cauna et al 1972). Basal to the epithelium and its basement membranes is a fibrous layer infiltrated with lymphocytes which often form diffuse lymphoid tissue, under which is a nearly continuous layer of mucous and serous glands, their ducts traversing the lymphoid layer to the surface. Abundant mucus from glands and goblet cells makes the surface sticky and dust in the inspired air is deposited on the surface, while the air is humidified and warmed. The mucous film is continually moved by ciliary action backwards into the nasopharynx at a rate of about 6 mm per minute (Proctor et al 1978). Palatal movements transfer the mucus and its entrapped particles to the oropharynx for swallowing, but some also enters the nasal vestibule anteriorly. The secretions of the nasal mucosa also serve many other functions, as they contain antibacterial lysozyme and immunoglobulins (IgA), to inhibit the proliferation of microbes in this very susceptible environment.

In the walls of the sinuses the epithelium is closely bound to the underlying periosteum to form a combined *mucoperiosteum*.

VESSELS AND NERVES OF THE NASAL CAVITY

The *arteries of the nasal cavity* are as follows: the anterior and posterior ethmoidal branches of the ophthalmic artery supplying the ethmoidal and frontal sinuses and nasal roof; the sphenopalatine branch of the maxillary artery, supplying the mucosa covering the conchae, meatuses and septum; the terminal part of the greater palatine artery, ascending through the incisive canal (p. 354); the septal ramus of the superior labial branch of the facial artery, supplying the septum in the region of the vestibule, anastomosing with the sphenopalatine and presenting a common site of epistaxis; the infraorbital and superior (anterior and posterior) alveolar branches of the maxillary, supplying the mucosa of the maxillary sinus; the maxillary artery's pharyngeal branch, distributed to the sphenoidal sinus. The ramifications of these vessels form a dense mucosal and submucosal plexus.

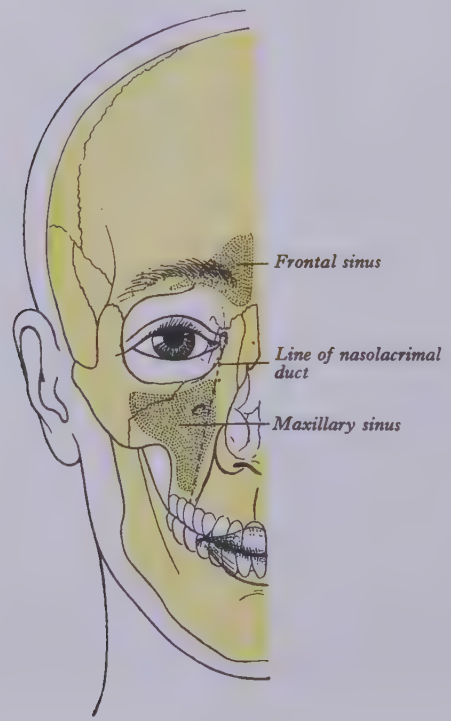
The *veins of the nasal cavity* form a rich submucosal cavernous plexus. Arteriovenous anastomoses also occur (Harper 1947). The plexus is especially dense in the lower part of the septum and in the middle and inferior conchae. Some veins drain to the sphenopalatine; others join the facial vein; some accompany the ethmoidal arteries to end in the ophthalamic veins; a few connect with veins on the orbital surface of the brain's frontal lobes, passing through the foramina in the cribriform plate. When the foramen caecum is patent it transmits a vein from the nasal cavity to the superior sagittal sinus.



The *lymph vessels* are described on p. 844.

The innervation includes branches of the trigeminal and olfactory nerves and autonomic vasomotor and secretomotor fasciculi. The *nerves of ordinary sensation* (7.213, 220) supplying the nasal cavity are as follows: the anterior ethmoidal branch of the nasociliary, supplying the anterior and upper parts of the septum, the anterior part of the roof; the anterior parts of the middle and inferior conchae with the lateral wall anterior to them; the infraorbital nerve, supplying the nasal vestibule; the anterior superior alveolar nerve, supplying part of the septum and the floor near the anterior nasal spine and the anterior part of the lateral wall as high as the opening of the maxillary sinus; the lateral posterior superior and medial posterior superior nasal nerves (including the nasopalatine nerve) which are branches from the pterygopalatine ganglion and the posterior inferior nasal branches of the anterior palatine nerve, supplying the posterior three-quarters of the lateral wall, roof, floor and septum; branches from the nerve of the pterygoid canal to the upper and posterior part of the roof and septum. It is to be noted that all these nerves are derived from the maxillary trigeminal division, with the exception of the nasociliary supply.

Accompanying the sensory fibres in these nerves are postganglionic vasomotor sympathetic fibres to the nasal blood vessels, whilst running with the branches from the pterygopalatine ganglion are postganglionic parasympathetic fibres from this ganglion, providing the secretomotor supply to the nasal glands.



THE PARANASAL SINUSES

The frontal, ethmoidal, sphenoidal and maxillary sinuses (7.284–286, 291–293) vary in size and form in different subjects. Their mucosa is continuous with that of the nasal cavity (a feature unfortunately favouring the spread of infections). The mucosa is similar to that in the respiratory regions of the nasal cavity but is thinner, less vascular and less adherent to bone. Mucus is secreted by glands of the mucosa and is swept into the nose through the apertures of the sinuses by cilia; these are not uniformly distributed but invariably exist near these openings. The functions of the sinuses are uncertain; they lighten the skull and add resonance to the voice; but saving in weight is trivial and the absence of sinuses does not add an equivalent volume of *solid* bone, as the weight of the trabecular bone and enclosed tissue which would occupy such a volume would not be large. It is more probable that sinuses are manifestations of an unusual growth pattern in the bones in which they occur, in part at least. Most sinuses are rudimentary or absent at birth; they enlarge appreciably during the eruption of the permanent teeth and after puberty, markedly altering the size and shape of the face.

7.291 A coronal section through the nasal cavity, viewed from the posterior aspect. On the right side the plane of the section is more anterior. The normal orifice of the maxillary sinus is shown on the right side and the not uncommon accessory orifice on the left side.

Two frontal sinuses, situated posterior to the superciliary arches, lie between the outer and inner tables of the frontal bone. On average, each underlies a triangular area on the surface, its angles formed by the nasion, a point 3 cm above the nasion and the junction of the medial third with the rest of the supraorbital margin (**3**.166, 7.292, 293). They are rarely symmetrical, the septum between them usually deviating from the median plane. Their average measurements are: height 3·2 cm; breadth 2·6 cm; depth 1·8 cm. Each extends upwards above the medial part of the eyebrow and back into the medial part of the orbit roof. A sinus is sometimes divided into a number of communicating recesses by incomplete bony septa. Rarely, one or both sinuses may be absent. The prominence of the superciliary arches is no indication of presence or size of the frontal sinuses. The upward extension in the frontal bone may be small and the orbital part large, or vice versa. Sometimes one sinus may overlap in front of the other. Posteriorly a sinus may reach the sphenoid bone (lesser wing) but does not invade it. Each opens into the anterior part of the corresponding nasal middle meatus by the *ethmoidal infundibulum* or *frontonasal duct*, traversing the anterior part of the ethmoid labyrinth. Rudimentary or absent at birth, they are generally well developed between the seventh and eighth years but reach full size only after puberty (p. 383). They are more prominent in males, giving the forehead an obliquity contrasting with the vertical or convex profile usual in children and females. Their blood supply is from supraorbital and anterior ethmoidal arteries and their venous drainage is into the anastomotic vein in the supraorbital notch connecting the supraorbital and superior ophthalmic veins. *Lymphatic drainage* is to the submandibular nodes. The *nerve supply* is from the supraorbital nerve.

7.292 An outline of the bones of the face, showing the positions of the frontal and maxillary sinuses.

The ethmoidal sinuses (see pp. 384, 385) are small, thin-walled cavities in the ethmoidal labyrinth, completed by the frontal, maxillary, lacrimal, sphenoidal and palatine bones. Ranging from three large to 18 small sinuses on each side, their openings into the nasal cavity are also variable in position. They lie between the upper part of the nasal cavity and the orbits, separated from the latter by the paper-thin orbital plates of the ethmoids, a poor barrier to infection, which may spread into the orbit to give orbital cellulitis. They form anterior, middle and posterior groups on each side. (Some anatomists recognize only an anterior and a posterior group, the anterior including those described here as anterior *and* middle.) The groups are not

sharply delimited from each other; one may encroach on territory usually occupied by another. They are, however, distinguished by their sites of communication with the nasal cavity. In each group the sinuses are only partially separated by incomplete septa. The *anterior group* (the infundibular sinuses), numbers up to 11 which open into the ethmoidal infundibulum or the frontonasal duct by one or more orifices; one sinus often lies in the agger nasi while the most anterior ethmoidal sinus may encroach on the frontal sinus. The *middle group* (bullar sinuses), usually three in number, opens into the middle meatus by one or more orifices on or above the ethmoidal bulla. The *posterior group* (varying from one to seven), usually opens by a single orifice into the superior meatus inferior to the superior concha though one may open into the highest meatus (when present) and one or more into the sphenoidal sinus. The posterior group is very close to the optic canal and optic nerve. The ethmoidal sinuses are small though of clinical importance at birth and grow rapidly between six and eight years and after puberty. Their blood supply is from the sphenopalatine artery (p. 741) and the anterior and posterior ethmoidal arteries and their drainage is by the corresponding veins. The lymphatics of the anterior and middle groups drain to the submandibular nodes, and those of the posterior group to the retropharyngeal nodes. The anterior and posterior ethmoidal nerves and orbital branches of the pterygopalatine ganglion supply the ethmoidal sinuses.

The two sphenoidal sinuses (p. 374, **3**.128, 129) are sited posterior to the upper part of the nasal cavity, within the body of the sphenoid bone. They are related above to the optic chiasma and hypophysis cerebri and on each side to the internal carotid artery and the cavernous sinus. If small, they lie anterior to the hypophysis cerebri. They vary in size and shape and are rarely symmetrical, one often being much larger and extending across the median plane behind the other; occasionally one overlaps above; rarely they intercommunicate. One or both may approach closely or even partly encircle the optic canal. Their average measurements are: vertical height 2 cm; transverse breadth 1·8 cm; anteroposterior depth 2·1 cm. They may extend, if exceptionally large, into the roots of the pterygoid processes, the greater wings of the sphenoid or they may invade the basilar part of the occipital bone. Gaps in their osseous walls may occasionally leave their mucosa in contact with the overlying dura mater. Bony ridges, produced by the internal carotid artery or pterygoid canal, may project into the sinuses from their lateral walls and floor respectively. A posterior ethmoidal sinus may invade the sphenoid to replace largely a sphenoidal sinus. Each sinus connects with a spheno-ethmoidal recess by an aperture high in its anterior wall. They are minute cavities at birth and their main development occurs after puberty. Their *blood supply* is via the posterior ethmoidal vessels; *lymph drainage* is to the retropharyngeal nodes and their *nerve supply* arises from the posterior ethmoidal nerves and orbital branches of the pterygopalatine ganglion.

The two maxillary sinuses, occupying most of the bodies of the maxillae (**3**.98A, 7.291–293), are the largest accessory air sinuses of the nose. Pyramidal in shape, the base of each is the lateral wall of the nasal cavity, the apex extending into the maxilla's zygomatic process. The roof is the floor of the orbit, frequently ridged by the overlying infraorbital canal; the floor is formed by the maxilla's alveolar process and is usually about 1·25 cm lower than the nasal floor, on a line drawn laterally from the lower border of the ala. Conical elevations corresponding to the roots of the first and second molar teeth project into the floor, which they sometimes perforate. Sometimes the roots of the first and second premolars and third molar, and occasionally the canine root, may also project into the sinus (p. 1318). The size of the sinus varies, even on the two sides of an individual skull; when large, its apex may invade the zygomatic bone. Average measurements are: vertical height opposite the first molar 3·5 cm; transverse breadth 2·5 cm; anteroposterior depth 3·2 cm. The sinus opens into the lowest part of the hiatus semilunaris by an aperture in the anterosuperior part of the sinus' base (7.291); a second orifice is often present in or just below the hiatus. Both are nearer the roof than the floor of the sinus. During early development, the sinus is a mere groove on the medial maxillary surface in the fourth prenatal month; it reaches full size after the eruption of all the permanent teeth. The *blood supply* is from the facial, infraorbital and greater palatine vessels; *lymph drainage* is to the submandibular nodes and the *nerve supply* is derived from the infraorbital and the anterior, middle and posterior superior alveolar nerves.

For details of the human and comparative anatomy of the paranasal sinuses consult Negus (1958).

7.293 The skull of an adult woman which has been decalcified and then cleared in methyl salicylate; the specimen was transilluminated and then photographed from the ventral aspect. Note particularly the profiles of the frontal and maxillary paranasal air sinuses, the orbits and superior orbital fissures and the nasal cavities and conchae. The specimen was prepared by D H Tompsett of the Royal College of Surgeons of England.

RADIOLOGICAL APPEARANCES

Normal sinuses are radiolucent, whereas diseased sinuses show varying degrees of opacity. In anteroposterior views (**3**.102C, 129) most of the sinuses are visible. The frontal sinuses appear above the nasal cavity and the medial part of the orbits; their asymmetry, vertical extent and the position of their septa can be assessed. The ethmoidal sinuses are superimposed on each other and on the sphenoidal sinuses in this view, lying between the orbits below the cribriform plate. The sphenoidal sinuses are obscured in this view. Each maxillary sinus is a pyramidal translucent area below the orbit and lateral to the lower part of the nasal cavity, extending inferiorly into the maxillary alveolar process. In lateral views, the extent of the frontal sinus both upwards into the frontal bone and back into the orbital roof can be assessed. The ethmoidal sinuses are seen to extend back from the frontal process of the maxilla as far as the sphenoidal sinus, which is clearly visible below and in front of the hypophysial

fossa, although the two sphenoidal sinuses appear superimposed; the individual sphenoidal sinuses are seen better from above. The maxillary sinus is clearly seen in a lateral view; it lies below the orbit and its relation to the roots of the teeth is obvious.

Maxillary and frontal sinuses can also be transilluminated. In a dark room, a light is placed in the mouth (for the maxillary sinus) or against the superomedial angle of the orbital opening for the frontal sinus. A red glow normally appears but may be absent when the sinuses are diseased. Both these sinuses show well in cleared preparations of the skull (7.293).

Applied Anatomy. Congenital nasal deformities can occur, e.g. a complete absence of the external nose, with only an aperture existing, or else suppression or malformation on one side. The nasal septum may be displaced by injury or congenital defect; sometimes deviation may be so great as to bring the septum and one lateral wall into contact, causing complete unilateral nasal obstruction. Suppuration in the paranasal sinuses occurs frequently and pus from the frontal or anterior ethmoidal sinuses may run via the hiatus semilunaris into the maxillary sinus, which thus becomes a secondary reservoir for pus. All paranasal sinuses can be infected from the nasal cavity but a maxillary infection may also spread from the teeth (p. 1318) and this sinus is most often chronically infected, resulting in the loss of mucosal cilia and an impaired flow of mucus. Because its opening is high above its floor, the natural drainage of the maxillary sinus is hindered but may be effected by puncture in the lateral wall of the inferior nasal meatus or through the canine fossa on the anterior surface of the maxilla, which is nearer to its floor.

THE VISUAL APPARATUS

Introduction

The all-pervading nature of sunlight, the environment of almost all animal and plant life, makes a response to this form of electromagnetic radiation inevitable. The photosynthetic processes in plants are paralleled by photochemical receptors occurring almost universally in the animal kingdom. Though the range of frequencies in solar radiation is much wider, the visible spectrum (400–760 nm) is the range within which most animal *photoreceptors* function. Some receptors react outside this range, either to ultraviolet or infra-red frequencies; in vertebrates some vipers and boas (Walls 1963) have facial pit organs responding to infra-red radiation. But in general *visual pigments*, the basis of photochemical response, display absorption maxima within the visible spectrum, e.g. human *rhodopsin* (visual purple), a retinal rod pigment, has a maximum at 497 nm. *Iodopsin*, a cone pigment, occurs in some avian species and several pigments exist in human cones, where differing absorption maxima may account for colour vision, though this is not fully determined (Rushton & Henry 1968). The basis of the sensory response is a light-induced 'bleaching', the pigment changing to another form, with an accompanying electrical flux propagated by chemical transmission from photoreceptors to primary neurons. A rapid restoration of the pigment is obviously essential. Many visual pigments have been identified; further details may be obtained in monographs (e.g. Rushton 1962, Pirenne 1967, Davson 1976).

Next in the elaboration of visual organs is the introduction of a lens to concentrate light energy on photoreceptors and impart spatial discrimination. Many such adaptations have occurred in invertebrates, mostly in two forms: the eyes, as we may now call them, with many separate lens-photoreceptor units, the *compound eyes* familiar in insects and crustaceans; and a *single lens*, focusing light on an array of photoreceptors, as in snails and squids. The latter type is universal in vertebrates.

Such true eyes not only respond to varying *luminance*, a simple function of photoreceptors; by projecting a focused image on an array of receptors, each with neural pathways of some degree of specificity, a new modality appears, sensitivity to *form*. In both modes movement (always of great biological meaning) is detectable but the vertebrate type of focusing eye has potentialities for greater precision.

Primitively, vision is used for reception at a distance, to activate warning systems and to orientate the animal advantageously in light and shade. The paired eyes of most vertebrates, being lateral in position, permit an almost panoramic view. Such *panoramic vision*, with muscles which rotate the eyes reflexly towards anything of interest, especially movements (of prey, mate, or predator) is typical of mammals, in a few of which, and in some raptorial birds, the orbits have changed position so that two uniocular fields, each subtended by one eye, overlap to a greater or lesser extent. Part of the field in front of the animal is hence binocular. By gradual refinement of the control of ocular muscles, with constant retinal feedback, ocular movements become concerted enough to 'fuse' the two slightly dissimilar retinal images, leading finally to full *binocular vision*. This advance is usual in carnivorous mammals, who may track prey partly by smell but rely on accurate directional vision for the final attack. Primates also have binocular vision; the arboreal factor in their evolution is generally regarded as leading to not merely binocular, but *stereoscopic vision*, allowing a higher motor 'understanding' of three-dimensional space. Olfaction is less useful in trees; acquisition of the skill in not merely climbing but swinging or leaping from branch to branch could only evolve with stereoscopic vision (see also p. 11). An arboreal habitat also favoured the retention and elaboration of pentadactyl, grasping extremities. Though man, and perhaps his immediate ancestors, is not arboreal, the terrestrial specialization of feet has not afflicted his hands. Freed from locomotion by the adoption of a bipedal gait, human hands have formed a most significant partnership with the eyes. This, with the associated development of a large brain, able to process with increasing intricacy highly detailed information from the eyes and other senses and to co-ordinate the eyes and hands in increasingly skilful and subtle tasks, these surely are the leading trio of factors in the extraordinary evolution of human abilities.

The eye, therefore, is not to be viewed in isolation. Its array of modalities—sensitivity to minute changes in luminosity, particularly in dark-adapted, *scotopic vision*, high discrimination of form, movement and colour in light-adapted, *photopic vision*—do not merely provide interesting information. The information is vital; a blind individual cannot long survive outside human society. The eyes continuously guide almost all that we do, especially in manual tasks. Visual communication has proved more useful and lasting than even auditory. The gradual evolution of visual signs, reacting with auditory communication, has led to language in all its permutations; and through language, with its potentialities for the exchange of increasingly precise information and conceptual influences, it becomes possible for generation after generation to profit from recorded knowledge in a unique extension of evolutionary progress. In human culture this now provides the mainstream of evolution. It is against this background that the structure of the visual apparatus should be studied.

THE PERIPHERAL VISUAL APPARATUS

The eyeball, the peripheral organ of vision, is situated in a skeletal cavity, the orbit, the walls of which help to protect it from injury; they also have a more fundamental role in the visual process itself in providing a rigid support and direction to the eye and in forming the sites of attachment to its external muscles. This setting permits the accurate positioning of the visual axis under neuromuscular control and determines the spatial relationship between the two eyes needed for binocular vision and conjugate eye movements. In the following account, the structure of the eyeball itself will first be considered and then certain accessory structures, including extrinsic muscles, fasciae, eyebrows, eyelids, conjunctiva and the lacrimal apparatus, will be described.

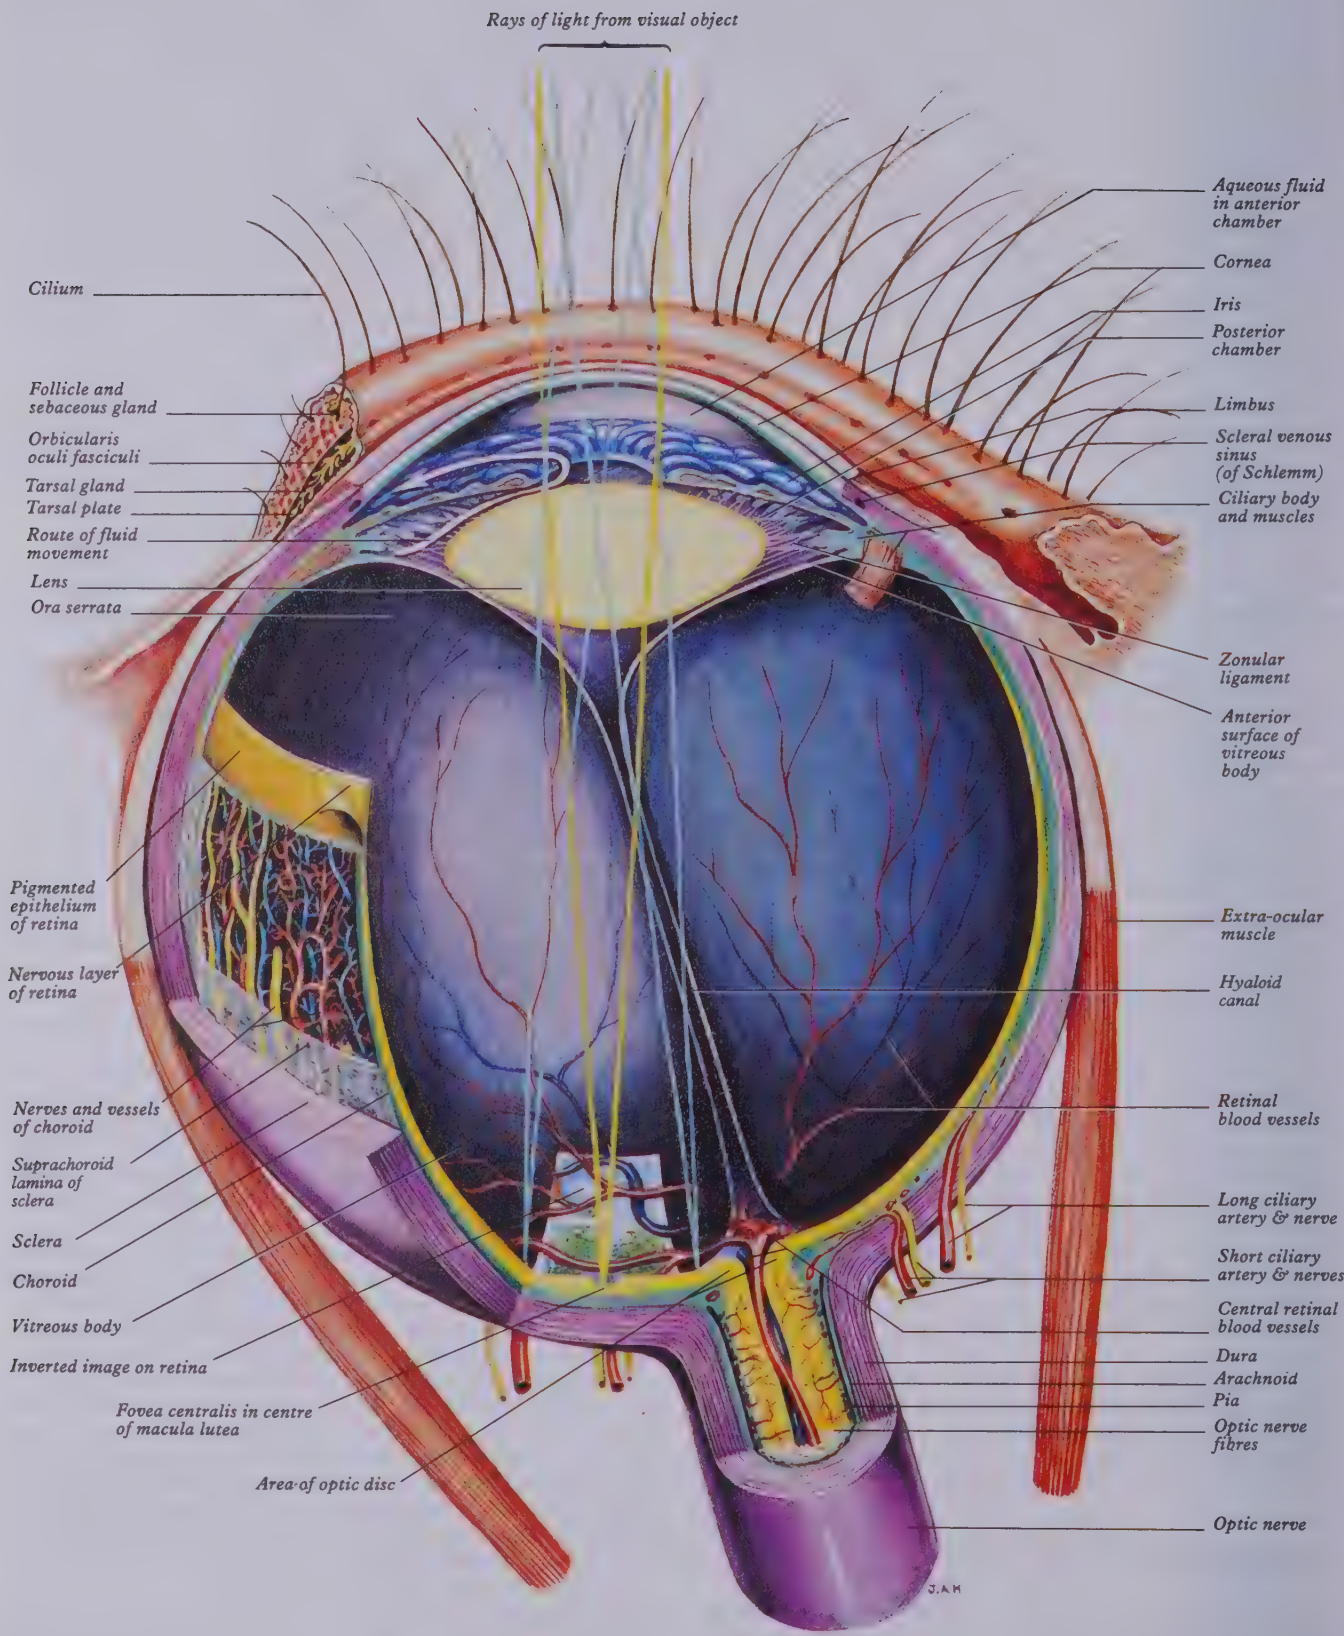
The eyeball is embedded in orbital fat, separated from it by a thin *fascial sheath* (capsule of Tenon) (p. 1213). The eyeball can be considered as being composed of the segments of two spheres of different radii. The anterior segment, part of the smaller sphere, is transparent and forms about one-sixth of the whole globe; it is more prominent than the posterior segment, which is part of a larger sphere and opaque, forming the remainder of the globe. The *anterior segment* is bounded by the cornea and the lens and is incompletely subdivided into *anterior* and *posterior chambers* by the iris, being continuous through its pupil. The anterior chamber's periphery is slightly overlapped by the sclera; thus the *angle* between the iris and cornea (p. 1183) forms an annulus of greater diameter than the *limbus*, the junction between the sclera and cornea. The difference between these two varies from 1 to 2 mm, the angle being deeper above and below than at the sides of the eyeball. The posterior chamber, between the posterior surface of the iris and the anterior aspect of the lens and its supporting ligament, the *zonule* (p. 1205), is triangular in section, the apex of the triangle being where the iris touches the lens; its base or zonular region is not the zonule itself, since the posterior chamber extends among the zonule's collagenous bundles and even into a *retrozonular space* (canal of Petit) between the zonule and the vitreous humour in the posterior segment of the eyeball. The *posterior segment* consists of the parts of the eye posterior to the zonule and lens.

The *anterior pole* is the centre of the anterior (corneal) curvature, the *posterior pole* the centre of its posterior (scleral) curvature; a line joining these two points forms the *optic axis*. (By the same convention, the eye has an *equator*, equidistant between the poles; any circumferential line joining the poles is a *meridian*.) The optic axes of the two eyes, in their primary position, are parallel and do *not* correspond with the orbital axes which diverge anterolaterally at a marked angle to each other (vide infra). The optic nerves follow the orbital axes and are therefore not parallel; each enters its eye about 3 mm medial (nasal) to the posterior pole. The ocular vertical diameter (23·5 mm) is rather less than the transverse and anteroposterior diameters (24 mm); the anteroposterior diameter at birth is about 17·5 mm and at puberty 20–21 mm; it may vary considerably in *myopia* (c 29 mm) and in *hypermetropia* (c 20 mm). In females all diameters are on average slightly less than in the male (Stenstrom 1946, Sorsby & Sheridan 1960).

The eye has three *tunics* enclosing its contents. From without they are: (1) a fibrous tunic consisting of the *sclera* behind and the *cornea* in front; (2) a vascular, pigmental tunic comprising from behind forwards the *choroid*, *ciliary body* and *iris*, collectively termed the *uveal tract*, (3) a neural layer, the *retina*.

The Ocular Fibrous Tunic

The fibrous layer of the eyeball (7.294) has an opaque, posterior *tunica sclera* and a transparent, anterior *tunica cornea*.



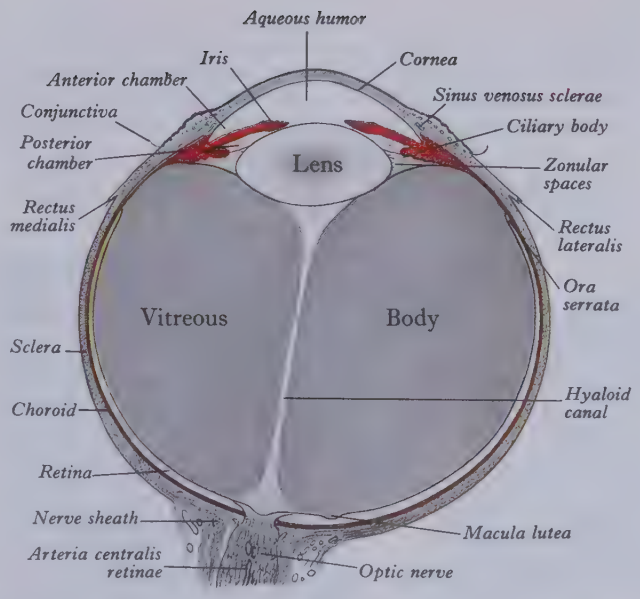
THE SCLERA (TUNICA SCLERA)

The sclera, so named from its relatively hard consistency, is a dense layer which, when distended by intraocular pressure, maintains the shape of the eyeball. It is thickest (about 1 mm) posteriorly, near the optic nerve's entry point and is thinnest (0·4 mm) about 6 mm behind the corneoscleral junction, near the attachments of the recti (p. 1208). Its *external surface* is white and smooth, except where the tendons of ocular muscles are attached; it is in contact with the inner surface of the fascial sheath of the eyeball (p. 1213). Its anterior part is covered by conjunctival epithelium, reflected on to it from the deep surfaces of the eyelids and continued on to the cornea anteriorly. The scleral *internal surface* is brown and is grooved by the ciliary nerves and vessels. It is separated from the external aspect of the choroid by an extensive *perichoroidal space*, traversed by an exceedingly delicate cellular tissue, the *suprachoroid lamina* (*lamina fusca sclerae*). Posteriorly, the sclera is pierced by the optic nerve and is continuous with the nerve's fibrous sheath and hence with the dura mater. Where the nerve pierces the sclera, the latter has the appearance of a cribriform plate, the *lamina cribrosa sclerae* (7.309, 310), the minute orifices in which transmit the optic nerve's fascicles. A larger, central aperture in this structure contains the central retinal artery and vein. The lamina cribrosa is the weakest part of the sclera and bulges outwards in the condition of a 'cupped disc' when intraocular pressure is raised in chronic conditions such as glaucoma. Around the perimeter of the cribriform lamina numerous small apertures transmit the ciliary vessels and nerves; about midway between these and the corneoscleral junction are four or five large apertures for veins (*vernae vorticosae*). The sclera is directly continuous with the cornea at the *corneoscleral junction* (*limbus*). In the sclera near this region is an annular, endothelial canal, the *sinus venosus sclerae*; in section this is an oval cleft, whose outer wall is formed by a groove in the sclera. Posteriorly this cleft extends as far as a rim of scleral tissue, the *scleral spur* which is in section a triangle with its apex directed forwards (7.295). The sinus (the so-called canal of Schlemm) may be double or multiple in parts of its course. Its inner wall, adjoining the aqueous chamber, consists of loose trabecular tissue continuous anteriorly with the posterior limiting lamina of the cornea; among its fibres are spaces through which aqueous humour filters from the anterior chamber into the sinus (7.299), thence draining peripherally into the anterior ciliary veins. Normally the sinus contains no blood; though the channels between the sinus and the veins have no valves, they are oblique and flattened, which may prevent the reflux of blood. However, this valvular mechanism is dubious and pressure gradients are more likely to prevent such a reflux; in venous congestion blood may indeed enter the sinus. To the scleral spur's anterior, external aspect are attached most of the fibres of the trabecular tissue mentioned above and to its posterior, internal aspect, the meridional fibres of the ciliaris. The anterior chamber's *iridocorneal angle* (7.295) lies between the trabecular tissue and the scleral spur anteriorly and externally and the periphery of the iris posteriorly and inwards.

Structurally, the sclera is composed of dense collagenous tissue mixed with fine elastic fibres and interspersed with flat fibroblasts, some of them being pigmented. The fibres are arranged in bundles arranged in patterns characteristic of various scleral regions: they are circumferential around the optic disc, reticular anterior to this and meridional near the attachments of the four rectus muscles (Kokott 1934). Individual *fibrils* vary in diameter from 28 to 280 nm with periodicities of 80 and 21 μm. Collagen forms 75% of the dry scleral weight. The sclera is viscoelastic, a factor important in the regulation of intraocular pressure (Gloster et al 1957, Helen & McEwen 1961). Its *vessels* are few and its capillaries small, uniting at wide intervals. Its innervation is derived from the ciliary nerves.

THE CORNEA

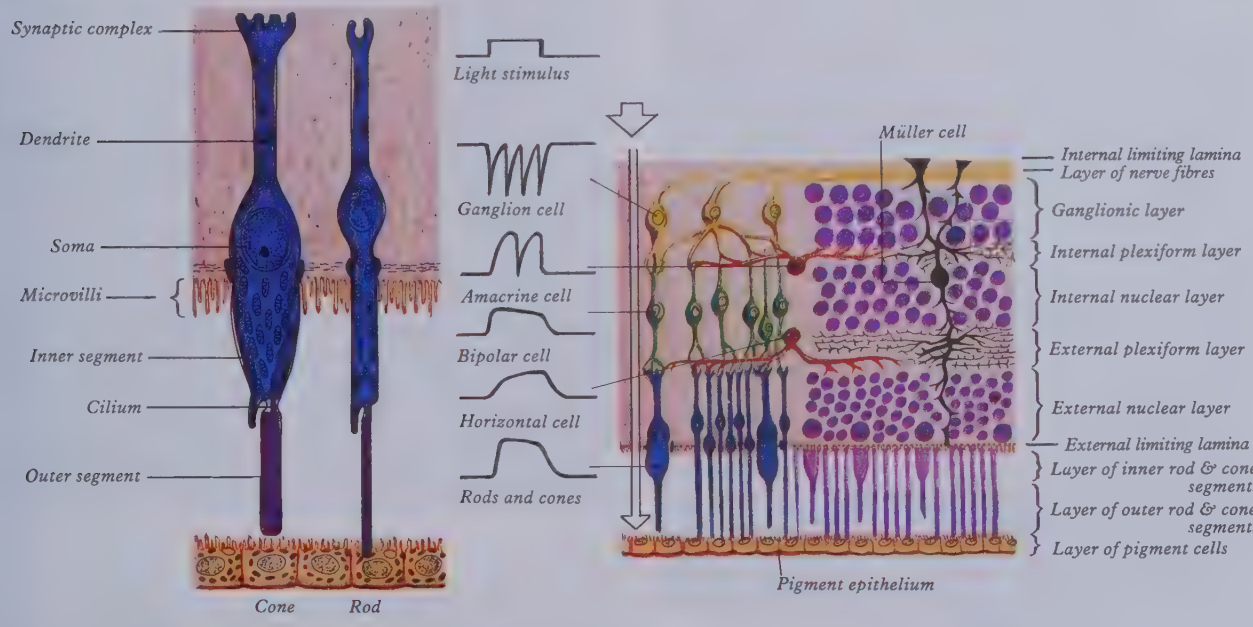
The cornea (7.294) is the anterior, projecting transparent part of the external tunic and the major site of refraction of light entering the eye. Convex anteriorly, it projects from the sclera as a flattened dome. Its curvature varies even in the same eye at different periods of life, being greater in youth than old age. Since it is more curved than the sclera, a slight *sulcus sclerae* marks the



7.294A The organization of the eye, viewed from above. In this illustration the right eye and part of the lower eyelid are depicted in horizontal section and also cut away to show internal structure (compare 7.294B).

corneoscleral junction. It is dense, about 1·2 mm thick at its periphery and 0·5–0·6 mm at its centre. Its anterior surface is slightly ellipitical, the transverse diameter being a little greater than the vertical; its posterior surface is circular and, because the corneoscleral junction is slightly oblique above and below, it is more extensive than the anterior surface in its vertical axis. The corneal diameter is about 11·7 mm on its posterior aspect; anteriorly it is 11·7 mm horizontally and 10·6 mm vertically. The cornea (7.296–298) consists from in front backwards of five layers: (1) the corneal epithelium, continuous with the conjunctiva; (2) the anterior limiting membrane (of Bowman); (3) the substantia propria; (4) the posterior limiting lamina (of Descemet); (5) the endothelium of the anterior chamber.

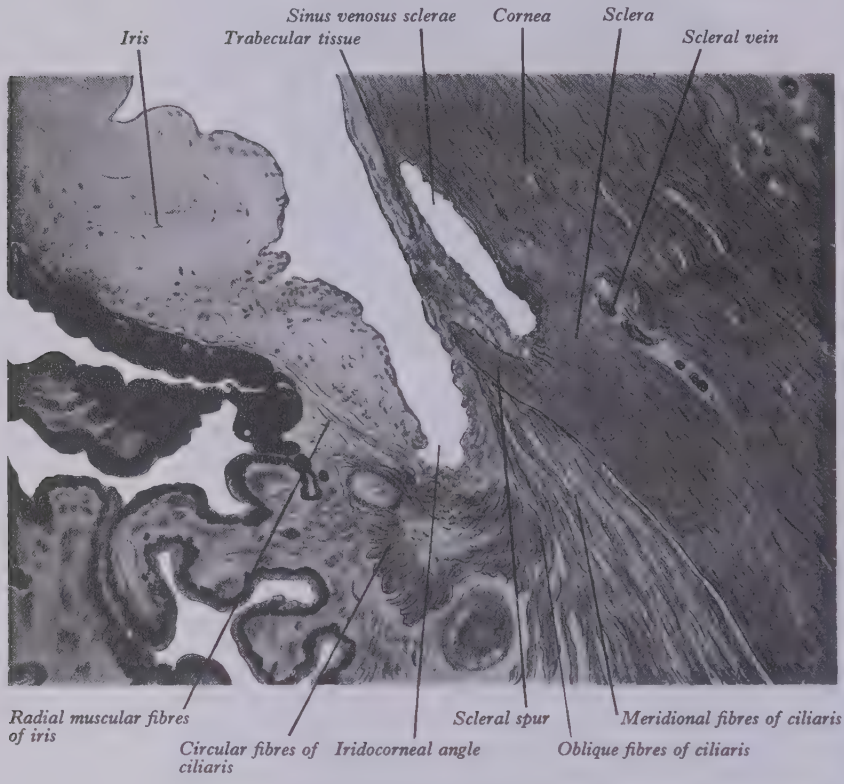
The *corneal epithelium* covers the cornea anteriorly and generally has five layers of cells, the deepest being columnar with flat basal surfaces and rounded apices; they have large round or oval nuclei. Cells in the second layer are polyhedral, with oval nuclei; in the more superficial layers the cells become progressively flatter but, unlike those in the epidermis, they contain flat nuclei and are not normally keratinized. Most corneal epitheliocytes are 'prickle' cells, like those in the epidermal stratum spinosum (p. 73). At the corneoscleral junction (limbus) the epithelium thickens to 10 or more layers and is continuous with the scleral conjunctiva. Surface corneal cells display, as in the conjunctiva, microvilli and microplicae (Dohlman 1971), which may help to maintain an unbroken film of secretion (Andrews 1975) at this primary refractive surface of the eye. Scanning electron microscopy (7.297) has confirmed the presence of these features; fine irregularities (microvilli) are mixed with more numerous sinuous, communicating ridges. These two types of surface structure appear to predominate in different cells, some displaying microvilli and some microplicae, while some have both in varying proportions and a few have them only in their central surface.



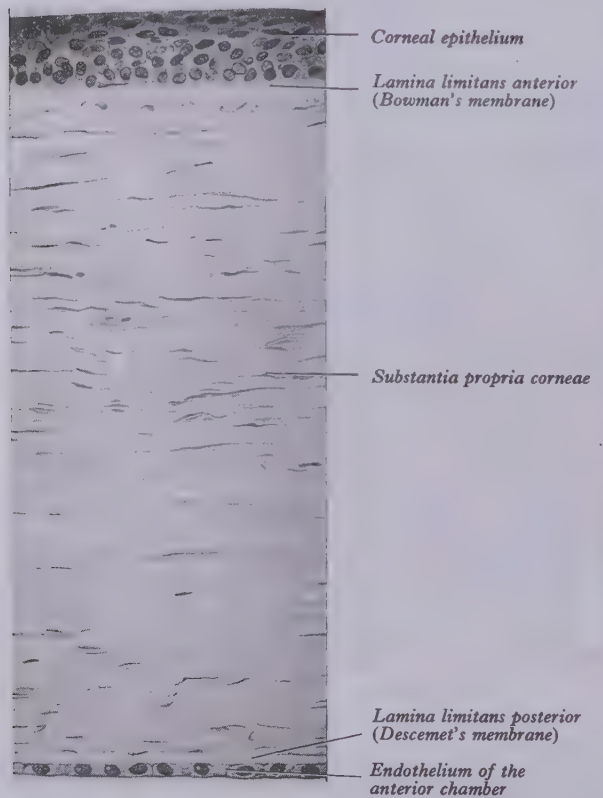
The *substantia propria* is fibrous, compact and perfectly transparent, composed of about 200–250 superimposed lamellae of Type II collagen fibres (p. 64) and some interstitial proteoglycans, continuous with the matrix of the sclera. Each lamella is about 2 μm thick and of variable width (10–250 μm). Fibres in each lamella are parallel but at large angles to those in the adjacent lamellae. They often pass between the lamellae and vary in size, being larger near the posterior limiting membrane; their diameters vary from 21 to 65 nm. Between lamellae is a little ground substance containing fibroblasts, stellate or dendritic in shape and interconnected. Nomadic macrophages, lymphocytes and polymorphonuclear leucocytes may invade the substantia propria.

7.294B A horizontal section through a right human eyeball: superior aspect.

Beneath the corneal epithelium is the *anterior limiting lamina* (Bowman's membrane) containing fine interweaving fibrils like those of the substantia propria but lacking fibroblasts. It is about 8 μm in thickness, its collagen fibres being randomly arranged; their width varies from 14 to 35 nm, being much narrower than those of the corneal stroma.



The *posterior limiting lamina*, covering the substantia's posterior surface, is thin, transparent and homogeneous. Microscopy with ultraviolet or polarized light shows it to be stratified and



7.294C Retinal structure, showing the organization of the photoreceptors (left) and the layers of the retina (right), including an indication of some of the electrical responses encountered at different depths. Details of neuronal circuitry are not depicted in this diagram; for further information see 7.315 and accompanying text.

fibrillar, as electron microscopy confirms. It is thicker than the subjacent endothelium, of which it is regarded as the basement membrane. It separates easily from both the endothelium and the corneal stroma. At the limbus of the cornea it disperses into the fibres of trabecular tissues adjoining the inner wall of the scleral venous sinus (7.299); between these trabeculae are the *spaces of the iridocorneal angle*, connecting with the sinus venosus sclerae and with the anterior chamber. Some trabecular fibres continue, internal to the scleral spur, into the iris as the *iridial pectinate ligament*; others connect with the spur's sloping external surface, a few reaching the anterior part of the choroid. The relationships of the trabecular spaces, anterior chamber and scleral venous sinus and their functional interconnections remain the subject of some controversy (see Davson 1976).

The *endothelium of the anterior chamber* covers the posterior limiting lamina, is reflected on to the front of the iris and lines the spaces at the iridocorneal angle. The endothelium is a layer of polygonal, flattened cells; at adjacent borders they have complex, interdigitating profiles when seen by scanning electron microscopy but their surfaces show only a few microvilli.

7.297 Scanning electrical micrographs of normal human corneal epithelial cells. In A (magnification × 5000) parts of the outlines of several cells are visible; in the upper and lower cells, microvilli predominate but some microplicae are seen. The cells at the right of the field display predominantly microplicae, with only a few microvilli. In B (magnification × 30 000) a small number of microvilli are scattered amongst abundant microplicae. By permission of Pfister & Burstein 1977.

Vessels and Nerves. The cornea is non-vascular, the capillaries of the conjunctiva and sclera ending in loops near its periphery. Lymph vessels are also absent. The *nerves* are numerous and arise as branches of the ophthalmic nerve, particularly the long ciliary nerves. They form an *annular plexus* around the periphery of the cornea, from which radial fibres enter the substantia propria, losing their myelin sheaths and endoneurium (Matsuda 1968) to ramify throughout its matrix in a delicate reticulum. Their terminal filaments form an intricate *subepithelial plexus*, from which fine, varicose fibrils traverse the anterior limiting membrane to form an *intra-epithelial plexus*. There are no specialized end-organs and in the epithelial nerve the fibres are devoid of Schwann cells; they do not arborize. Electron microscopy of simian corneal nerves suggests that stromal nerves do not enter the epithelium, whose nerves arise instead directly from the limbus (Lim & Ruskell 1978).

The fibrous tunic of the eye is often described as being merely protective, but its common, continuous functions are to provide a smooth translatable external surface (vide infra), a suitable attachment for muscles and a resistance to the intraocular pressure. It is thus essential to the maintenance of the shape and dimensions of the eye. For further details of the cornea and sclera see Jakus (1964), Laugham (1969), Davson & Graham (1974) and Davson (1980).

The Vascular Tunic

The vascular tunic, or *uveal tract*, comprises the choroid, ciliary body and iris (7.294), forming a continuous structure. The choroid covers the internal scleral surface, extending forwards to the ora serrata. The ciliary body continues from the anterior edge of the choroid to the circumference of the iris. The iris is a circular diaphragm behind the cornea, presenting an almost central aperture, the pupil.

THE CHOROID

The choroid is a thin, highly vascular, dark brown tissue which lines almost the posterior five-sixths of the eye; it is pierced behind by the optic nerve and is here firmly adherent to the sclera. Posteriorly it is thicker. Its external surface is loosely connected to the sclera by the *suprachoroid lamina* (lamina fusca); internally it is firmly attached to the retinal pigmented layer. At the optic disc it is continuous with the pia-arachnoid tissues around the optic nerve.

Structurally, the choroid consists largely of a dense capillary plexus, with its small arteries and veins of supply. The blood flow through the choroid is high, a feature probably associated with an intra-ocular pressure of 15–20 mmHg, requiring a venous pressure above 20 mmHg to maintain circulation. Metabolic demand is low; the blood loses only 3% of its oxygen (Bill 1970). The warming effect of the choroidal circulation on the eye may be important. Externally is the *suprachoroid lamina*, about 30 μm thick, composed of delicate non-vascular lamellae, each a network of fine collagen and elastic fibres with stellate cells containing dark brown granules. Ganglionic neurons and neural plexuses are enmeshed in the connective tissue. Mesothelium-lined spaces, sometimes described, are unconfirmed by more recent ultrastructural observations and pathological accumulations of fluid may split the suprachoroidal lamellae, exaggerating a potential 'perichoroidal' space. All such potentially weak zones of connective tissue are a great attraction to those in search of ocular lymph spaces.

The choroid proper (7.301) lies internal to the suprachoroid lamina (which is partly scleral tissue) and has a number of layers. Although descriptions of these vary, those generally recognized are: (1) an external *vascular lamina* of small arteries and veins and loose connective tissue, with scattered pigment cells; (2) an intermediate *capillary lamina* (choroidocapillaris); (3) a thin, apparently structureless *basal lamina* (membrane of Bruch). The vascular lamina is sometimes subdivided on the basis of blood vessel calibre, which naturally decreases towards the capillary lamina. But these vessels are relatively small whereas the capillaries are large and dominant. The vascular lamina contains the terminals of short posterior ciliary arteries (7.306) which extend meridionally from their entry through the sclera near the optic disc. The veins are larger, converging spirally on to four or five principal *vorticose veins*, which pierce the sclera to reach tributaries of the ophthalmic veins. The capillary lamina, separated from the retina only by the thin basal lamina of the choroid, provides a nutritive supply to the layers of the retina, at least in part. It constitutes a close meshwork of vessels, especially in the posterior region of the eye; but its meshes widen towards the ciliary body, where they connect with capillaries in the ciliary processes. The basal lamina is a glassy, homogeneous layer (lamina vitrea) under the light microscope, only 2–4 μm thick. Electron microscopy reveals that it has a more complex substructure. It has a middle stratum of elastic tissue between an internal and an external layer of collagenous tissue, united externally to the choroidocapillary basement membrane and internally to the basement membrane of the retinal pigment cell layer (Lerche 1965, Nakaizumi 1964). Its function is uncertain but is obviously related to the passage of fluid and solutes from the choroidal capillaries to the retina. It is also said to provide a smooth surface for the precise orientation of retinal pigment cells and receptors. It is formed by both the retina and the choroid (Takei & Ozanics 1955), the former contributing the basement membrane of the retinal pigment epithelium. Its external stratum is associated and perhaps identical with the basement membrane of the choroidal capillary endothelium. The functions of choroidal pigment cells are uncertain; they may prevent the passage of light through

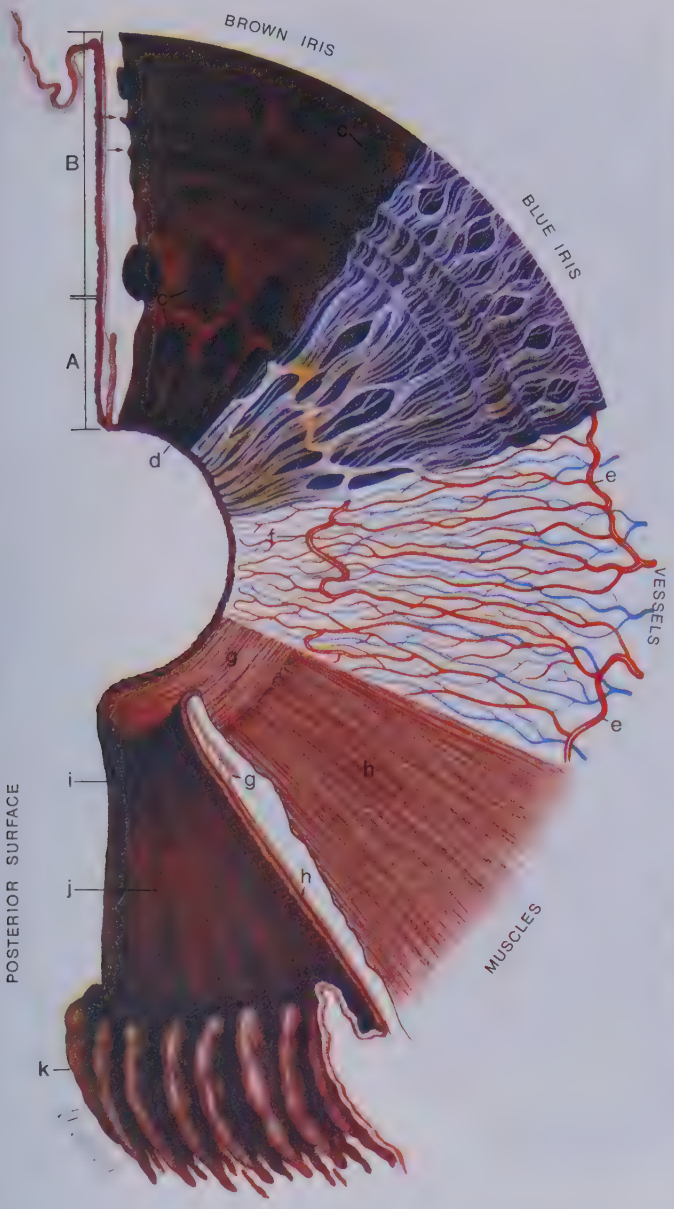
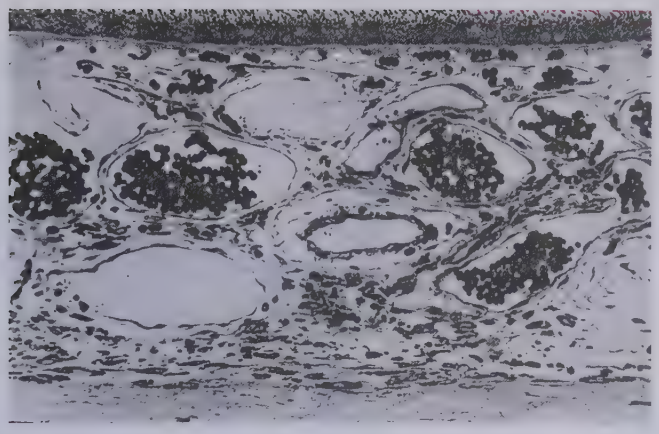
7.299 The iridocorneal angle and adjoining structures, showing the proximity of the scleral venous sinus (aa) to the pectinate ligaments (ff). The trabecular meshwork of the latter is partly uveal, being continuous with the iris (h) and ciliary body (CB) and muscle (i). Anterior to the scleral spur (d), scleral trabecular tissue (c) is even closer to the scleral venous sinus. Aqueous fluid percolates through this trabecular region, reaching the lumen of the sinus through small apertures (b). The pectinate ligament diminishes as it approaches the corneal limbus (e) and in this junctional zone the posterior limiting membrane (of Descemet) also terminates (g). The endothelium of the anterior chamber (posterior corneal epithelium) is continuous with the endothelium of the trabeculae (j) at the limbus. From Hogan et al 1971, by permission of the authors, artist and publishers. 7.300, 303, 304, 305, 321 and 324 are from the same source.



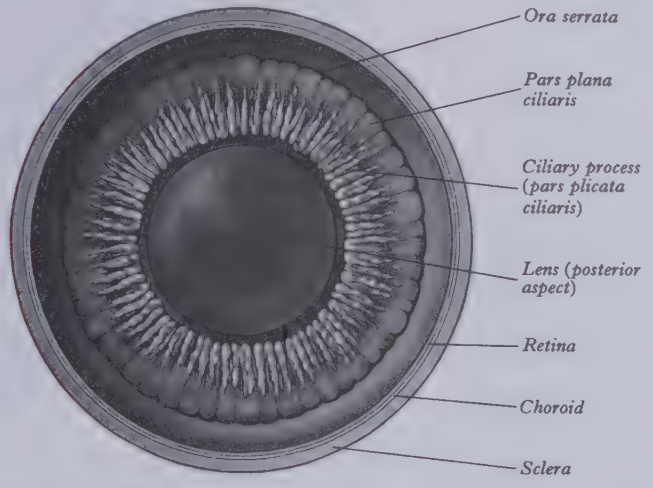
the sclera to the retina but they are more likely to absorb light traversing the retina, preventing internal reflexion within the posterior chamber of the eye. In many mammals, especially those of nocturnal habit, specialized choroidal cells form a reflecting *tapetum*, responsible for the greenish glare in their eyes at night (Walls 1963); its function is uncertain but it may be a mechanism of aggression or a means of augmenting the stimulation of retinal receptors under low light conditions.

Although clinical evidence suggests that the choroid has a nerve supply, the anatomical evidence is scant. Crush lesions of the ophthalmic nerve (Bergmanson 1977) in simians yielded no evidence of any suprachoroidal fibres from ciliary nerves and no degenerating fibres were found terminating within the choroid.



THE CILIARY BODY

The ciliary body is directly continuous with the choroid and extends into the iris; all these regions of the uveal tract have various features in common but also have regional differences related to variations in their function. The ciliary body is concerned with the suspension of the lens and with accommodation, accounting for the accumulation of muscle fibres which cause it to bulge internally (7.303). It is also a major source of aqueous fluid for the anterior segment of the eye, which its anterior aspect faces. Posteriorly it is contiguous with the vitreous humour and probably secretes some of the glycosaminoglycans of the vitreous body. The anterior and the long and short posterior ciliary arteries meet in the ciliary body (7.305), which is therefore a highly vascular region, involved not only in secretory and muscular activities but also in the blood supply to the iris and limbus. The ciliary body is traversed by the major nerves to all the anterior tissues of the eyeball.



Externally the ciliary body extends from a line about 1·5 mm posterior to the limbus of the cornea (corresponding also to the scleral spur) to a line about 7·5–8 mm posterior to this on the temporal side and 6·5–7 mm on the nasal. The ciliary body is thus slightly eccentric and extends posteriorly from the scleral spur which is its attachment, with a meridional width varying from 5·5

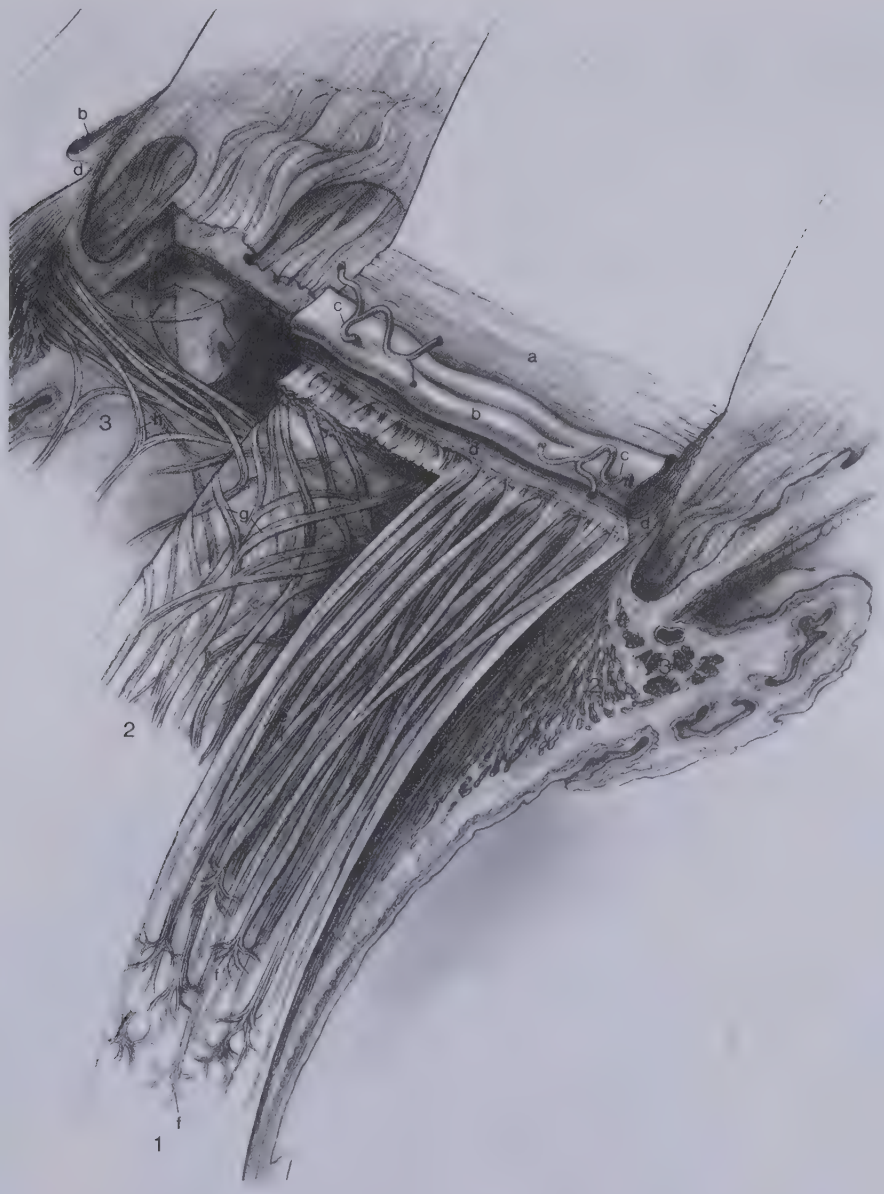
7.300 Composite view of the surfaces and internal strata of the iris. In a clockwise direction from above, the pupillary (A) and ciliary (B) zones are shown in successive segments. The first (brown iris) shows the anterior border layer and the openings of crypts (c). In the second segment (blue iris), the layer is much less prominent and the trabeculae of the stroma are more visible. The third segment shows the iridial vessels, including the major arterial circle (ee) and the incomplete minor arterial circle (f). The fourth segment shows the muscle stratum, including the sphincter (g) and dilatator (h) of the pupil. The everted 'pupillary ruff' of the epithelium on the posterior aspect of the iris (d) appears in all segments. The final segment depicts this aspect of the iris, showing radial folds (i and j) and the adjoining ciliary processes (k). See 7.299 for acknowledgement.

7.301 Light micrograph of a section of human eyeball showing full thickness of the choroid coat and adjacent parts of the retina (above) and sclera (below). Note, from above downwards: rod and cone processes projecting among pigment cells, the basal lamina (membrane of Bruch), layer of capillaries (choriocapillaries), layer of larger vessels and loose connective tissue merging into the sclera. Numerous pigment cells are scattered throughout the choroid. Provided by John Marshall, Institute of Ophthalmology, London. Magnification × 350.

7.302 The interior aspect of the anterior half of the eyeball.

to 6·5 mm. Internally it shows a posteriorly crenated or scalloped periphery where it is continuous with the choroid, termed the *ora serrata*. Anteriorly it is confluent with the periphery of the iris, lateral to which it bounds the anterior chamber's iridocorneal angle. The ciliary body is grey, due to melanin in the deeper layer of its epithelium. It has an anterior plicated part, the *corona ciliaris* (pars plicata), surrounding the base of the iris and posterior to this is a smooth, annular *orbiculus ciliaris* (pars plana, ciliary ring). The orbiculus forms more than half of the meridional width of the ciliary body, being 3·5–4 mm across; its peripheral rim is the ora serrata, at which the *optical* or sensory part of the retina is suddenly reduced to two layers of epithelial cells, extending over the whole ciliary body as the *pars ciliaris retinae* and beyond this on to the posterior surface of the iris. The corona ciliaris, a smaller annular region within the orbiculus, is ridged meridionally by 70–80 *ciliary processes* radiating from the base of the iris to the orbiculus (7.302). Branching from the sides of these ridges into valleys between them are numerous minor ridges, the *ciliary plicae*, forming a complex pattern of intricate microscopic folds (7.253). Fibres of the *zonule* (the suspensory ligament of the lens) extend into the valleys, passing beyond the ciliary processes to fuse with the basement membrane of the superficial epithelial layer of the orbiculus ciliaris. Their sites of attachment are marked by striae passing back from the valleys of the corona across the orbiculus almost as far as the apices of the dentate processes of the ora serrata (7.303).

The ciliary epithelium is bilaminar, its two layers of simple epithelium being derived from the optic cup's two layers. The *superficial lamina*, made up of columnar cells overlying the orbiculus and cuboidal cells over the ciliary processes, becomes irregular and more flattened between the processes. These cells, containing little or no pigment, are the sole anterior continuation of the *neural* layers of the retina, apart from its pigment epithelium, which is continuous with the *deeper layer* of the ciliary epithelium. The cells of the latter are also approximately cuboidal and are loaded with pigment. The two layers are firmly united, although pathologically fluid may separate them, just as the retina



7.303 A magnified view of the ciliary region seen from the ocular interior. Above is the periphery of the lens, attached by the fibres of the *zonule* (suspensory ligament) to the processes of the *corona ciliaris* (pars plicata) of the ciliary body (a). The *orbiculus ciliaris* or pars plana ciliaris (b) has a scalloped boundary, the *ora serrata* (c), which separates it from the retina (d). Flanking the 'bays' (e) of this are the *dentate* processes (f), with which linear ridges or *striae* (g) are continuous. These striae extend forwards between the main ciliary processes, providing an attachment for the longer zonular fibres. The posterior aspect of the iris shows radial (h) and circumferential (i) sulci. See 7.299 for acknowledgement.

detaches from its own pigment epithelium. A basement membrane exists between the two epithelia. Basally the superficial cells are much infolded, like other secretory epithelia. These superficial cells are connected by desmosomes; their cytoplasm contains many mitochondria and a well-developed endoplasmic reticulum, often stacked in perinuclear arrays. Lipid and melanin granules are often present but are not prominent.

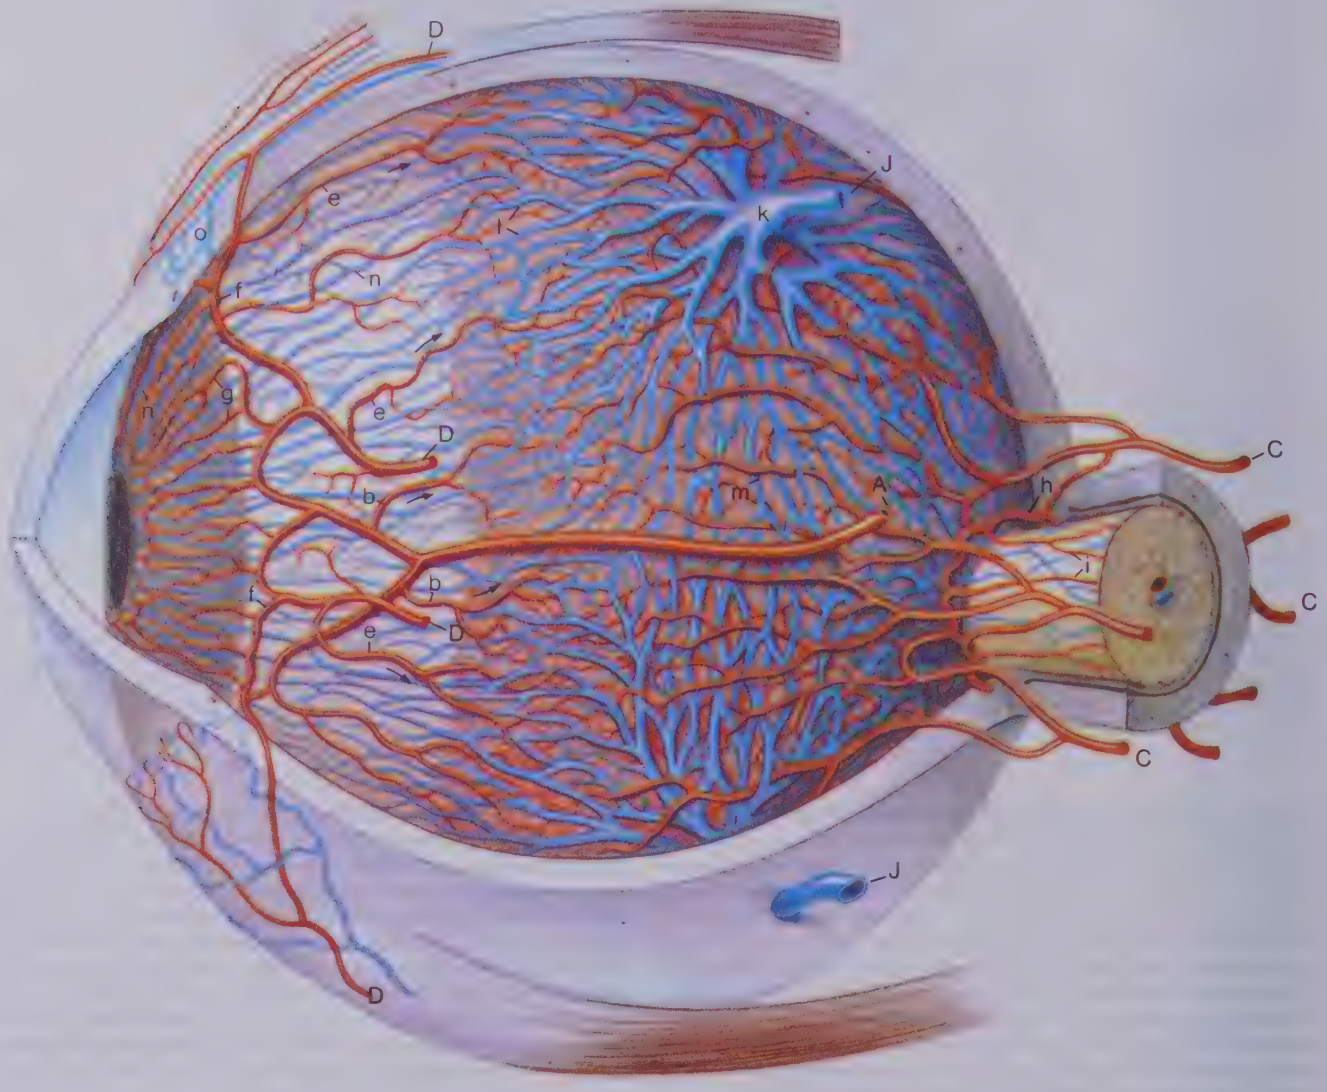
The pigment layer is united to the stroma of the ciliary body by its basement membrane, which continues back into the basal lamina of the choroid (p. 1185). The cytoplasm of these cells contains abundant rounded melanin granules 0·6–0·8 μm in diameter. Cells are linked by a few lateral desmosomes, which are more numerous between the two epithelial strata, despite the intervention of a basement membrane.**The ciliary stroma** is composed largely of loose collagen fasciculi, aggregated into a considerable mass between the ciliary muscle and overlying processes, extending into both of them. In this inner stratum of connective tissue are numerous larger branches of the ciliary vessels, with a dense reticulum of large capillaries, most of them adjacent to the epithelium and especially concentrated in the ciliary processes, where they are chiefly of the fenestrated type. Numerous vessels also enter the ciliary muscle but its capillaries show far fewer fenestrations. Anteriorly, near the periphery of the iris is the major arterial circle (7.300, 305), formed chiefly by long posterior ciliary branches of the ophthalmic artery (p. 746) which enter the eye some distance behind the ocular equator, passing between the choroid and sclera to the ciliary body. Ciliary veins, also draining the iris, pass posteriorly to join the vorticose veins of the choroid.

The ciliary muscle has been variously described, the differences being mainly in the subdivision of this small annular mass of non-striated muscle. Most authors recognize three parts: *meridional*, *radial* or oblique and *circular* or sphincteric; but other views have been stated (Calasans 1953, Rohen 1964). Most, perhaps almost all ciliary muscle fibres are attached to the scleral spur (7.304), spreading in several directions, upon which the somewhat arbitrary division of the muscle depends. The outermost fibres are meridional or longitudinal, passing posteriorly into the stroma of the choroid, where many exhibit terminal branchings or *epichoroidal stars*. The innermost fibres swerve acutely from the spur (7.304) to run circumferentially as a sphincteric

7.304 The ciliary muscle and its components. The meridional or longitudinal (1), radial or oblique (2) and circular or sphincteric (3) layers of muscle fibres are displayed by successive removal towards the ocular interior. The cornea and sclera have been removed, leaving the pectinate ligament (a), the scleral venous sinus (b), collecting venules (c) and scleral spur (d). The meridional fibres often display acutely angled junctions (e) and terminate in epichoroidal stars (f). The radial fibres meet at obuse angles (g) and similar junctions, at even wider angles (h), occur in the circular stratum of the ciliaris. See 7.299 for acknowledgement.

element near the periphery of the lens. Between these two muscular strata are obliquely interconnecting fibres, frequently forming an interweaving lattice, often referred to as *radial* in direction. In ultrastructure the ciliary muscle differs from other non-striated muscle, the myocytes containing unusually abundant mitochondria and endoplasmic reticulum. A small bundle of fibres is usually surrounded by a common fibroblastic sheath to form units unlike those in any other non-striated muscles. Gap junctions (p. 24) couple the myocytes electrically. Three types of nerve ending have been noted, the most common being an indirect contact of the presynaptic membranes with the interposed basal lamina; contact without the basement membrane also occurs; rarest are larger contacts in depressions in the surfaces of myocytes.

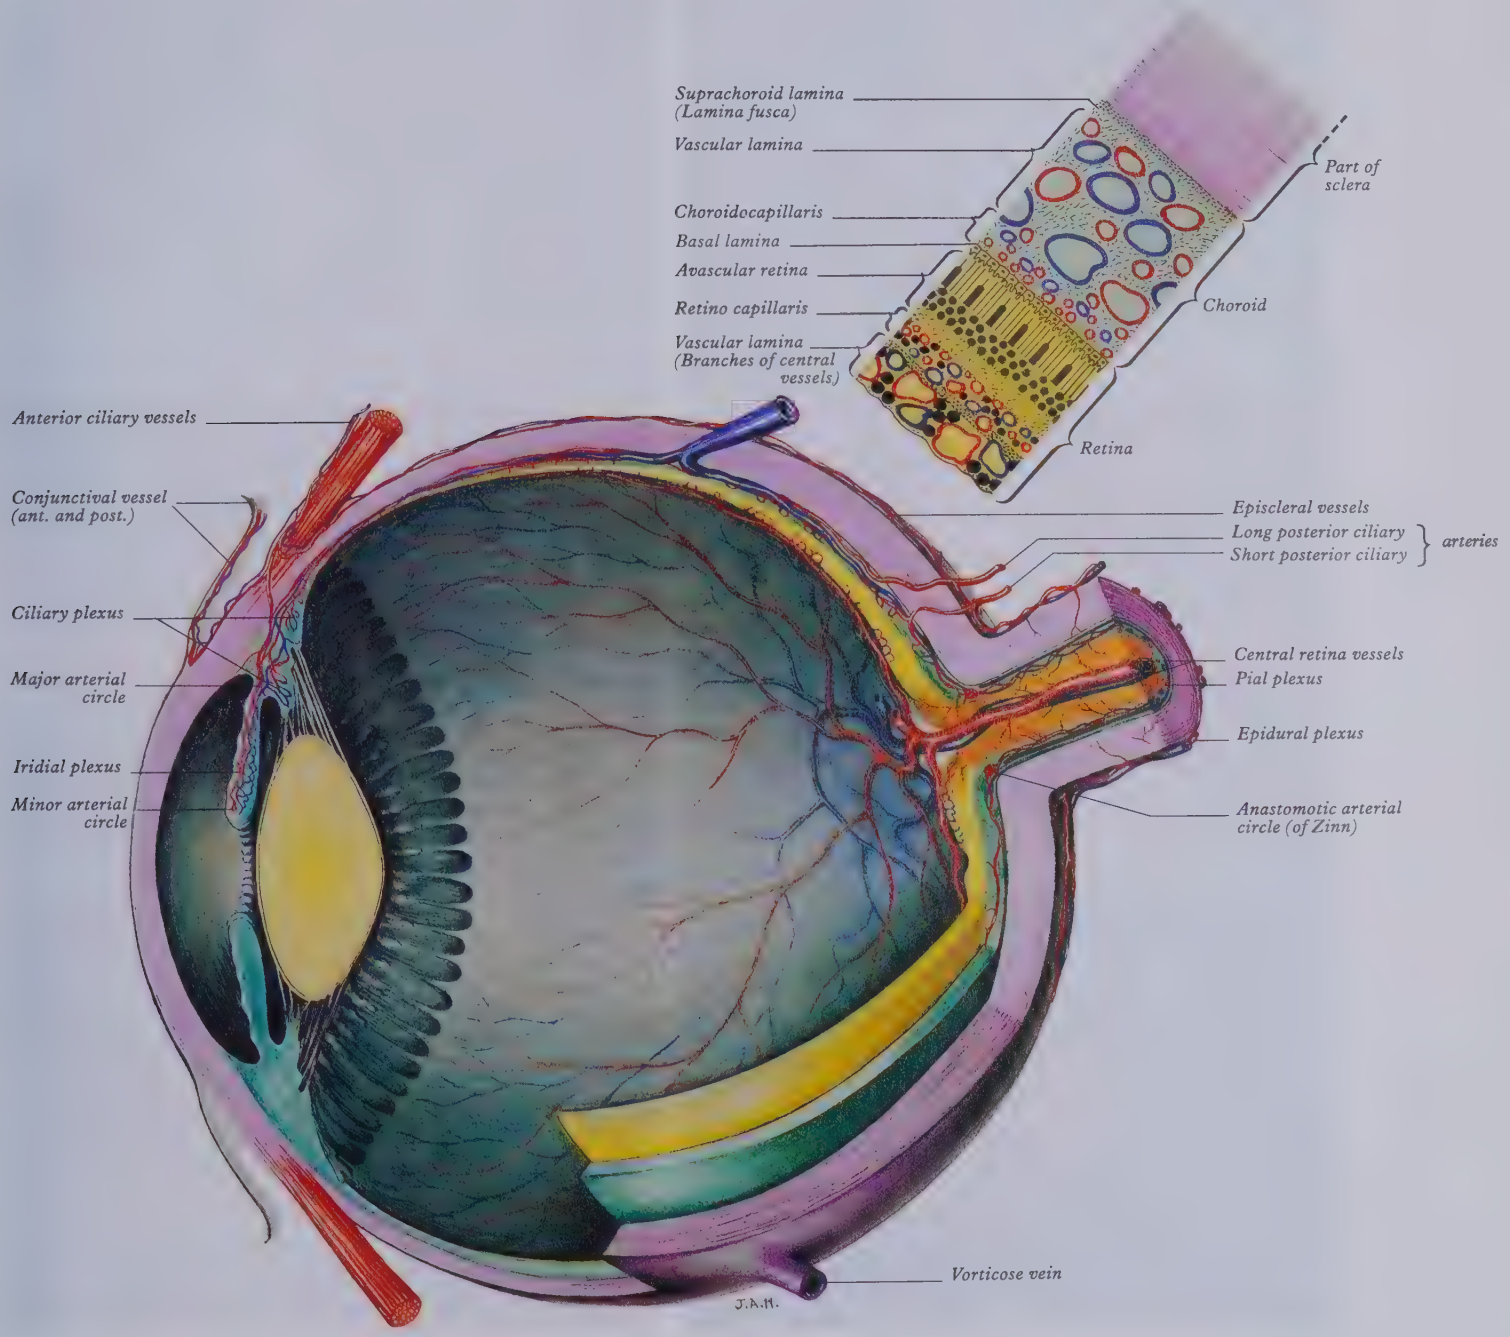
Myelinated and non-myelinated nerve fibres abound in the ciliary muscle and ciliary body, the latter being postganglionic parasympathetic axons from the ciliary ganglion, where they link with the oculomotor parasympathetic outflow; but some fibres appear to be sympathetic, according to much evidence. The parasympathetic supply stimulates the ciliary muscle to contract but the role of the sympathetic innervation is unsettled. Cervical sympathetic stimulation in experimental animals causes the lens to flatten, tantamount to the relaxation of accommodation, but the mechanism of this is uncertain; it may be due to an inhibition of the ciliary muscle or the ciliary body volume may be reduced by vasoconstriction, tensing the zonule and hence the periphery of the lens, the reverse of the slackening effects of the zonule in ciliary contraction (Morgan 1944, Alpern 1969). Electron microscopy of the ciliary autonomic plexus in rhesus monkeys reveals a cycle of degeneration and regeneration which becomes more marked in older animals (Townes Anderson & Raviola 1979).



THE IRIS

The iris is an adjustable diaphragm around a central aperture (slightly medial to true centre), the *pupil*, which controls the amount of light entering the eye. Pupillary diameter varies from 1 to 8 mm at least and has an even wider range under the influence of drugs. This gives an aperture range in excess of *f*20–*f*2·5, and a ratio of 32:1 in the amount of light permitted to enter the eye.

While this is not enough to save the retina from the effects of intense illumination, it moderates the great range of luminosity encountered in ordinary use, preserving useful vision under highly variable conditions. (The pupillary diameters noted above and the average iridial diameter of about 12 mm are of course estimated through the cornea, introducing a magnification factor of about 12%.) Pupillary *constriction* and *dilatation* are self-explanatory terms, for which meiosis and mydriasis are used clinically, though more properly reserved for the extreme limits of contraction and dilatation. The erudite surveys of the immense literature on the pupil and the iris by Loewenfeld (1958) and Loewenstein & Loewenfeld (1970) should be consulted for further information on this subject.



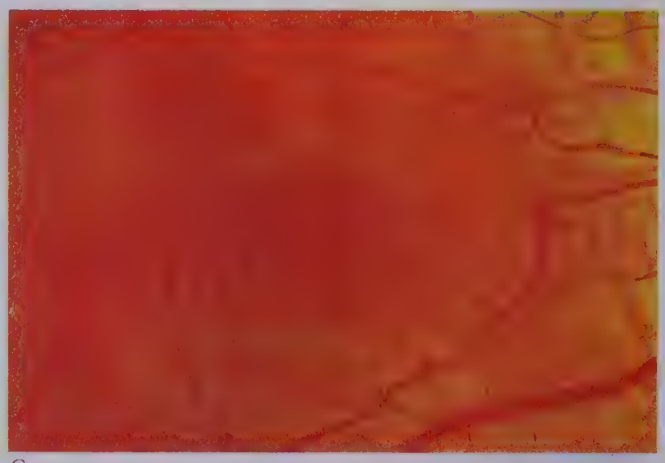
Though the iris is named after the rainbow, its range of colour extends only from light blue to very dark brown, often varying in the two eyes and even within the same iris. The colour is the combined effect of the iridial connective tissue and the pigment cells in selectively absorbing and reflecting different frequencies of light energy. When pigment is largely absent, as at birth, the colour is light blue; some pigment is necessary to confine light transmission to the pupil and central lens, where optical aberrations are least. The concentration of melanocytes is the main factor determining the hue of the iris, but the distribution of pigment is often irregular, producing a flecked or maculated appearance.

The iris is not a flat diaphragm; the lens causes it to bulge a little, so that it is more accurately a shallow cone, truncated by the pupillary aperture. Sited between the cornea and lens (7.294A) and immersed in *aqueous fluid*, it partially divides the *anterior segment* into an *anterior chamber*, enclosed by the cornea and iris (meeting at the *iridocorneal angle*) and a confusingly termed *posterior chamber*, between the iris and the lens (p. 1181). Into the latter, ciliary processes protrude from the periphery a little between the divisions of the zonular ligament of the lens and here most of the aqueous fluid is produced, traversing the pupil into the anterior chamber to its exit via the scleral venous sinus (p. 1181) at the iridocorneal angle: the 'filtration angle' in clinical parlance.

7.305 The vascular arrangements of the uveal tract. The long posterior ciliary arteries, one of which is visible (A), branch at the ora serrata (bb) and feed the capillaries of the anterior part of the choroid. Short posteriorly ciliary arteries (CC) divide rapidly to form the posterior part of the choriocapillaris. Anterior ciliary arteries (DD) send recurrent branches to the choriocapillaris (ee) and anterior rami to the major arterial circle (ff). Branches from the circle extend into the iris (g) and to the limbus. Branches of the short posterior ciliary arteries (CC) form an anastomotic circle (h) (of Zinn) round the optic disc and twigs (i) from this join an arterial network on the optic nerve. The vorticose veins (JJ) are formed by the junctions (k) of suprachoroidal tributaries (l). Smaller tributaries are also shown (m, n). The veins draining the scleral venous sinus (o) join anterior ciliary veins and vorticose tributaries. See 7.299 for acknowledgement.

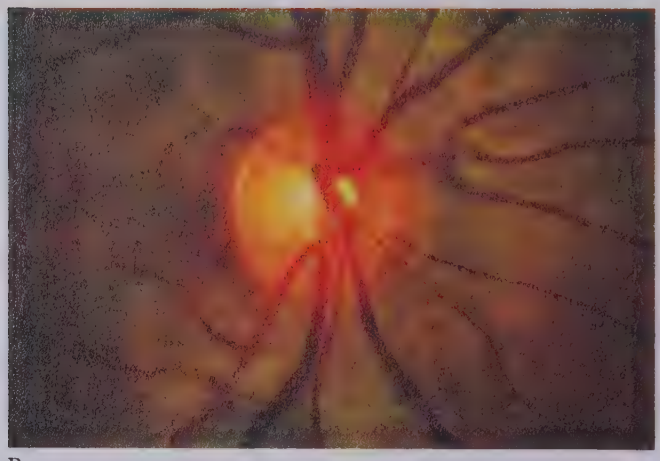
The microscopic structure of the iris includes several unusual features (7.300). Its anterior surface, forming the posterior boundary of the anterior chamber, possesses no distinct epithelium, despite statements to the contrary; this surface is merely a modified 'anterior border layer' of the general iridial *stroma*. This stroma contains the regional vessels and nerves and, near the pupillary rim, there is an aggregation of non-striated myocytes forming an annular contractile *sphincter pupillae*. The

7.306 The main features of the vascularity of the eye. The thickness of the sclera, cornea, choroid and neural retina are exaggerated, although representing relative thicknesses, and the regional variations should be noted. The section of ocular wall at higher magnification is included for particular reference to the avascular zones of the retina (which contain the photoreceptors) and their dual relationship to the vascular laminae and capillary plexuses of the choroid and retina.



epithelial strata of the posterior aspect of the iris is a continuation of the bilaminar epithelium of the ciliary body representing the two layers of the optic cup. The pupil, through which this epithelium curves for a short distance on to the *anterior* iridial surface as the *pigment ruff* or 'border', therefore corresponds to the opening of the optic cup. The deeper and hence on the back of the iris the posterior of these two epithelial layers is confusingly termed the *anterior epithelium*; although it is really *posterior* to its stroma. Its cells are pigmented, as are those of the same layer in the ciliary epithelium; closely associated are the radially arranged non-striated myocytes of the dilatator pupillae, which like the sphincter has a most unusual embryological origin, from the neural ectoderm of the optic cup. Superficial (posterior) to this layer is a stratum of heavily pigmented cells, the so-called *posterior epithelium*, continuous with the internal *non-pigmented*, retinal layer of the ciliary epithelium.

The anterior iridial surface (anterior border layer) has been much studied at low magnification by slit-lamp microscopy; it then appears somewhat fluffy, except when heavily pigmented. *Crypts*, through which vessels may be visible in the stroma, and various radial and circular folds and striae can be observed (Vogt 1942). The constituents of this anterior border lamina are mainly dendritic fibroblasts and melanocytes, with no vestige of the endothelium which covers it at birth but rapidly disappears during the early postnatal years (Vrabec 1952). Electron microscopy confirms this (Tousimis & Fine 1959). Fibroblasts form an almost continuous surface monolayer; their branching processes form no actual junctions (Smelser & Ishikawa 1966). At the iridial periphery they blend with the trabecular connective tissue (pectinate ligament) of the iridocorneal angle. At the pupillary rim they meet the epithelium of the posterior iridial surface. Melanocytes are also intricately branched, again with no special junctions between them. Some capillaries invade the border layer. Naked axons, presumed to be sympathetic, have also been found closely apposed to the melanocytes and fibroblasts, suggesting the release of transmitter substances into the anterior chamber (Ringvold 1975).



The *stroma of the iris* is, like the anterior border layer, derived from the mesoderm between the developing lens and optic cup and is also formed of fibroblasts, melanocytes and a loose collagenous matrix. The intercellular spaces appear to communicate freely with the anterior chamber and interchange of fluid between the two may permit the large changes in volume occurring during contraction and relaxation of the iris. The mesodermal stroma also contains not only abundant blood vessels and nerves but also the ectodermal sphincter and dilatator muscles. There is no elastic tissue. The elastic recoil sometimes

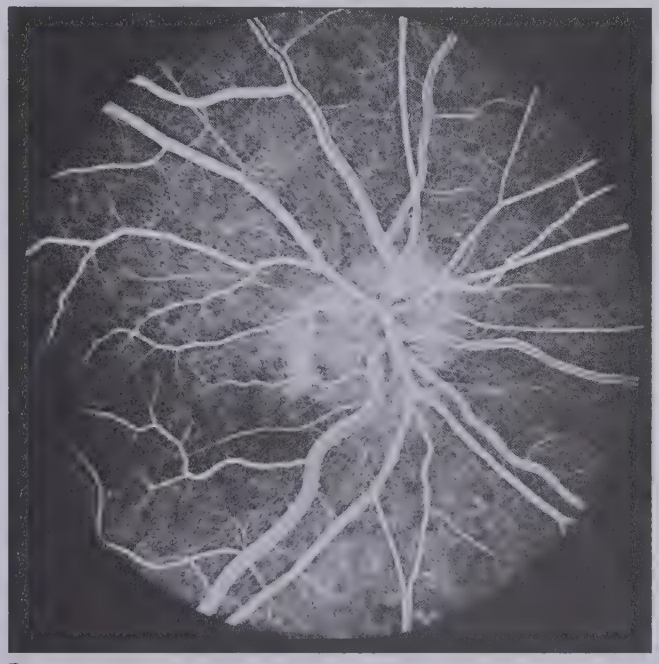
7.307 Opthalmoscopic photographs of the right human retina.

A. Note dichotomous branching of vessels, arteries being brighter red and showing a more pronounced 'reflex' to light, as a pale stria along their length. The veins are also larger in calibre; more of them cross arteries superficially than is usual. The optic disc, around the entry of the vessels, is a light pink, with a surrounding zone of heavier pigmentation. Compare with 7.308A from the same Caucasian adult.

B. Appearances in a heavily pigmented individual (Negroid adult), with a paler optic disc than in A. Note accentuation of the edge of the disc by retinal and choroidal pigmentation. The arteries cross the veins superficially in this retina.

C. Normal macula of a young Caucasian subject. Note the fovea, showing as a central, paler, circular area. The macular branches of the central retinal artery are approaching from the right. The macula is largely free of vessels of macroscopic size, but the capillaries here form a particularly close network, except at the fovea.



D. The region of the optic disc in an eye with poorly developed pigmentation. Three cilioretinal arteries are curving round the edge of the disc (two on the left, one on the right). Between the two cilioretinal arteries a single macular artery is apparent. Due to the depressed pigmentation choroidal vessels are also visible, especially veins; and on the left of the photograph two large vorticose venous tributaries can be seen.

attributed to the iris as a dilator force when the sphincter is relaxed must reside in other structures, if it exists at all. Collagen fibrils, about 60 nm in diameter, are loosely arranged, many describing incomplete circumferential loops around the pupil. 'Clump' cells, mast cells, macrophages and lymphocytes have also been described in the stroma.

The sphincter pupillae is a flat annulus of non-striated muscle about 0·75 mm wide and 0·15 mm thick. Its densely packed fusiform myocytes are often arranged in small bundles, as in the ciliary muscle, and pass circumferentially around the pupil. Collagenous connective tissue lies in front of and behind the muscle fibres and is very dense posteriorly, where it binds the sphincter to the pupillary end of the dilator muscle. Ultramicroscopy shows that muscle fascicles are not pervaded by nerve fibres, usually only one myocyte of each group being innervated, excitation causing contraction presumably spreading to other fibres at

7.308 Fluorescence angiograms of the retina. These are produced by photography with a fundus camera at known periods of time following introduction of fluorescein into the circulation. For details of the technique consult Rosen (1969) to whom we are indebted for all the colour photographs and angiograms in this illustration.

A. Angiogram of the same retina as that appearing in 7.307A taken in 'mid-venous' phase. The arteries display an even fluorescence, but the veins appear striped, due to laminar flow. This appearance is the reverse of and not to be compared with the arterial 'reflex' which is seen in 7.307A. The background mottling is due to fluorescence from the choroidal vessels.

B. Angiogram of the left optic disc, showing the major arteries and veins and also their smaller branches. Note particularly the radial pattern in the retinal capillaries. The laminar flow in the veins is less obvious than in 7.308A.

C. Angiogram showing the macular region of a right eye. The main macular vessels are approaching from the right. The subject was an elderly person with considerable macular pigmentation, which masks fluorescence from the choroidal circulation. Compare with 7.308D.

D. Angiogram of the macula of a young subject (left eye) showing the macular capillaries in detail. Note the central avascular fovea. Compare with 7.308C.

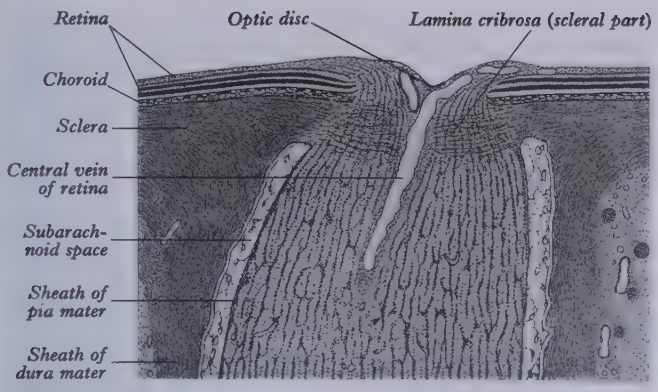
gap junctions. Small nerves ramify in the connective tissue between bundles, most of their fibres being non-myelinated and often enclosed in common Schwann cell sheaths. They do not approach the surfaces of myocytes more closely than 0·1 μm.

The dilatator pupillae, its very existence subject to a prolonged, vexed and at times almost ridiculous controversy, is now a well-established entity confirmed by microscopic, physiological and pharmacological observations (Alphen 1963, Loewenfeld 1958). It is a thin stratum lying immediately anterior to the epithelium of the posterior iridial surface. Its fibres are in fact the muscular processes of the anterior layer of this epithelium, whose cells are therefore myoepithelial; their apical processes form the epithelium itself. Myofilaments appear in both parts of these cells but more abundantly in their fusiform basal muscular processes, which are about 4 μm thick, 7 μm wide and 60 μm in length; they form a stratum 3–5 elements thick through most of the iris, from its periphery to the outer perimeter of the sphincter which it slightly overlaps. Here the dilator thins out, sending spurs to blend with the sphincter; unlike the apical parts of the myocytes these have a basal lamina and are joined by gap junctions like those between the sphincteric myocytes. Non-myelinated nerve fibres appear near their muscular processes or 'fibres' and these terminate close (about 20 nm) to their surfaces.

The arteries of the iris (7.300, 305, 306) arise from the long posterior and anterior ciliary arteries and from those in the ciliary processes. Both long ciliary arteries, on reaching the attached margin of the iris, divide into an upper and a lower branch anastomosing with corresponding arteries from the opposite side and with the anterior ciliary arteries, to form a vascular circle, the *circulus arteriosus major*. From this, vessels converge to the free margin of the iris, anastomosing to form a *circulus arteriosus minor*; this is incomplete and some regard its vessels as venous. The smaller arteries and veins are very similar in their mural structure and also share some peculiarities; they are often slightly helical, perhaps to adapt to changes in iridial shape as the pupil varies in size, which may also account for the peculiar structure of their vascular walls. All these vessels, including the capillaries, have a non-fenestrated endothelium and a prominent, often thick basal lamina. In the arteries and veins, there is no elastic lamina and myocytes are few, especially in the veins; connective tissue in the tunica media is loose and external to this a remarkably dense collagenous adventitia appears to form almost a separate tube external to this. The loose stratum of the media has been regarded as a lymph space but this is improbable; it is about 7 μm in width and contains matrix probably derived from the endothelial basement membrane (Hogan et al 1971).

Nerves of the iris, as in the choroid, come chiefly from branches of the long ciliary rami of the nasociliary nerve and from the short ciliary rami of the ciliary ganglion, the latter providing postganglionic non-myelinated axons innervating the sphincter pupillae. The dilatator is supplied by non-myelinated postganglionic fibres from the superior sympathetic ganglion; their routes are not certain and may vary in different species and they may be multiple in man. The internal carotid sympathetic plexus is said to send a branch via the ciliary ganglion, reaching the eye in the short ciliary nerves; but some may travel in the long ciliary nerves. (For other routes in simians, see p. 1102.) The innervation of iridial muscles, as also of the ciliaris, is probably more complex; both the sphincter and the dilatator may have a double autonomic supply. Histochemical stains for acetylcholinesterase and fluorescent techniques have demonstrated cholinergic and adrenergic activity in both muscles (Ehinger & Falck 1966, Lowenstein & Loewenfeld 1970). Though ganglion cells have been noted in the iris, almost all nerve fibres are probably postganglionic and non-myelinated. They form a plexus around the periphery of the iris, from which small nerves and fibres extend to the two muscles, to vessels, the anterior border layer and the anterior epithelium (though not the pigment layer) of the posterior layer of the iris. Some fibres may be afferent and some are vasomotor but little is known of either. (For distribution of non-myelinated autonomic nerve fibres in the choroid consult Ruskell 1971.) It is difficult to identify afferent nerve endings in the iris and ciliary body or to distinguish them from efferent autonomic endings, but such endings have been described in monkeys, using mitochondrial accumulations as a criterion (Bergmanson 1978, Cauna 1966, Macintosh 1974). Trigeminal (ophthalmic division) terminals and also autonomic endings in these sites are said to display this feature.

The pupillary membrane. In fetuses the pupil is closed by a thin, vascular *pupillary membrane* (p. 203). Its vessels are partly from those of the iridial marginal and partly from those of the lens capsule; they end in loops near the membrane's centre, which is avascular. About the sixth month of gestation, the membrane begins absorption from the centre towards the periphery; at birth only scattered fragments remain but exceptionally it may persist and interfere with vision.



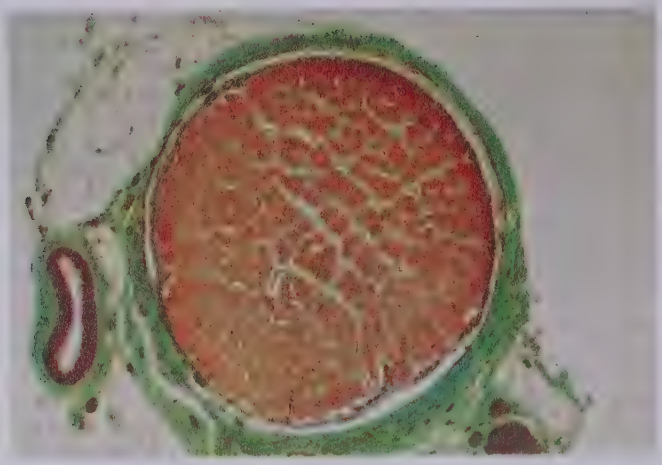
The Retina

The retina (7.294) is the neural, sensory stratum of the eyeball. It is thin, being thickest (0·56 mm) near the optic disc, diminishing to 0·1 mm anterior to the equator and continuing at this thickness to the ora serrata (7.302, 303). It is even thinner at the optic disc and fovea of the macula (Spence et al 1969). External to it is the choroid, internal to it the hyaloid membrane of the vitreous body. At the disc it is continuous with the optic nerve. Anteriorly, at the ora serrata (p. 1187), a thin, non-neural prolongation extends forwards over the ciliary processes and iris as the *ciliary* and *iridial parts of the retina*, which consist of retinal pigmented and columnar epithelial layers only (vide supra). From the optic disc to the ora serrata extends the *optic part of the retina*, soft, translucent and purple in the fresh, unbleached state, due to the presence of *rhodopsin* (*visual purple*) but soon becoming opaque and bleached when exposed to light. (It is hence difficult to demonstrate rhodopsin; in eyes preserved for dissection the *fixed* retina is cloudy white.) Near the centre of the retina is an oval, yellowish area, the *macula lutea* (7.307, 308), which has a central depression, the *fovea centralis*, where visual resolution is highest. At the fovea, the retina is exceedingly thin, some of its layers being absent, and the dark choroid is distinctly visible through it. About 3 mm nasal to the macula lutea the optic nerve is continuous with the retina at the *optic disc*, about 1·5 mm in diameter. The circumference of the disc is slightly raised, while centrally it has a shallow depression, being pierced in this area by the central retinal vessels (7.307, 308). The disc ('blind spot') is insensitive to light. By ophthalmoscopy it is normally pink but it is much paler than the retina and may be grey or almost white. In optic atrophy the capillary vessels disappear and the disc is white. The name 'optic papilla', often applied to the disc, is a misnomer; almost all of the normal disc is level with the retina and centrally *depressed*.

The Structure of the Retina

The retina is derived from the two layers of the invaginated optic vesicle (pp. 189, 201), the outer becoming the lamina of the *pigment cells*; the inner develops into a complex multi-laminar structure containing: the *photoreceptors* (rod and cone cells), their *first order neurons* (bipolar cells) and the somata and axons of the *second order neurons* (ganglion cells) and *interneurons* arranged amongst these centripetal paths (horizontal and amacrine cells). It also contains *neurological elements* and a *vascular system*, chiefly of capillaries. Some authorities separate the region of the retina posterior to the ora serrata (*pars optica retinae*) from its pigment epithelium as the 'retina proper' but, since these two layers are functionally integrated, this arbitrary division into *the stratum pigmentosum* and *stratum nervosum* will be ignored in the present account. Description will, however, be limited to the *sensory* retina, whose ciliary and iridial parts have already been considered (pp. 1186, 1189). The potential space between the pigment cells and photoreceptors can be equated with ventricular cavities since it is developmentally a hollow outgrowth of the brain (p. 201).

Though, following custom, 10 layers in the retina will be described in the present account (7.259–262), this division is merely a convenience in the primary analysis of the highly integrated nervous elements of the retina. For a concise comparative review of structure and function in the vertebrate retina see Boycott (1974).



7.309 A horizontal section through the optic nerve at its point of exit from the human eyeball.

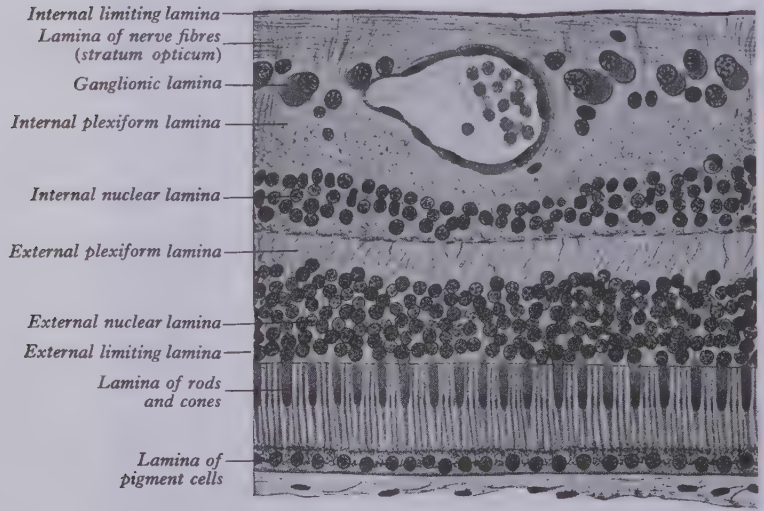
THE RETINAL PIGMENT EPITHELIUM

This is a single lamina of regularly arranged cells extending from the periphery of the optic disc to the ora serrata and continuing on into the ciliary epithelium (p. 1187). The cells are flat rectangles in radial sections and hexagonal or pentagonal in tangential aspect (7.313). They number about 4–6 million in the human eye, increasing with age. Near the macula they are about 10 and 14 μm in their radial and tangential dimensions respectively but are much flatter near the ora serrata (Ts'o & Friedman 1967, 1968). Their nuclei are basally placed, near the basal lamina of the choroid (p. 1185) and separated from it by their own basal lamina (Bruch's membrane) which is much infolded into grooves in the basal plasma membrane. Apically they project between the processes of the rods and cones as microvilli 5–7 μm in length; the intermediate cytoplasm contains mitochondria, pigment granules and organelles associated with melanin synthesis, including arrays of granular and agranular endoplasmic reticulum, premelanosomes

7.310 Schematic representation of the exit of the human optic nerve from the eyeball, showing the distribution of collagenous (blue) and neuroglial (magenta) tissues. Sep = septa of collagenous connective tissue carried into the nerve from the pia mater and dividing the nerve fibres into numerous fascicles. Gl.M = astroglial membrane separating nerve fibres from connective tissue. Gl.C = astrocytes and oligodendrocytes among the fibres in their fascicles. Du, Ar, Pia = dura, arachnoid and pia maters respectively. (1a) is the internal limiting lamina of the retina, which is continuous with an astroglial membrane (of Elschnig) covering the optic disc (1b). An accumulation of astrocytes forms a central meniscus of Kuhnt in the centre of the disc (2). The anterior or so-called 'choroidal part' of the lamina cribrosa (6) is separated from the choroid by a spur of collagenous tissue (3). The 'border tissue of Jacoby' (4), which is largely astroglia, frequently extends beyond the choroid (5) to separate much of the retina from the 'retinal part' of the optic nerve head. The posterior part of the lamina cribosa (7) contains collagenous tissue derived from the optic nerve septa and fenestrated sheets of collagen fibres continuous with those of the sclera. Reproduced by permission of Anderson & Hoyt 1969.

7.311 A transverse section of the optic nerve and its meningeal coverings is visible at the side of the nerve. The dural and pial sheaths are stained green, the subarachnoid pink. Note the fasciculation of the nerve. Material stained by Masson's trichrome technique and provided by N A Locket, Institute of Ophthalmology, London.

and melanosomes (Breathnach & Wylie 1966, Seyi 1967). Lipofuscin also occurs (Feeney et al 1965), probably as an end-product of a phagocytic activity of great importance to retinal function. Autoradiography and ultramicroscopy (Young & Bok 1969, Spitznas & Hogan 1970) have shown that the microvilli of pigment epithelium cells aid the continuous erosion of the external ends of rod and cone processes and that the lamellar inclusions in their cytoplasm are the shed terminal parts of outer segments of these photoreceptors; these phagosomal vacuoles are continually degraded by lysosomal action as they pass deeper into the cells (Marshall & Ansell 1971), the whole process being a vital part of the receptor membrane renewal cycle of photoreceptors (see p. 1198).

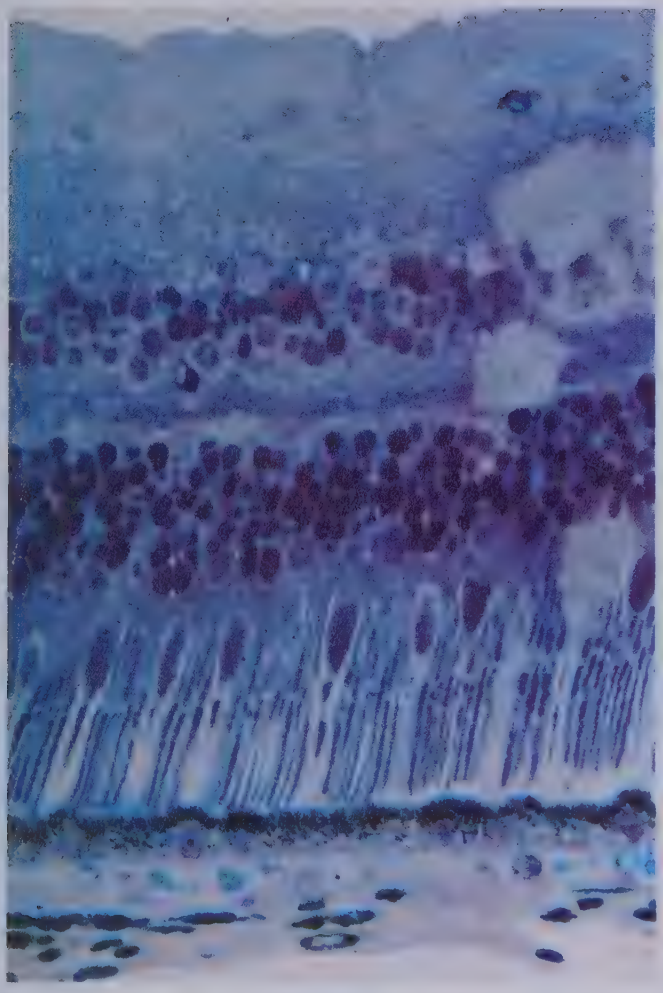


The bases of the pigment epithelial cells are much infolded by the basement membrane, as already noted. The latter structure is fibrillar, some fibrils joining the basement membrane of the choroid; this may explain adherence of the pigment epithelium to the choroid rather than to the rest of the retina. The membranes of adjacent pigment cells do not interdigitate much; the variable space between them is sealed off apically from the space between the microvilli and photoreceptors by zonulae occludentes. Other junctions also occur: Miki et al (1975) have described retino-choroidal attachment sites in mammals, including humans; these include reciprocal interdigitations, as noted above, and desmosomal junctions. A viscous glycosaminoglycan-rich substance fills the space between the pigment epithelium and the neural retina.

Though the functions of pigment epithelium are far from fully understood, it certainly has a phagocytic activity, possibly a nutritive role and some stabilizing action on photoreceptor placement, and the absorption of light, thus preventing back reflection.

THE PROCESSES OF ROD AND CONE CELLS

Retinal photoreceptors (7.312–318) are radially disposed, elongated cells which have a cylindrical photoreceptive portion at one end (nearest the pigment epithelium and choroid), a soma containing the nucleus nearer their other pole and, furthest from the choroid, a terminal synaptic region which is in functional apposition with a bipolar neuron. The photoreceptor part (*outer segment*) is connected to the soma by a region of cytoplasm rich in mitochondria, the *inner segment*. The outer segments are of two types, *rod* and *cone* processes, differentiated respectively by their cylindrical and conical shapes; the cells which bear them are accordingly rod and cone cells or, more simply, rods and cones. They are also differentiated by a constricted *outer fibre* connecting the rod processes to their somata (7.316), a feature absent from cones, though these may show a small 'waist'. At the junctions of rod processes with the outer fibres and of cone processes with their somata is the *external limiting membrane*, through which these photoreceptor processes appear to be thrust (7.316), as if through a sieve; it is described below (see the external limiting lamina).



Rod and cone processes are densely packed and regularly arrayed, but density progressively diminishes towards the ora serrata, where they abruptly cease. In human retinae they are most numerous in and near the *macula*, the region which is best adapted to the discrimination of form and colour, but least adapted to function in low luminosities. They are entirely absent from the optic disc, where centrifugal retinal fibres leave to form the optic nerve. The *central retinal area* is a region 5–6 mm in diameter, containing the *macula lutea*, an area about 2 mm horizontally and 1 mm vertically, its colour being due to the presence of xanthophyll or to a great reduction in the capillary bed or perhaps to other cell inclusions in bipolar and ganglion cells. The macula's *fovea centralis* is a deep conical depression where almost all elements except cones are absent, on its floor at least; its diameter is said to be about 0·4 mm. This *foveola*, as it is often called, is positioned about 4 mm lateral and 1 mm inferior to the centre of the optic disc (the latter corresponding to the 'blind spot' in the uniocular visual field). The minuteness of the foveola accounts for the accuracy with which the visual axes must be directed to achieve the most discriminative vision. The macula has been further divided into peri- and parafoveal areas. The macula

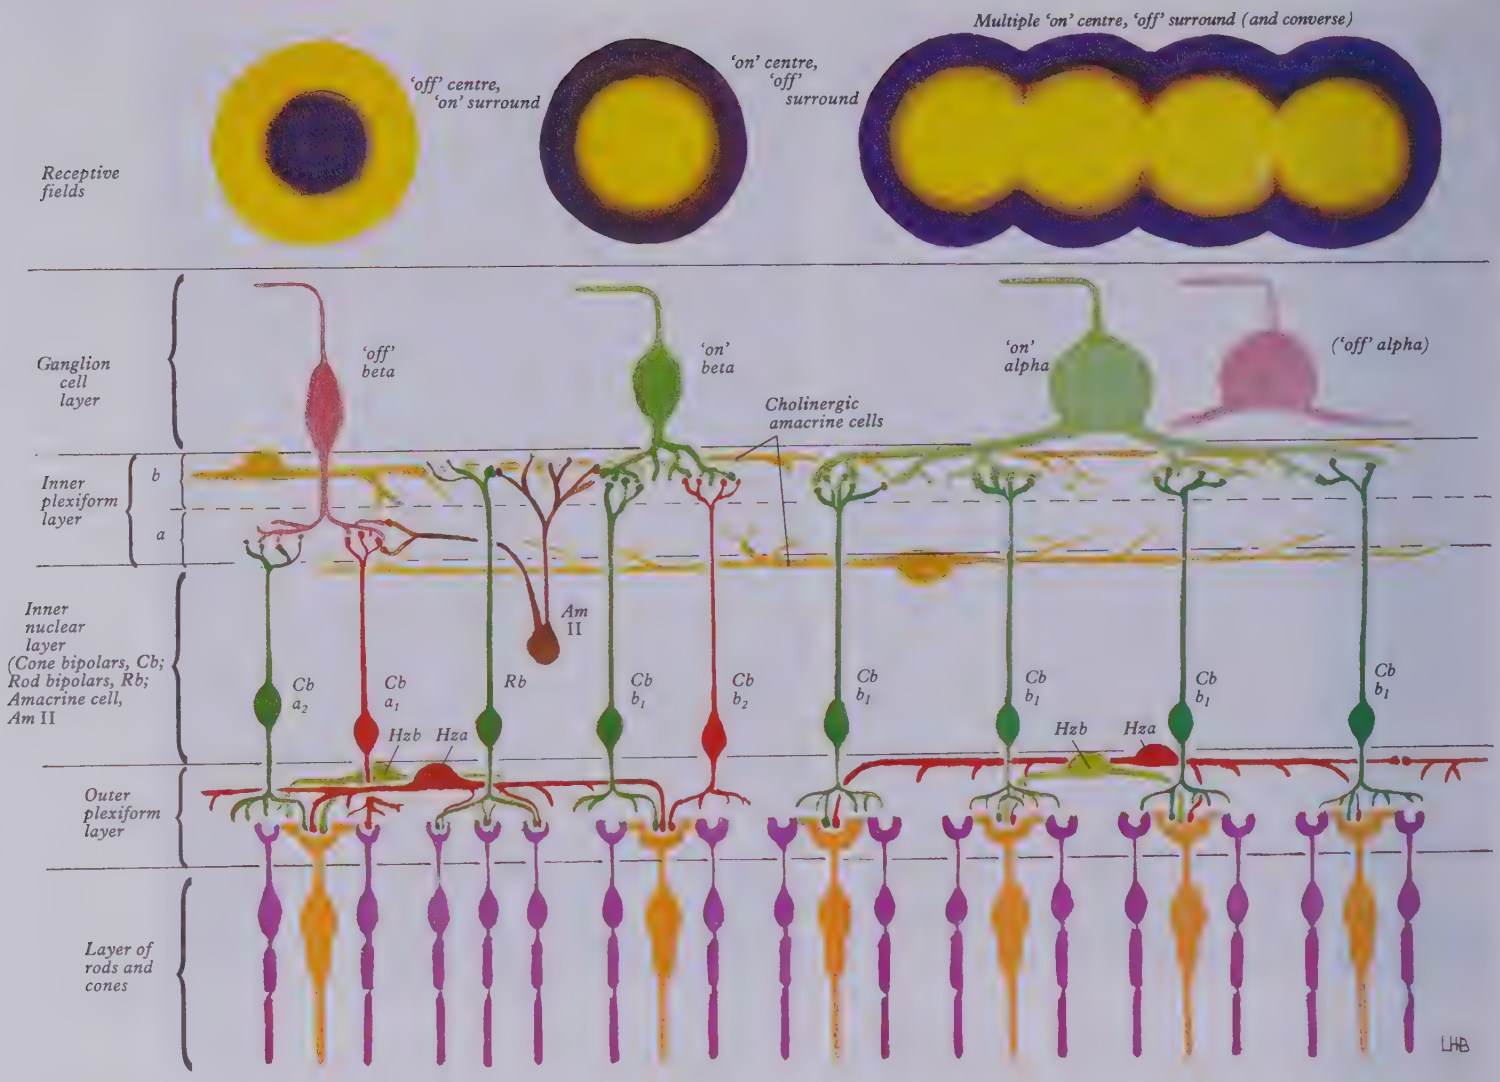
and fovea centralis will be considered further after the general retinal structure has been described (p. 1203).

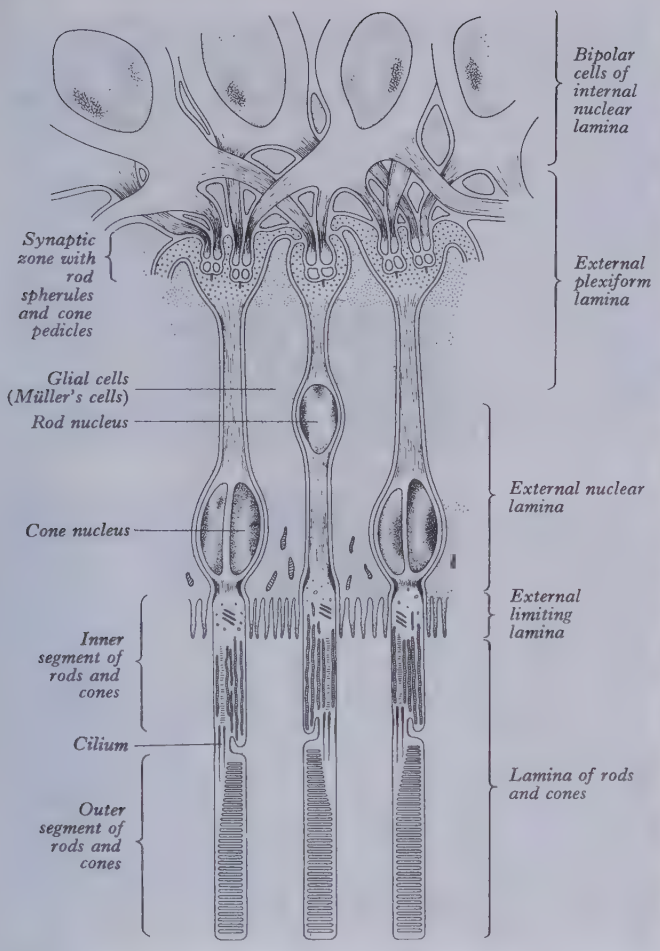


The total number of rods in the human retina has been estimated at 110–125 million and of the cones at 6·3–6·8 million (Osterberg 1935). Their distribution differs; the cones are densest at the rod-free foveola (about 147 000 per mm²), but diminish rapidly to a 10° circle round the macula where their density is about 5000 per mm², a frequency which is maintained to the edge of the ora serrata. Rods are almost the reverse of this in their distribution, rising from zero at the foveola to a greater density than the cones at the 10° circle (160 000 per mm²), then diminishing to the peripheral retina, where, however, there are still approximately 30 000 per mm²; the rods are thus six to 30 times more numerous in the peripheral retina outside the 10° circle. This distribution accords well with the phenomena of photopic (cone) and scotopic (rod) vision. The correlation of rod and cone distribution with photopic and scotopic vision is well illustrated in the feline retina; in the area centralis the concentration of cones, though greater than elsewhere, is about one-sixth of the human level but rods, at 275 000 per mm² in the area centralis, reach a maximum of 460 000 per mm² peripheral to this, a level greater than any in the human retinae.

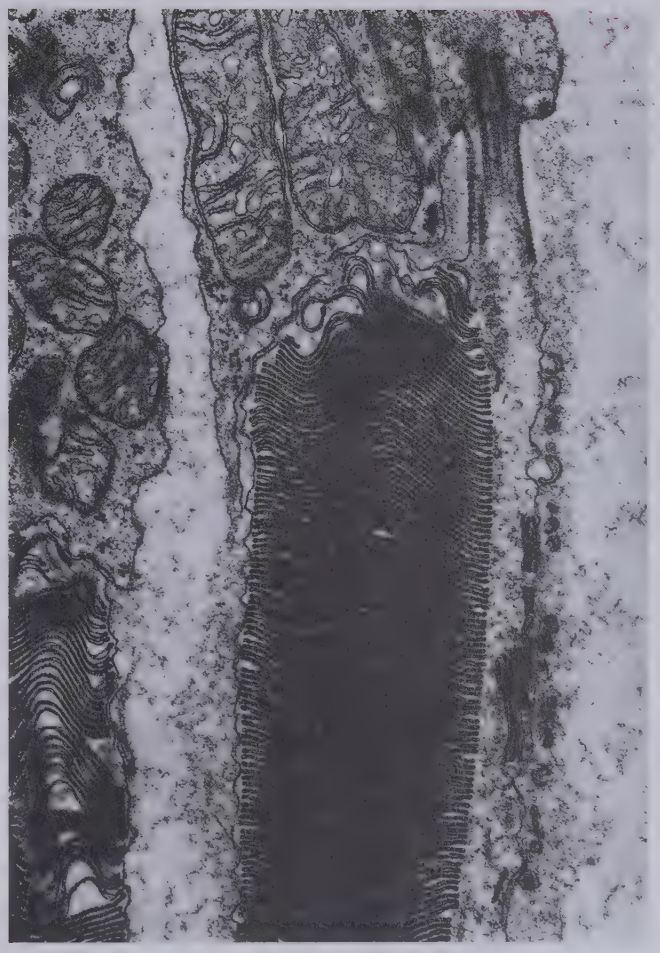
Even under the light microscope, retinal neurons are clearly seen to be less numerous than rod and cone cells; ganglion cells (vide infra, p. 1202), whose axons form the optic nerve, probably total about one million in the human retina. Hence large numbers of photoreceptive cells must activate single axonal paths in the optic nerve and beyond.

Structure of Rod and Cone Processes

These exhibit greater differences by light than is evident by electron microscopy. Even with the former both show an external, *outer segment*, which is refractile with the customary stains, positively birefringent and PAS-positive, and an *inner segment* staining deeply and with a fibrillar structure. The combined outer and inner segments of a rod process measure about 100–120 µm long in freshly fixed human retinae, cone processes being about 65–75 µm (Eichner 1957); both diminish in length towards the ora serrata, especially the process of cones, which are also much narrower at the fovea where they closely resemble rods in their dimensions. The outer segments of rods contain *rhodopsins* (visual purple); in cones (Rushton 1962, Pirenne 1967, Dowthall & Knowles 1977) similar photosensitive pigments have been detected but display different absorption qualities, accounting for the distinctive types of behaviour of rods and cones in high and low luminosities. Different absorption maxima have also been observed amongst cones themselves in primate retinae; there is at least some accord between these data and the trichromatic theory of colour vision. (For a survey of vertebrate photoreceptors and pigments consult Crescitelli 1972).



In their *ultrastructure* rods and cones are broadly similar and may be described together; rod processes have been the more extensively studied of the two (Sjostrand 1953, 1961, Villegas 1964, Misotten 1962, Dowling 1965, Cohen 1965, Boycott 1974). The rod *outer segment* appears as a remarkably regular series of discoidal membranous sacs, stacked like thin coins and surrounded by a cell membrane, to the outer end of which are opposed the microvilli of pigmented epithelial cells (vide supra, p. 1195). These *discs*, numbering 600–1000 in rods of various species, are flat vesicles separated from each other by a less electron-dense *intradisc space* (7.317). In some vertebrates the discs are formed as continuous infoldings of the lateral cell membrane but in human rods this continuity is lost. However, in cones, this connection



7.315 Simplified diagram of the main cell types and interactions in the mammalian (cat) retina. Cells depicted green are involved in excitatory actions, pink ones are inhibitory. Note also two types (a and b) of horizontal cells (Hza, Hzb). See text for further details.

persists even in mammals (Cohen 1970, Laties & Liebman 1970, Ripps & Weale 1976). In transverse section the discs of cones are circular, whereas those of rods have a scalloped profile (Cohen 1972). Discs of cones are also flatter than those in rods but are separated by a greater interval. Consequently the numbers in unit lengths are similar in both types, at about 30 discs per μm. Both are continually formed at the end closest to the soma and are progressively pushed away from this point towards the pigment epithelium as new discs are added; thus the oldest discs are nearest to the pigment epithelial cells and they eventually break off and are phagocytosed by this epithelial layer (p. 1196). Young (1971) has shown that in rhesus monkeys almost 1000 discs are thus generated proximally and removed peripherally in a rod outer segment in 11 days. (Since each pigment cell may interdigitate with 24–45 rod segments, its voracious 'appetite' may engulf 2000–4000 discs per diem!) This renewal was established by analysing the progression of radioactively labelled disc membranes in rats, mice and monkeys by a technique invented by Droz (1968). Evidence for renewal in the outer processes of cones is less certain, although Hogan (1972) has described similar phagocytosis in cones of the human fovea. Such a rapid turnover of complex intracellular structures is probably related to a limited lifespan in the photoreceptive molecular assemblies which may be degraded gradually by exposure to light. The discal membrane is now considered to consist of a regular array of rhodopsin molecules orientated transversely to the photoreceptor process and embedded in a lipid bilayer (Schmidt 1938, Weale 1970). Each of these consist of two closely associated components, a transmembrane glycoprotein (*Mr* about 50 000) and the chromophore, 11-cis-retinal. There are also various other proteins within the outer segment cytosol, concerned with amplifying the light signal greatly. Briefly, when rhodopsin is activated by light, it catalyses the loading of a second protein, *transducin* (G-protein) with guanine nucleotide triphosphate (GTP). This then activates an enzyme, a cyclic guanine monophosphate phosphodiesterase (cGMP-PDE), which in turn depletes cyclic GMP within the cell. The final step is related to the permeability of the membrane to sodium ions; in the resting (dark) state there is a steady inward flow of ions through sodium channels in the membrane but to keep the channel open there must be sufficient cGMP available. When this is reduced by the enzyme activity described above, it causes the sodium gate to close and the electrical state of the cell changes, the outer segment becoming hyperpolarized. This change causes a hyperpolarizing current flow in the synaptic area, inhibiting chemical transmission to the next cell in the series (a bipolar cell). This system, though complex, ensues maximum multiplication of the signal, so that e.g. a rod is able to detect as little as four photons. For further details, see the reviews by Lamb (1986), Baehr & Applebury (1986).

The *inner segments* of rods are longer and broader than the outer segments and even more so in cones. The inner segment is also divisible into an outer *ellipsoid* with acidophilic staining reactions, containing glycogen and many mitochondria, and an inner *myoid*, adjacent to the soma and containing much randomly scattered

7.316 Schematic representation of the ultrastructure of retinal photoreceptors and of their connections with bipolar nerve cells. Note the stacked discs in the outer segments and refer to 7.319–7.321 and to the text for further details of the synaptic zone. Reproduced from Sjöstrand 1961.

7.317 An electron micrograph of a section of a human retinal rod, showing the junction between the outer and inner segments. The outer segment is made up largely of photoreceptive lamellae (or discs), connected by a short cilium (top right) to the inner segment containing large mitochondria. Provided by N A Locket, Institute of Ophthalmology, London. Magnification × 50 000.

agranular endoplasmic reticulum and free ribosomes. Myoids are basophilic and contain much more glycogen than the ellipsoids. From the inner to the outer segment stretch bands of ellipsoidal cytoplasm covered by plasma membrane, which are closely applied to the outer segment. Another cytoplasmic process, the *cilium*, connects the ellipsoid to the outer segment; it originates in a basal body and has the microtubular structure of a cilium within it, although lacking the central pair of microtubules (De Robertis 1960). The processes of cones are like those of rods, their differences being largely dimensional (Dieterich & Rohen 1970).

Though these processes have been minutely described, their remarkable features have not been entirely correlated with function. The stacked discs have been likened to photomultipliers, intensifying the electrical energy of photochemical processes; but this is merely an analogy. Despite the physiological demonstration of at least three types of human cone based on sensitivity to light, no structural distinctions yet exist. Variations in colour sensitivity in different parts of the retina are not in accord with regional variations in cone shape or dimensions. Known variations in sensitivity (e.g. achromatism at the retinal periphery) may be due to differences in neuronal connections; the duplicity theory of vision and the equation of photopic and scotopic vision with cones and rods may both be explicable in the same terms.

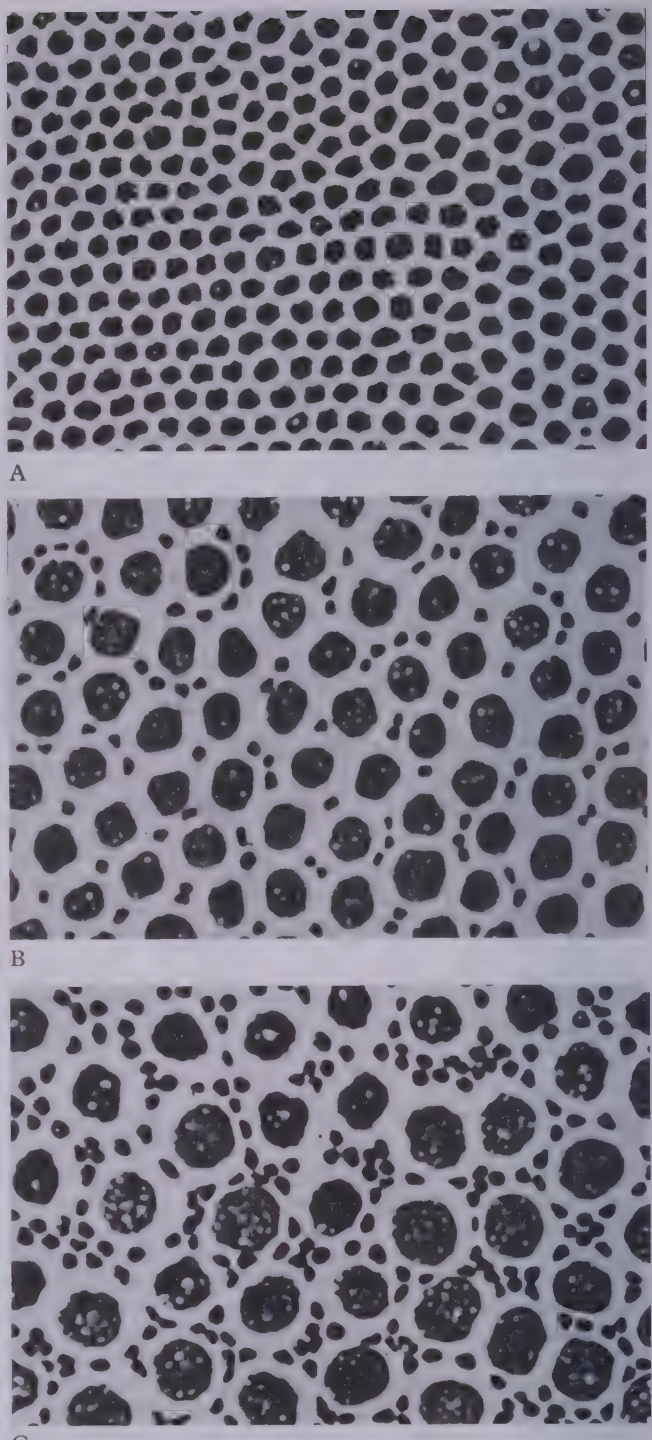
THE EXTERNAL LIMITING LAMINA

At the level of the junctions of the rod and cone processes with the outer fibres of rods and the somata of cones, light microscopy shows a thin densely-staining line which the rods and cones perforate. It extends throughout the neural retina and was considered for decades to be the fused terminal expansions of the 'fibres of Müller', an elaborate type of neuroglial element, with a soma in the internal nuclear layer, whose long processes stretch radially through the retina from the vitreal surface almost to the pigment epithelium. From these vertical fibres numerous processes spread horizontally in a dendriform manner into the plexiform laminae, embracing the somata of cells in the nuclear and ganglionic laminae. Similar 'fibre baskets' surround the proximal segments of photoreceptors. Their arrangement suggests that these *retinal gliocytes* (Müller cells) provide physical support, like neuroglia elsewhere. Moreover, other processes of these cells form an *internal limiting membrane* on the retina's vitreal aspect. Arey (1932) described the external limiting membrane as serial unions between the cell membranes of rods and cones with the 'fibres of Müller'. Electron microscopy has corroborated this view (see Fine & Zimmerman 1962 for a review of the earlier literature) but there is much variation in the types of junction described. They occur between the glial processes and the rod and cone inner segments and may be zonulae adherentes, which also sometimes unite adjoining Müller cell processes (the classic view) and adjacent photoreceptor processes (Spitznas 1970).

In the plexiform layers the horizontal gliocytic rami intermingle with the dendrites and axons of retinal neurons and may form helical lamellae around their neurites, without, however, producing myelin. Like other neuroglia they also contact blood vessels, especially capillaries; here their basement membranes fuse with those of non-striated myocytes in the media of larger vessels or

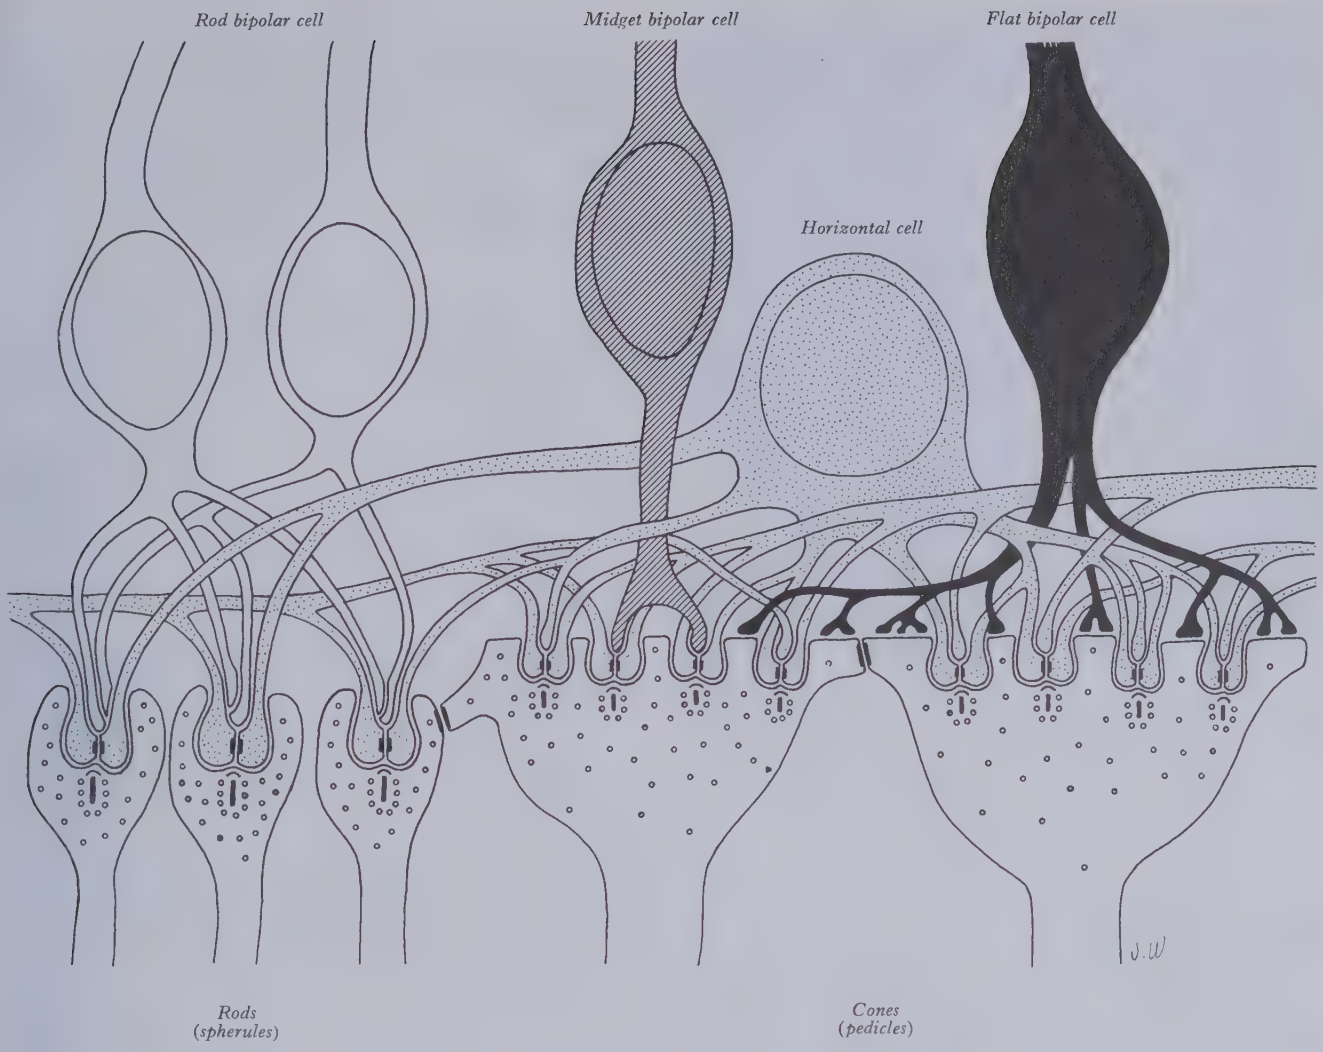
with endothelial basement membrane in the case of capillaries. These extensive gliocytes form much of the total retinal volume, almost totally filling the extracellular space. All glial processes are cytoplasmic extensions and other functions have been ascribed to them, e.g. the transport of glucose to retinal neurons and the synthesis and storage of glycogen (Cogan & Kuwabara 1967, Radnot & Lovas 1968).

THE EXTERNAL NUCLEAR LAMINA



This layer contains the parts of rod and cone cells that are internal to the external limiting membrane and do not lie in the external plexiform layer; and this refers particularly to their somata. As they traverse the external limiting membrane, photoreceptor processes become the narrower 'outer fibres' of rods and cones, those of rods more slender and elongate (7.315). The outer 'fibres' of cones are more like short 'waists' between the process and soma. The cytoplasm in both types contains long mitochondria, vesicular agranular endoplasmic reticulum and many free ribosomes; as the 'fibres' spread into the soma around the nucleus, aggregations of microtubules are visible. The thickness of the external nuclear lamina and rows of cells in it varies from 27 μm in peripheral retina to 50 μm in the fovea (p. 1203), representing in the former a single row of cones with four of rod nuclei and in the latter about 10 rows of cone nuclei.

THE EXTERNAL PLEXIFORM LAMINA



The 'inner fibres' of the rods and cones pass centrally (i.e. towards the vitreous) forming a most intricate zone of synapses (7.316) with the dendrites and axons of bipolar and horizontal neurons of the internal nuclear lamina. These fibres resemble axons, containing mitochondria and vesicles, free ribosomes, neurofilaments and microtubules. Rod axons are 15–25 nm in diameter and 1 μm or more in length, those of the cones being thicker and with more microtubules. Rod axons end in oval, invaginated *rod spherules*, cone axons as *cone pedicles*; they form complex multiple junctions with bipolar and horizontal neurons, whose neurites approach from the internal nuclear layer. The external plexiform layer is sometimes analysed into *three sublaminae*: an outer one of rod and cone inner fibres or axons, an intermediate one of spherules and pedicles and an internal one of bipolar and horizontal cell neurites. (For reviews consult Dowling & Boycott 1966, Misotten & Van den Dooring 1966, Boycott & Dowling 1969, Boycott 1974).

The rod spherule (7.319) is part of a synaptic complex of three elements, namely, *presynaptic* (the spherule itself), *synaptic* (contacts of the spherular membrane with the dendrites of bipolar cells and neurites of horizontal cells) and *postsynaptic* (neurites of bipolar and horizontal cells). The spherule is invaginated, enclosing in its hollow the terminations of two to seven dendrites or processes; the dendrites are those of *rod bipolar cells* (vide infra) and processes from *horizontal neurons*, the latter conducting in either direction and thus not strictly axons or dendrites. The cytoplasm of rod spherules contains many presynaptic vesicles and a *synaptic ribbon*, a peculiar osmiophilic, lamellar structure (7.319, see also p. 886). The presynaptic (rod) and postsynaptic (bipolar and horizontal cell) membranes are not thickened as in typical synapses. Postsynaptic vesicles may also occur at these sites.

The cone pedicle, also invaginated, is more complex (7.319). Its cytoplasmic organelles are like those of rod spherules but many more neurites are involved. The contacts are of three types: (1) deeply infolded synapses containing three terminal neurites, two more deeply situated than the other, and forming *triads*, of which there are 24 in each pedicle; (2) slightly depressed contacts, on the pedicle's basal aspect, numbering up to 500; (3) interreceptor contacts between the peripheral surfaces of adjacent cone pedicles or rod spherules. Triads contain two terminals from horizontal cells and one dendrite from a *midget bipolar neuron* (vide infra) or from a horizontal process. The contacts of cone pedicles are synapses with the dendrites of 'flat' bipolar cells (vide infra). Interreceptor contacts have no synaptic vesicles and are gap junctions (electrical synapses, see pp. 24, 888) (Raviola & Gilula 1973, Witkovsky et al 1974) but do contain microtubules; each pedicle has six to twelve such contacts; they are most frequent among foveal cones and elsewhere are usually between rod and cone cells. In view of the high resolution mediated by the fovea, such contacts have been reluctantly accepted as synapses and perhaps routes of low resistance for electrotonic excitation. If so, a separate mechanism of interaction exists between the photoreceptors, in parallel with the effects of horizontal and amacrine cells (vide infra).

7.318 Tangential sections through the primate retina to show the variations in distribution of rod and cone processes in the foveola (A), fovea (B) and macula (C). Note the *small* cone processes in the foveola, from which rods are absent. The cones, which are elsewhere larger than the rods, predominate in the fovea, rods becoming more numerous towards the periphery. Preparations supplied by John Marshall, Institute of Ophthalmology, London. Magnification × 5000.

7.319 Scheme of the synaptic arrangements involving the rod spherules and cone pedicles of the retina. For details consult text. From Hogan et al 1971, modified from Dowling & Boycott 1966.

To summarize, each rod cell has direct connections with two bipolar and perhaps several cone cells and a horizontal neuron. Cone cells have more complex and numerous contacts, probably between 575 and 600, involving midget and flat bipolar cells, horizontal cells and rod and cone cells. The possible routes for convergence and interaction between photoreceptors are bewilderingly numerous and the precise functional significance of such intricate intercommunications remain uncertain. Inter-photoreceptor contacts are confirmed as gap junctions. These and other details emphasize the central nervous nature of the retina and the complex interactions which are typical of the brain from which it is derived embryonically but do not yet explain the retinal modus operandi.

THE INTERNAL NUCLEAR LAMINA

This layer is perhaps unfortunately named. By light microscopy the retina displays *three* tiers of 'nuclei' or cell somata, the ganglion cells providing the most internal (i.e. nearest the interior of the eye). The 'internal' nuclear layer is therefore *intermediate* between this and the layer of rod and cone 'nuclei' and would be more appropriately termed the *middle* nuclear layer. It contains the somata of the *retinal gliocytes* (Müller cells), and of the bipolar, horizontal and amacrine neurons, arranged in regular strata. The most external in this layer are the somata of the *horizontal neurons*, whose processes extend into the adjacent external plexiform layer to the rod spherules and cone pedicles (vide supra). Internal to this are the *bipolar neurons*, the primary sensory neurons of the retino-geniculate tract (p. 1019); their dendrites also connect with the rods and cones, their axons passing centrally into the internal plexiform lamina (lamina 7) to synapse with the ganglion cells (lamina 8). Internal again to this are the somata of retinal gliocytes, which have already been considered (p. 1199). Most internal are the somata of the *amacrine neurons*, whose neurites spread into the adjacent internal plexiform layer to contact the dendrites of ganglion cells and the axons of bipolar neurons.

Each of the three categories of neurons in the internal nuclear layer—horizontal, bipolar and amacrine—contains several subtypes, distinguished by their connections and physiology rather than their cytological differences, which are not easily defined by any form of microscopy.

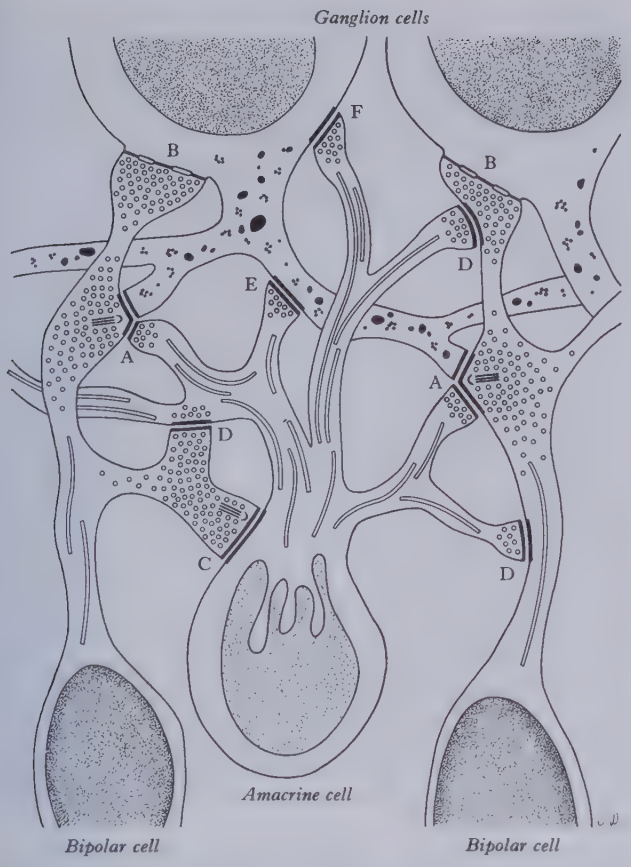
Horizontal neurons are of large inhibitory (*a*) and smaller excitatory (*b*) types; they have multipolar somata, from which extend a single long and several short processes (seven in cone and 10–12 in rod horizontal cells). Their cytoplasm is like that of bipolar cells (vide infra) but contains an organelle rich in ribosomes (Kolmer's crystalloid) which is peculiar to them. The long processes may be up to 1 mm long, a very long neurite by retinal standards, with branches contacting both rod spherules and cone pedicles. The short neurites of *cone* horizontal neurons synapse with seven cone pedicles, taking part in the formation of several triads in each (p. 1200). The short processes of *rod*

7.320 An electron micrograph of a part of the outer plexiform layer of the retina (monkey), showing synapses at the pedicle base of a cone (centre) and adjacent rod spherules. Note the presence of mitochondria and of synaptic ribbons surrounded by synaptic vesicles in the cone pedicle. The neuropil composed of interweaving dendritic processes of bipolar, horizontal and other cells is shown below. Supplied by NA Locket, Institute of Ophthalmology, London.

horizontal neurons synapse with 10–12 rod spherules. The long and short neurites of horizontal neurons are neither axons nor dendrites and probably conduct in both directions (7.321).

The bipolar neurons are *rod bipolar* cells, synapsing with a number of rod spherules, or *cone bipolar neurons*, involved in forming triad synapses of cone pedicles (7.320). Each rod bipolar axon connects to an amacrine II cell, while the cone bipolars connect with a single midget (X or β) ganglion cell (vide infra). Electrophysiology coupled with dye injection of single cells has shown that there are a number of different types of cone bipolar cells. Cone bipolars a_1 and a_2 connect cones to 'off' β ganglion cells, and cone bipolars b_1 and b_2 connect them with 'on' β ganglion cells and also with the large 'on' α ganglion cells. These pairs operate electrically in opposite directions: when a cone is activated, one cell depolarizes and the other hyperpolarizes. The term 'cone bipolar' is, however, a little misleading from the physiological viewpoint, since rods can communicate with them indirectly via rod gap junctions on cone pedicles. Even by electron microscopy, the somata of these types of bipolar cell are almost indistinguishable; they vary somewhat in size and shape but have similar organelles: abundant mitochondria, free ribosomes, agranular endoplasmic reticulum and microtubules.

Amacrine neurons (7.321), so named because they lack a large axonal neurite, have processes like dendrites, which are said to show the cytoplasmic features of both axons and dendrites; the direction of conduction in any process is determined by polarization of whichever synapses are active. Each neuron has one or two thick processes from which branch dendritic trees of variably complex patterns, on the basis of which at least 12 types of cell have been distinguished, including dopaminergic and cholinergic types (Masland & Tauchi 1986). They contain an indented nucleus, many cisternae of granular endoplasmic reticulum, ribosomes, microtubules and sometimes crystalline bodies and have surface cilia. Superficial cisterns have been described in amacrine, bipolar and ganglionic neurons in simian retinae by Spoerri & Glees (1977). The processes of amacrine neurons contain groups of synaptic vesicles at scattered sites, representing synapses with the axons of bipolar cells and dendrites of ganglion cells. Kolb & West (1977) have shown these to send their processes into the internal and external plexiform laminae; in the internal plexiform lamina, type II amacrine cells form gap junctions with 'rod' bipolar neurons and chemical synapses with 'off' β ganglion cells. Since they also have presynaptic connections with rod and cone bipolar neurons, they may mediate the feedback between plexiform laminae, although whether excitatory or inhibitory is uncertain. Similar neurons have been described in the retinae of goldfish by Dowling et al (1976), where they are considered to be excitatory.



THE INTERNAL PLEXIFORM LAMINA

Between the internal nuclear and ganglionic laminae is a dense neuropil composed of the neurites of bipolar, amacrine and ganglionic neurons, and their occasionally displaced somata. Outer and inner layers can be distinguished (laminae a and b); the *lamina b* consists of the dendrites of 'on' ganglion cells and synapsing terminals of b_1 and b_2 cone bipolar cells (Cb), plus amacrine dendrites. In *lamina a* are the dendrites of 'off' ganglion cells and incoming cone bipolars (Cb a_1 and a_2). Cone bipolars are in pairs, one inhibitory, the other excitatory (7.315, vide supra) (7.321). The bipolar axons form axodendritic and axosomatic synapses with ganglion cells and axosomatic contacts with amacrine neurons. Amacrine neurites synapse with bipolar cell axons and ganglion cell somata. These synapses are superabundant; near the fovea they are estimated at 2 million per cubic millimetre.

THE GANGLIONIC CELL LAMINA

The ganglion cells are second order neurons of the visual pathway, their dendrites being connected with processes of the bipolar and amacrine neurons in the internal plexiform lamina and their axons forming the layer of nerve fibres (lamina 9) beneath the inner surface of the retina. Here they turn tangentially to the optic disc, by which they leave the eye as fibres of the optic nerve. Ganglion cells form a single stratum in most of the retina and are progressively more numerous from its periphery to the macula, where they are ranked in about 10 rows, diminishing again towards the fovea, from which they are almost absent. They are multipolar neurons, varying from 10–30 μm in diameter, and have a large nucleus. Their dendrites are variable in number and branching patterns, usually emerging opposite the axon. According to their dendritic pattern they have been classified into at least six types (midget, stratified, diffuse, etc., see Cajal 1911, Polyak 1941, Boycott & Dowling 1969, Boycott 1974, Kolb & Nelson 1984, Sharpey & Perry 1986, Dowling 1987).

The midget beta ganglionic neurons are monosynaptic in their connections and possess relatively simple dendrites. They are the commonest type in the central retina, synapsing with the terminal axons of cone bipolar neurons (7.315, 319); since these are usually each connected centrally to a midget ganglion cell and distally to one cone pedicle, especially in the fovea, they provide specific pathways for individual cones. But, as the connections of cones show (p. 1201 and 7.315, 319, 320), this does not entail that a cone discharges exclusively through its midget bipolar and ganglion cell. **Polysynaptic ganglion cells** (rod and flat ganglion cells) include all other ganglionic neurons. They have one or two large dendrites spreading much more widely than those of midget cells; they synapse with the terminal axons of many bipolar neurons, probably with hundreds. The bipolar neurons are obviously more numerous than the ganglion cells (but by less than two orders of magnitude); hence many bipolars must transmit to one ganglion cell; there is also some evidence that the reverse may also be sometimes true. Such intricate connections form the structural bases for summation and lateral inhibition, long established in general terms and more recently explored by techniques of unit recording and accompanying intracellular injection of dyes to relate cell type to physiological response. Their axons are the main component of the nerve fibre lamina, to be considered next. The arrangement of cone bipolar cells, with their input of both cone and rod activity and their synaptic contacts with midget (β) ganglion cells, or the larger 'giant' (α)

7.321 A scheme of the synaptic arrangements in the internal plexiform lamina of the retina. Note that bipolar axonal terminals of three types are shown: *axodendritic* (A) in *dyads* involving neurites of amacrine and ganglion cells, *axosomatic* involving ganglion cells (B) and amacrine cells (C). Similarly the neurites of amacrine cells also make three types of contact: with the axons of bipolar neurons (D) and with the dendrites (E) and somata (F) of ganglion cells. From Hogan et al 1971, modified from Dowling & Boycott 1966.

ganglion cells, permits the sharpening of punctate photic stimuli, with either an 'on' centre and 'off' surround or vice versa (see 7.315). Complex interconnections of amacrine and horizontal cells are involved in these processes.

THE LAMINA OF NERVE FIBRES

The axons of ganglion cells converge on to the optic disc from the whole retina, forming the *stratum opticum*, which is consequently deepest (20–30 μm) at the disc's periphery. They converge in a simple radial pattern from the medial (nasal) half of the retina but the macular area, inferolateral to the optic disc, complicates the course of the lateral (temporal) axons. Those from the macula form a *papillomacular fasciculus* which passes almost straight to the disc; the more temporal fibres, being more peripheral, swerve circumferentially above and below to reach the disc.

Axons of ganglion cells are non-myelinated within the retina, an optical advantage since myelin is refractile. The myelin sheaths commence as the axons enter the optic disc to become the optic nerve. A few small myelinated fibres may appear in human retinae; myelination is usual in parts of the retina in many other mammals. The axons within the retina are surrounded by the processes of retinal gliocytes (Müller cells) and other retinal astrocytes (Wolter 1959). Like their somata, the axons of ganglionic neurons vary in size, ranging from 0·6–2·0 μm in diameter, with a typical axonal ultrastructure.

Centrifugal axons have often been described and almost as often denied (Bowin 1895, Mukai 1970). Their existence in the human retina is still an open issue. Various sources have been suggested including the lateral geniculate nucleus (p. 1016), superior colliculus, hypothalamus, etc. Such retinal efferents might be vasomotor; but since efferent terminals have been described in relation to amacrine cells by Ramony Cajal and others, it is tempting to assume in the visual pathway an analogue of the cortico-olivo-cochlear connections of the auditory system (p. 1233). The majority of such studies have been in birds (Cajal) or mammals phylogenetically remote from man, a fact rarely made plain in textbooks or even monographs. Nevertheless, there is good evidence for a corticogeniculate pathway, modifying the activity of the afferent visual paths (p. 1019) and it is possible that such a connection reaches the retina.

THE INTERNAL LIMITING LAMINA

Classically, the conical branching terminals of the fibres of retinal gliocytes were held to coalesce at the surface of the vitreous body into a continuous membrane separating the stratum opticum from the vitreous gel and thus 'limiting' the retina. Some early observers denied this, considering the '*membrana hyaloidea*' (the surface layer of the vitreous) to be the sole boundary between the retina and the vitreous. Electron microscopy has led to a combination of both views. Gliocytic processes have at their terminations a basal lamina of about 0·5 μm, sinuously adapted to them externally but smooth on its internal aspect, where they are adjacent to the vitreous; the collagen fibrils of the latter blend with the glial basement membrane, which consequently can be said to be a composite structure. The internal limiting membrane is inevitably involved in fluid exchange between the vitreous and the retina and perhaps through the latter with the choroid.

PECULIARITIES OF THE MACULAR AREA

The general details of the central, macular and foveal retinal areas have already been noted. All the retinal laminae are modified in its central region and to a marked degree in the *fovea*, in the floor of which (the *foveola*, p. 1196) there are no rod cells but about 2500 close-packed elongated cones, greatly resembling rods; the *somata* of even these small cone cells are displaced peripherally to the sloping foveal wall so that only the cone *processes* are present in the foveola. Despite this distorting effect, the foveolar cone processes are strictly vertical and radial in orientation, the only other element present (which light must traverse) being the fibrous cytoplasmic processes of the gliocytes, which even here form internal and external limiting membranes. At the rim of the conical wall of the foveolar pit other modifications appear. The fovea is largely devoid of rod cells or processes, which reach only to its periphery. Its rod-free central part contains approximately 35 000 cones and in the whole fovea (about 1·75 square millimetres) there are about 100 000 of these cells. Hence, in the fovea cones are most slender and most compacted and all other layers absent, a condition which greatly favours photopic vision; here, the cones have their most specific connections (with individual midget bipolar and ganglionic neurons) according with the high degree of spatial discrimination typical of foveal vision.

Because of the general displacement of the outer nuclear lamina to the foveal periphery, the internal processes of the photoreceptors are stretched out tangentially in the external plexiform layer and hence no cone pedicles or rod spherules are present in the central fovea and foveola. The inner nuclear layer is displaced to the edge of the foveal depression and the internal plexiform, ganglionic and nerve fibre laminae are almost absent from the whole fovea. Therefore, even on the foveal wall the retina is thinner and more transparent. Capillaries reach the foveal margin, invading only the ganglionic layer at its circumference. The fovea is thus normally devoid of all blood vessels.

In the *parafoveal region*, extending about 0·5 mm around the fovea (diameter 1·5 mm), the retina is thickest, partly due to the accumulation of displaced bipolar and ganglionic neurons. Outside this a *perifoveal region* is described in which the density of cones begins to diminish rapidly, the incidence of rods increasing.

The fovea is the last part in the primate retina to attain full development, which is not completed until about the fourth postnatal month in mankind. Prenatal development of the primate

foveae has been chiefly studied in rhesus monkeys and the details are beyond the present scope of this book; Hollenberg & Spira (1973) and Hendrickson & Kupfer (1976) have reviewed the literature (p. 202).

THE OPTIC DISC AND RETINAL BLOOD VESSELS

The retina is placed between two sets of arteries and veins: the ciliary vessels of the choroid and the branches of the central retinal vessels. It depends on both circulations, neither alone being sufficient to maintain full visual activity in the retina. The choroidal circulation (p. 1185) and the orbital and intraneural parts of the central retinal vessels are described elsewhere (pp. 746, 1095).

The **central retinal artery** enters the optic nerve as a branch of the ophthalmic artery, about 1·2 cm behind the eyeball. It travels in the optic nerve to its 'head', where its fascicles (about 1000 in man) are traversing the lamina cribrosa. This region, where retinal tissues meet the neural elements of the optic nerve (including astrocytes and oligodendrocytes) and also the connective tissues of the sclera and meninges, is a highly complex area. It also provides a point of entry and exit for the retinal circulation and moreover is the only site of anastomoses with other arteries (the posterior ciliary arteries, vide infra). It is visible, by ophthalmoscopy, as the **optic disc** (7.307, 308), a region of much clinical importance since it is here that the central vessels can be inspected directly, the only vessels so accessible in the whole body. Oedema of the disc (papilloedema) may be the first sign of raised intracranial pressure, transmitted into the subarachnoid space around the optic nerve and compressing the central retinal vein where it crosses the space. The optic disc, being superomedial to the posterior pole of the eye, lies away from the visual axis. It is round or oval, usually about 1·6 mm transversely and 1·8 mm in the vertical, and its appearance is very variable; for details see Duke-Elder & Wybar (1961). In light-skinned people the general retinal hue is a bright terracotta-red and the pale pink of the disc contrasts sharply with this; its central part is usually even paler and may be light grey. These differences are due to the degree of vascularization of the two regions, which is much less at the optic disc, and to a total absence of choroidal or retinal pigment cells, the retina being represented by little more than the internal limiting lamina. Even this does not pass far on to the disc, for the retinal gliocytes are replaced by the astrocytes of the optic nerve (Anderson & Hoyt 1969). In individuals with strongly melanized skins both retina and disc are darker (7.307D). The optic disc does not project at all in many eyes and rarely enough to justify the term *papilla*. It is usually a little elevated on its lateral side where the papillomacular nerve fibres turn into the optic nerve; where the retinal vessels traverse its centre there is usually a slight depression.

The central retinal vessels occupy their own apertures in the lamina cribrosa. At this level, which is usually just beyond ophthalmoscopy, the *central retinal artery* divides into two equal branches: first into a superior and an inferior and again, after a few millimetres, into superior and inferior nasal and superior and inferior temporal branches. Each of these four supplies its own 'quadrant' of the retina, their territories being in fact much more than quadrants, since they ramify as far as the ora serrata. Corresponding veins unite to form the central retinal vein but the courses of the venous and arterial vessels do not correspond exactly and arteries often cross veins, usually lying superficial to them. In severe hypertension the arteries may press on the veins and cause visible dilations distal to these crossings. Arterial pulsation is not visible by routine ophthalmoscopy without higher magnification. The branching of the artery is usually dichotomous, equal rami diverging at angles of 45–60°; but smaller branches may leave singly and at right angles. Arteries and veins ramify in the nerve fibre layer, near the internal limiting membrane, accounting for their clarity when seen through an ophthalmoscope (7.307). Arterioles pass deeper into the retina and may penetrate to the internal nuclear lamina, from which venules return to larger superficial veins. A dense capillary bed extends between these vessels and is diffusely organized, showing no laminar pattern. The structure of blood vessels resembles that of vessels elsewhere, except that the internal elastic lamina is absent from the arteries and myocytes may appear in their adventitia. Capillaries have a non-fenestrated endothelium and numerous mural *pericytes*, extended along the vascular axis outside the endothelium and sharing its same basement membrane. The cytoplasm of both is similar in structure but pericytes do not contain myofilaments; their function remains uncertain. (For the ultrastructure of retinal capillaries see Tominaga & Ikui 1964.) Microcirculatory studies of the human retina in flat preparations, stained after trypsin digestion, reveal many details of capillary arrangement resembling those in the renal glomeruli, a network of capillaries connecting individual arterioles and venules with little connection with nearby vessels. This separation of the capillary beds is not as exclusive as in the larger vessels which feed them; the whole retinal arterial and arteriolar tree is devoid of anastomoses and arteriovenous shunts. For example, the territories of the arteries supplying a particular quadrant do not overlap nor do the branches within a quadrant anastomose with each other. In consequence, a blockage in a retinal artery causes loss of vision in the corresponding part of the visual field; the only exception to this endarterial pattern is in the vicinity of the optic disc; the posterior ciliary arteries enter the eye near the disc (7.305) and, apart from supplying the adjacent choroid, their rami form an anastomotic circle (of Zinn) in the sclera around the head of the optic nerve. Branches from this ring join the pial arteries of the nerve (Hayreh 1969) and from any arteries in this region small *cilio-retinal arteries* may enter the eye to anastomose with a retinal artery (7.307); similarly, small retino-ciliary veins may sometimes also be present. For further details see Singh & Dass (1960), who have surveyed the anastomoses between the central retinal artery and pial branches of the ophthalmic artery in the optic nerve.

Retinal capillaries do not pass towards the external surface of the retina beyond the internal nuclear lamina; they show regional differences in density, being especially numerous in the macula but absent from the central fovea. They become less numerous in the peripheral retina and are altogether absent from a zone about 1·5 mm wide adjoining the ora serrata. The central artery is innervated by sympathetic fibres and probably also has a parasympathetic supply (Ruskell 1970).

The Ocular Refractive Media

The components of the eye which transmit and refract light are the cornea, the aqueous humour, the vitreous body and the lens. Of these, only the refracting power of the lens can be varied.

THE AQUEOUS HUMOUR OR FLUID

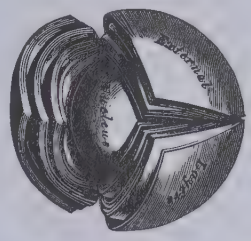
The aqueous fluid fills the anterior and posterior chambers. Its total quantity is small; it is formed by active transport and diffusion from capillaries in the ciliary processes, from which it enters the posterior chamber, passes into the anterior through the pupil and escapes at the iridocorneal angle into the anterior ciliary veins via spaces in the angle and the scleral venous sinus. Any interference with its resorption into the sinus increases the intraocular pressure, the condition known as *glaucoma*; if this persists the optic disc becomes 'cupped' and retinal degeneration leads to blindness. Partial iridectomy may re-establish the flow from the posterior to the anterior chamber, in cases where glaucoma is due to obstructive adhesions between the iris and the lens. The aqueous fluid is a nutrient, metabolic avenue for the avascular tissues of the lens and cornea; but it also maintains and regulates the intraocular pressure and hence the constancy of the optical dimensions of the eyeball. It carries glucose, amino acids and respiratory gases. It also has a high content of ascorbic acid.

THE VITREOUS BODY

This fills the vitreous chamber, occupying about four-fifths of the eyeball. It is hollowed in front as a deep concavity, the *hyaloid fossa*, which is adapted to the lens. It is a colourless, apparently

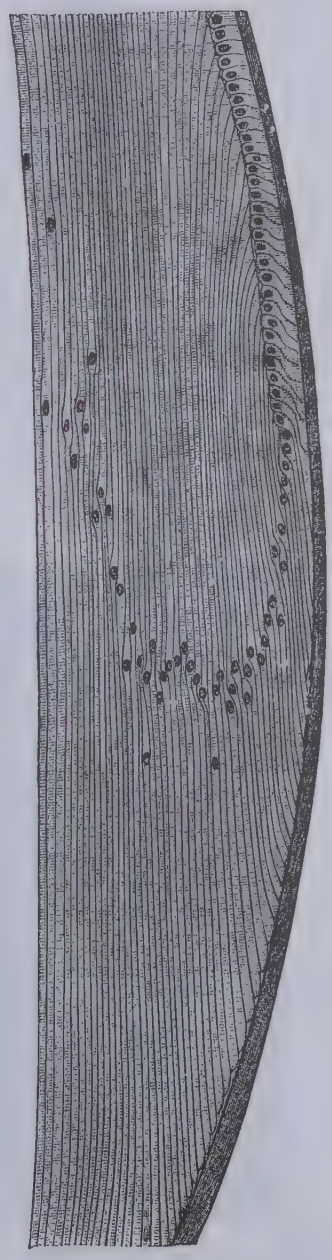
structureless, transparent gel, about 99% of water, with some salts, a little glycoprotein and hyaluronate (vide infra). Fibrils of type II collagen (p. 64), about 16 nm diameter and with a 22 nm periodicity, and an interfibrillary substance, the *vitreous humour*, can be distinguished by electron microscopy (Schwarz 1961). Peripherally the gel is condensed into a so-called *vitreous* (*hyaloid*) *membrane*. A narrow *hyaloid canal* runs from the optic disc to the central posterior surface of the lens. In fetuses this contains the hyaloid artery (p. 202) which normally disappears about six weeks before birth. The vitreous membrane is attached to the ciliary epithelium and processes and to the optic disc's rim. Anterior to the ora serrata it is thickened by radial fibres as the *ciliary zonule*, where it shows a series of radial furrows in which the ciliary processes adhere; hence some of their pigment remains attached to the zonule when they are removed. The zonule splits into two layers: a thin one lining the vitreous hyaloid fossa; and a thicker one composed of zonular fibres, collectively forming the *suspensory ligament of the lens*, which passes over the ciliary body to be attached to the capsule of the lens a little anterior to its equator. Some of the ligament's fibres are attached behind the equator (7.303) and some delicate ones to the equator itself. The ligament supports the lens and links it to the ciliaris muscle in the activities of accommodation (p. 1214).

Vitreous structure has been studied in much detail, by light and electron microscopy and X-ray diffraction (Suguira 1957, Fine & Tousimis 1961, Brini et al 1968). Its collagen fibrils vary regionally, in particular being condensed cortically. Rounded cells, *hyalocytes*, are revealed by phase contrast microscopy (for details, see Hogan 1963). No blood vessels penetrate the vitreous body and its nutrition is maintained by diffusion from the retinal and ciliary vessels.



THE LENS

The lens (7.322–324), enclosed in a capsule, lies between the iris and the vitreous body. It is encircled by the ciliary processes, which slightly overlap its equator. The *capsule* is a transparent, elastic membrane, thicker anteriorly than posteriorly. It contains no elastic tissue, its elasticity residing perhaps in the disposition of the fine fibrils of which it is formed. It has been described as a very thick basement membrane, being PAS positive. Its fibrils have a periodicity of 60 nm, differing from those of the zonule, with which they are continuous around the equator. Posteriorly the lens abuts the hyaloid fossa of the vitreous body; anteriorly it is in contact with the free border of the iris but recedes from it peripherally, so forming the posterior chamber.



The *lens* is a transparent, biconvex body, its anterior convexity being of greater radius than the posterior. The central points of these surfaces are the *anterior* and *posterior poles*; a line connecting these is the *axis* of the lens and the marginal circumference is its *equator*. Its dioptric power is much less than that of the cornea. All ocular optical media have a refractive index quite close to that of water (1·33) but the corneal surface is in contact with air and most of the 58 dioptres of which an eye is capable are effected here. The value of the lens is its ability to *vary* its dioptric power, a quality partly dependent upon a gradient in its refractive index from 1·386 at its periphery to 1·406 at its core. It contributes about 15 dioptres to the total of the eye. Its *range* in dioptric power, however, does not quite reach this, even at birth. Most young children show minor refractive errors (Sorsby et al 1961) and the available dioptric range decreases with age, being halved at 40 years, and reduced to 1 or 2 dioptres at 60. For further information on physiological optics consult Bennett & Francis (1962) and Duke-Elder (1969).

STRUCTURE OF THE LENS

The lens consists of a soft cortical substance and a firm, central part, the nucleus (7.322). Faint sutural lines (*radii lentis*) radiate from the poles to the equator; in adults there may be six of these lines or more but in fetuses there are only three, diverging at angles of 120° like a Y which is upright on the anterior surface and inverted on the posterior (Mann 1924). These lines, made of an amorphous substance, correspond with the free edges of septa which dip into the lenticular substance. When hardened the lens appears to be composed of a series of concentric laminae, interrupted at the septa. Each lamina is built of lens fibres (7.323B), like ribbons, with serrated edges, the serrations being reciprocally interlocked and in part connected by desmosomes (Wanko & Gavin 1961); their ends are apposed at the sutures. The contacts between the lenticular fibres have been described as gap junctions in mice (Rafferty & Esson 1974) and in human and bovine lenses (Philipson et al 1975) but Kuwabara (1975) considered that the

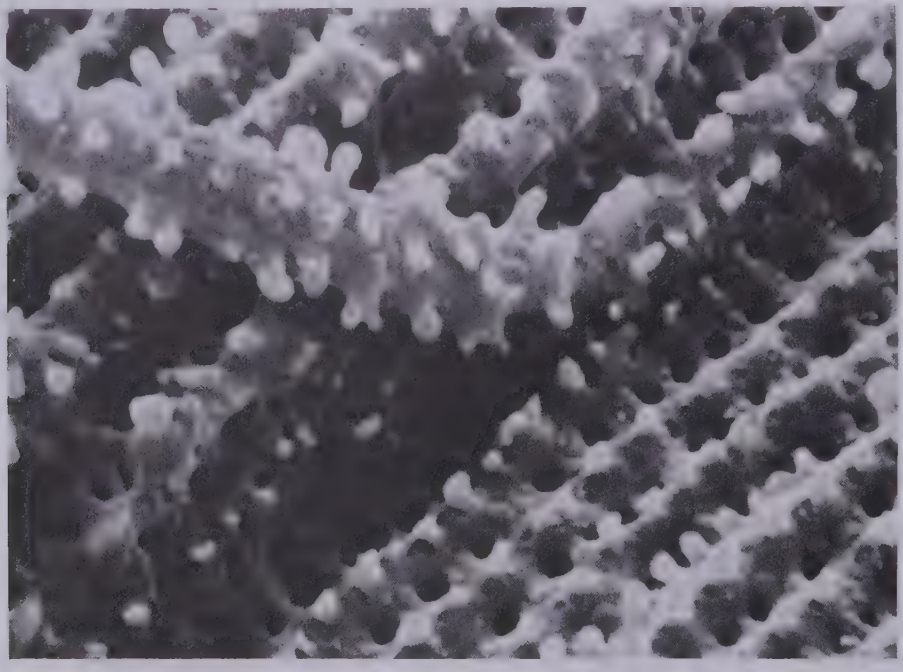
cortical cells of the lens adhere by reciprocal 'knob and socket' junctions and the deeper cells by fine ridges. These *lens fibres* curve from the anterior to posterior sutures (7.324). No fibres pass from pole to pole; those beginning near the pole on one surface end peripherally on the other and vice versa. Fibres in the outer laminae are nucleated, forming a nuclear layer, equatorially most distinct. The deeper fibres, which have lost their nuclei, are less flexible and their contours more deeply serrated. Superficial fibres, more recently formed, are more flexible, hexagonal in cross-section, with two opposite sides longer than the rest. Adhesion on these longer sides is considered less firm than elsewhere, perhaps permitting moulding of the lens by its capsule in accommodation. The total number of lens cells or fibres is estimated at about 2000 in adult lenses. They contain semi-stiff transparent proteins (crystallins) which give the lens its transparent, deformable properties.

The anterior surface of the lens is covered by a transparent layer of nucleated cuboidal epithelium. At the equator these cells elongate and their gradual transformation into fibres can be traced (7.323A). In tangential section or surface view these cells are polygonal and about 15 μm across. In the anterior central area they may be flattened to a mere 6 μm. More peripherally they diminish in width but increase greatly in length and mitoses are more frequent. At the equator mitotic activity is maximal. Lens 'fibres' retain their nuclei for a long period; but the oldest and hence the deepest fibres lose them. Despite their very slow growth, the epithelial cells are relatively active; experimental injuries in mice (Rafferty 1976) heal completely within three days.



In fetuses the lens is nearly spherical, with a slight reddish tinge, and is soft, breaking up on the slightest pressure. A hyaloid artery from the central retinal artery traverses the vitreous body to the posterior pole of the capsule of the lens, whence its branches spread as a plexus covering the posterior surface and continuous round the capsular circumference with the vessels of the pupillary membrane and iris. *In adults* the lens is avascular, colourless, transparent and firm in texture. *In old age*, it is less curved on both surfaces, slightly opaque, of amber tint and denser. In *cataract* the lens gradually becomes opaque and blindness ensues.

The dimensions of the lens are optically and clinically important. Its diameter at birth is 6·5 mm, increasing to 9·0 mm at 15 years and continuing to grow very slowly throughout life. Its axial

7.324 The structure of the fetal (A) and adult (B) human lens, showing the major details of arrangement of the lens cells or fibres. The anterior (a) and posterior (b) triradiate sutures are shown in the fetal lens and it is clear that fibres pass from the apex of an arm of one suture to the angle between two arms at the opposite pole, as shown in the coloured segments. Intermediate fibres show the same reciprocal behaviour, ending nearer to one pole, where they start further from the other, and so on. The suture pattern becomes much more complex as successive strata are added to the exterior of the growing lens, the original arms of each triradiate suture showing secondary and tertiary dichotomous branchings. See 7.299 for acknowledgement.

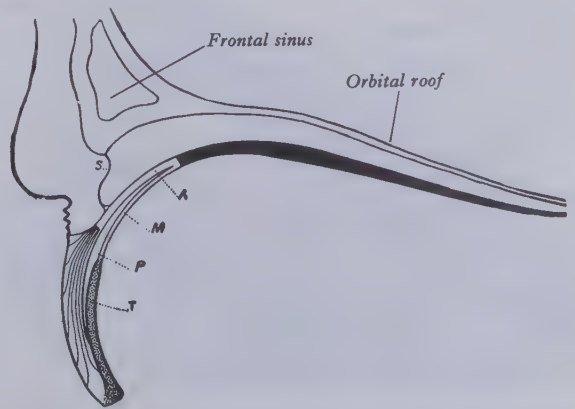
7.324B

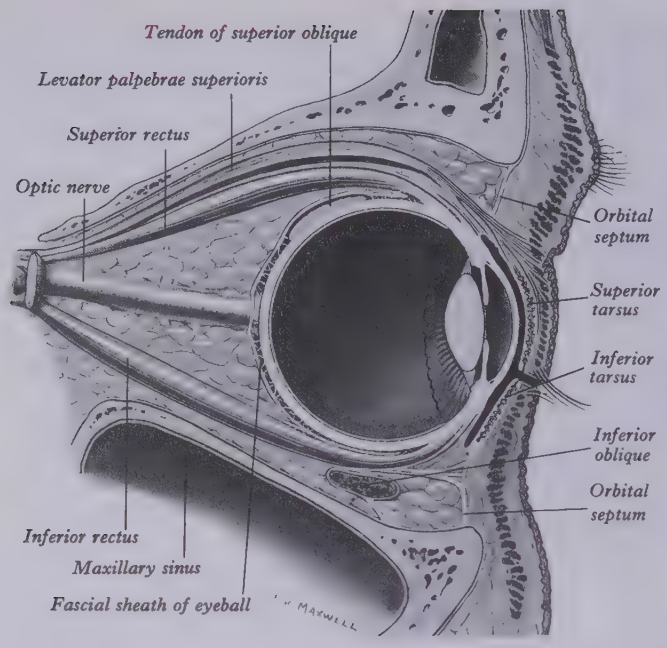
dimension increases from 3·5–4·0 mm at birth to 4·75–5·0 mm at 95. Its anterior radius (about 10.0 mm) is greater than its posterior (about 6·0 mm), but both are reduced during accommodation. Continued lenticular growth is due to a continual slow production of new cells in its equatorial epithelium. The ultrastructure of the capsule and epithelium have been studied (Wanko & Gavin 1960, Cohen 1965); the capsule consists largely of fine filaments with a periodicity of 60 nm. The fibre consist essentially of a fine fibrillary substance. In adults there are 2100–2300 fibres and they may be 8–12 mm in length in the cortical zone. Microfilaments of human fibres are 5–9 nm in diameter and, according to Rafferty & Goosens (1978), their arrangements, constitution and sizes in different mammals may be associated with differing accommodative capacities.

THE ACCESSORY VISUAL APPARATUS



This includes the extraocular muscles, fasciae, eyebrows, eyelids, conjunctiva and lacrimal apparatus.

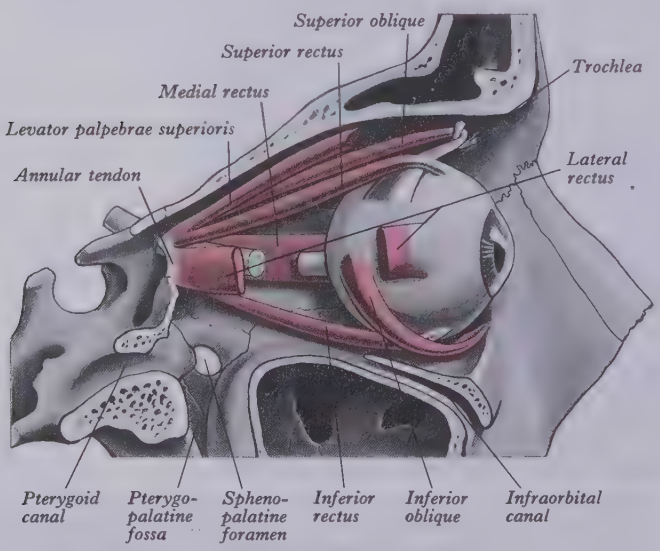
The Extraocular Muscles



Extraocular or extrinsic ocular muscles (7.325–330) include an elevator of the upper eyelid, *levator palpebrae superioris*, and six muscles capable of rotating the eye in almost any direction; these comprise four *recti* (*superior*, *inferior*, *medialis* and *lateralis*) and two *obliqui* (*superior* and *inferior*). This is a phylogenetically ancient pattern of muscles, extending with slight modification through almost the entire vertebrate phylum, apart from the levator palpebrae superioris, a later delamination from the rectus superior to serve the upper eyelid in tetrapods.

In general structure extraocular muscles resemble skeletal muscles elsewhere but differ in some features particularly in their innervation, contraction and pharmacological properties (Bach-y-Rita et al 1971, Hogan et al 1971, Davson 1976). At least two types of fibre occur: a slender (9–11 μm), slow-contracting form and a thicker (11–15 μm), 'twitch' type of fibre. The former have motor endings of the 'en-grappe' category, the latter motor end-plates (Davidowitz et al 1977).

The levator palpebrae superioris (7.325–329), thin and triangular, arises from the inferior aspect of the lesser wing of the sphenoid, anterosuperior to the optic canal and separated from it by the attachment of the rectus superior. At its posterior attachment it is narrow and tendinous but anteriorly it becomes broad and fleshy, its medial margin being almost straight and its lateral concave. The muscle ends in a wide anterior aponeurosis splitting into two lamellae; some fibres of the superior lamella are attached to the anterior surface of the superior tarsus (p. 1215) while others



7.325 The levator palpebrae superioris, showing its connections. A = superficial lamella of aponeurosis; M = deep lamella, superior tarsal muscle (of Müller); P = interval between superficial and deep lamella of aponeurosis; T = tarsus; S = orbital septum.

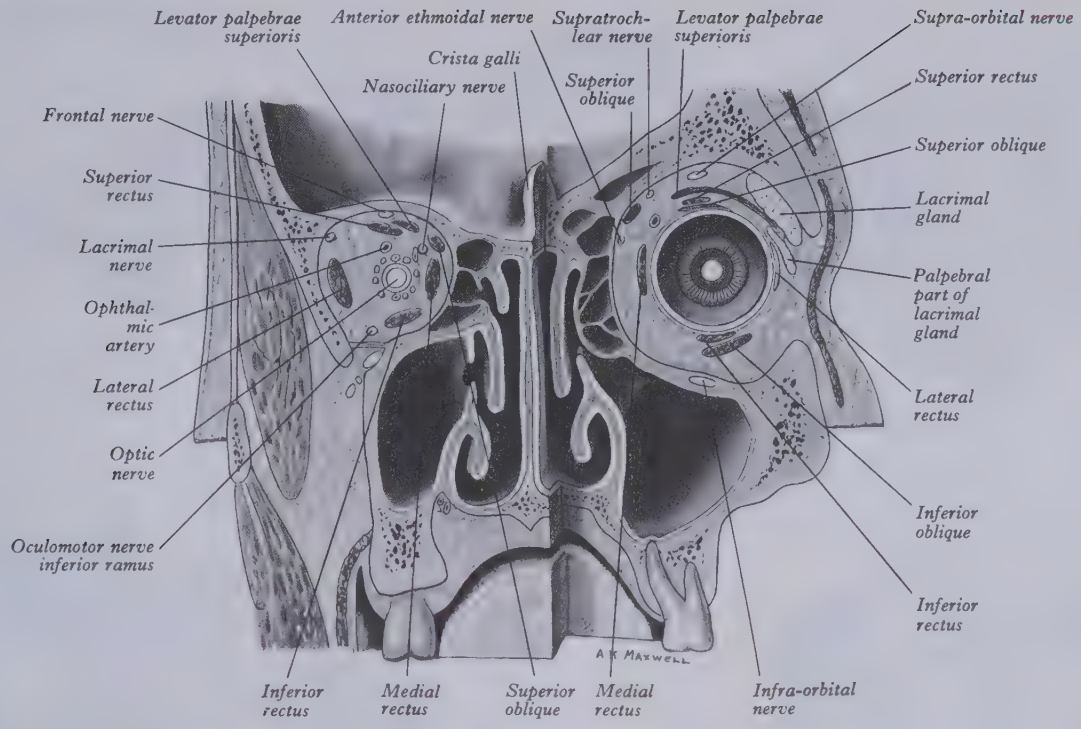
7.326 Sagittal section through the right orbital cavity.

radiate, traversing the overlying orbicularis oculi to the skin in the upper eyelid. The inferior lamella contains non-striated myocytes, the so-called *superior tarsal muscle*; it is attached directly to the upper margin of the superior tarsus and covered inferiorly by conjunctiva. A less prominent stratum of non-striated muscle, the *inferior tarsal muscle*, also exists in the lower lid, uniting the inferior tarsus to the fascial sheath of the rectus inferior and its expansion to the sheath of the inferior oblique. Another thin layer of non-striated muscle, *orbitalis*, bridges the inferior orbital fissure; its function is uncertain. The superior and inferior tarsal muscles presumably assist in the elevation of the upper and depression of the lower eyelid. All three non-striated muscles have a sympathetic innervation.

The connective tissue on the adjoining surfaces of the levator palpebrae superioris and rectus superior is fused; where the two muscles separate to reach their anterior attachments, the fascia between them forms a thick mass attached to the superior conjunctival fornix, which is usually described as an additional attachment of the levator palpebrae superioris. Traced laterally, the aponeurosis of the levator passes between the orbital and palpebral parts of the lacrimal gland to a tubercle on the zygomatic bone, just within the orbital margin (p. 346); traced medially it loses its tendinous nature as it passes closely over the reflected tendon of the obliquus superior, continuing to the medial palpebral ligament as loose strands of connective tissue. Levator palpebrae superioris raises the upper eyelid but during this process the lateral and medial parts of its aponeurosis are stretched and thus limit its action; the elevation is also said to be checked by the orbital septum (p. 1215). ('Check' mechanisms abound in the orbit but there is little direct evidence that connective tissue structures thus implicated do function in this manner. See also p. 1213.)

7.327 The muscles of the right orbit: lateral aspect.

The four recti (7.326–330) are attached posteriorly to a *common annular tendon* around the superior, medial and inferior margins of the optic canal (7.329); this fibrous annulus continues laterally across the inferomedial part of the superior orbital fissure and is attached to a tubercle on the margin of the greater wing of the sphenoid. The tendon is closely adherent to the optic nerve's dural sheath and the surrounding periosteum. Within it are: (1) the anterior aperture of the optic canal, transmitting the optic nerve and ophthalmic artery; and (2) the medial part of the superior orbital fissure transmitting the two divisions of the oculomotor and the nasociliary and abducent nerves. The superior ophthalmic vein may pass within or above the annular tendon, the inferior ophthalmic vein within or below it. Two specialized parts of this ring may be discerned: a lower, to which are attached the rectus inferior, part of the rectus medialis and the lower fibres of the rectus lateralis; and an upper, providing attachment to the rectus superior, part of the rectus medialis and the upper fibres of the rectus lateralis; a second small tendinous slip of the rectus lateralis is attached to the orbital surface of the greater wing of the sphenoid, lateral to the annulus. Each muscle passes forwards, in the position implied by its name, to be attached anteriorly by a tendinous expansion into the sclera, posterior to the margin of the cornea, and at average distances from the latter as follows: medialis 5·5 mm; inferior 6·5 mm; lateralis 6·9 mm; superior 7·7 mm.



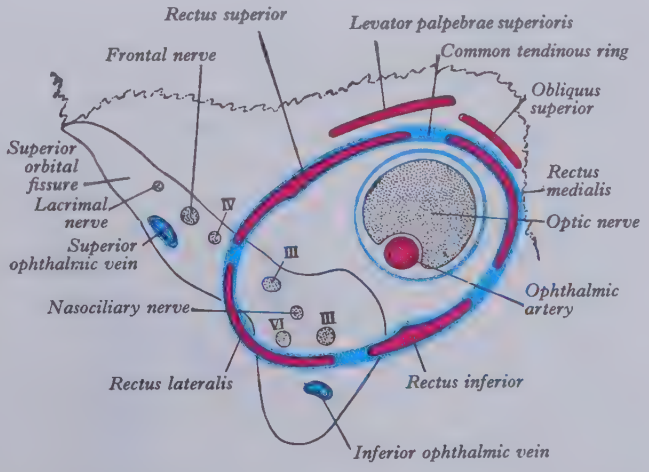
The obliquus superior (7.327) is fusiform and lies superomedial in the orbit; it arises from the body of the sphenoid superomedial to the optic canal and to the tendinous attachment of the rectus superior. Passing forwards it ends in a round tendon, which plays through a fibrocartilaginous loop, the *trochlea*, attached to the trochlear fossa of the frontal bone. Tendon and trochlea are separated by a delicate synovial sheath. After traversing the trochlea the tendon is deflected posterolaterally and inferior to the rectus superior to be attached to the sclera *behind* the equator in its superolateral posterior quadrant, between the recti superior and lateralis.

The obliquus inferior (7.327), a thin, narrow muscle near the anterior margin of the floor of the orbit, arises from the orbital surface of the maxilla lateral to the nasolacrimal groove. Ascending posterolaterally at first between the rectus inferior and the orbital floor and then between the eyeball and the rectus lateralis, it is attached to the sclera *behind* the equator in its inferolateral posterior quadrant between the rectus inferior and rectus lateralis, near to but slightly posterior to the attachment of the obliquus superior.

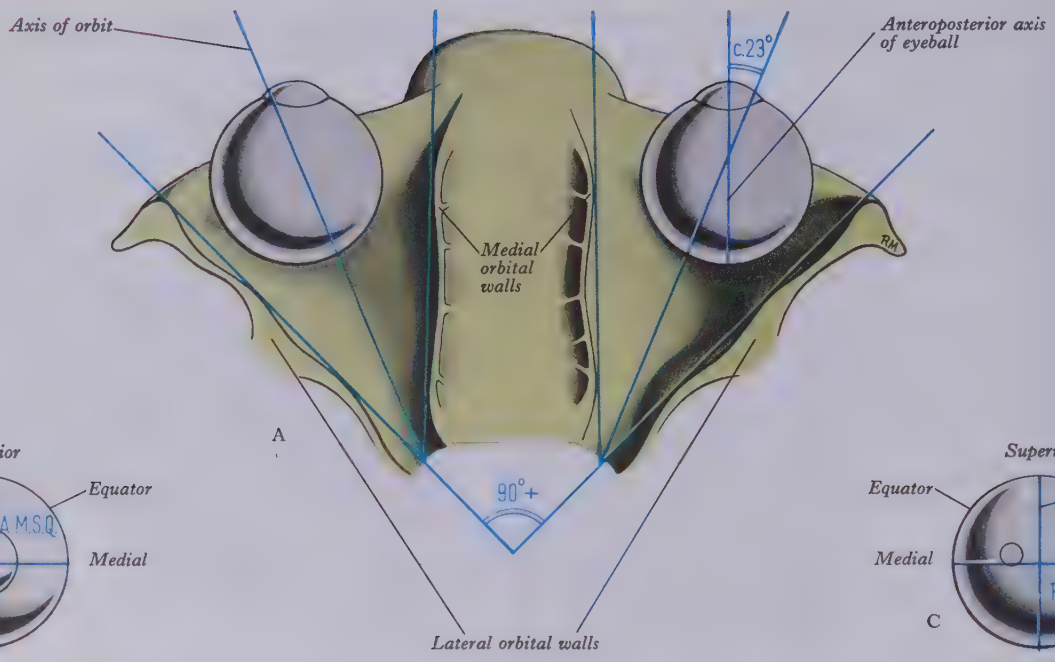
Nerve supply. The levator palpebrae superioris, obliquus inferior and recti superior, inferior and medialis are supplied by the oculomotor nerve, the obliquus superior by the trochlear and the rectus lateralis by the abducent nerve.

ACTIONS OF EXTRAOCULAR MUSCLES

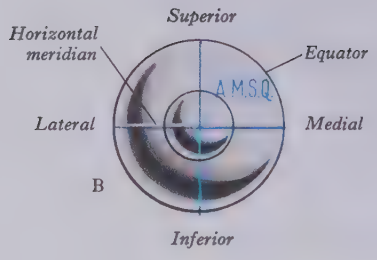
Levator palpebrae superioris elevates the upper lid, its antagonist being the orbicularis oculi. The degree of elevation which, apart from blinking, is maintained for long periods during waking hours is a compromise between the adequate exposure of the optical media and control of the entering light. The amount of light, in very bright sunshine, can be reduced by lowering the upper lid, reducing glare. Though much is known of the physiology of blinking (McEwen & Goodner 1962) and its significance in the distribution of lacrimal secretions, the continuous activity of the levator in keeping the lid raised has attracted little interest.



7.328 Coronal sections through the two orbits: posterior aspect. On the left side the plane of the section is more posterior and passes behind the eyeball.

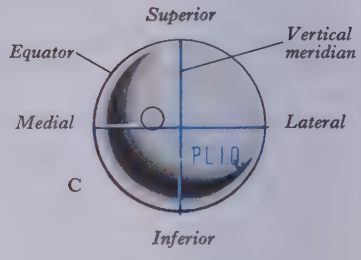


The respective roles of its main, striated, voluntary part and small, inferior non-striated stratum (superior palpebral, tarsal or Müller's muscle) have not been clarified.



The *six extraocular muscles* all *rotate* the eyeball in directions dependent upon the geometrical relation between their osseous and global attachments (7.330), which are, of course, altered by the ocular movements themselves. Before considering their activities it must be recognized that *human* extraocular muscles are not generally accessible to inspection; consequently many opinions regarding them depend on deductions from malfunction due to disturbance of innervation. A complete assessment of the exact extent of neural injury is rarely possible; but this is not to say that, in the vast clinical literature available, there are not at least some valid observations. It is also essential to appreciate that any movement of an eye alters the tension and/or length in *all six* muscles, though direct observation of this has rarely been attempted, even in experimental animals (Sherrington 1905, Szentágothai 1950). It is at least likely that all six muscles are continuously involved and it is therefore merely a preliminary but necessary exercise to consider each in isolation. Because they form more obvious groupings as antagonists or synergists, it is useful to consider the four recti and two obliques as separate groups, remembering always that they act in concert.

Of the four *recti*, the *medial* and *lateral* exert comparatively straightforward forces on the eyeball. Being approximately horizontal when the visual axis is in its primary position, directed to the horizon, they rotate the eye medially (adduction) or laterally (abduction) about an imaginary vertical axis (7.330). They are antagonists; by reciprocal adjustment of their lengths the visual axis can be swept through a horizontal arc. When both eyes are involved, as is usual, the four medial and lateral recti can either adjust both visual axes in a *conjugate* movement from point to point at infinity, their axes remaining parallel, or they can *converge* or *diverge* the axes to or from nearer or more distant objects of attention in the visual field. But since they do not rotate the eye around its transverse axis, the medial and lateral recti cannot effect the extremely frequent act of elevating or depressing the visual axes as gaze is transferred from nearer to more distant objects or the reverse. This is the contribution of the *superior* and *inferior recti* (aided, as will become apparent, by the two oblique muscles). However, the geometry of these is a little less simple and the key to the rotations which they effect is the obliquity of the orbit (7.330), whose axis does not correspond with the visual axis in its primary position but diverges from it at an angle of approximately 23°, a value varying in different individuals, being dependent upon the angle between the orbital axes and the median plane (7.330A). Hence, the simple rotation caused by an isolated *superior rectus*, analysed with reference to the three hypothetical ocular axes, appears to be complex, being primarily *elevation* (transverse axis), and secondarily a less powerful *medial rotation* (vertical axis) and slight *intorsion* (anteroposterior axis) in which the mid-point of the upper rim of the cornea (often referred to as '12 o'clock') is rotated medially towards the nose. These actions, compounded in fact as a single, simple rotation, are easily



7.329 Scheme to show the common tendinous ring, the origins of the recti and the relative positions of the nerves entering the orbital cavity through the superior orbital fissure. Note that the ophthalmic veins frequently pass through the common tendinous ring. Modified from a figure in Whitnall 1932.

7.330. The geometrical basis of ocular movements.
A. The relationship between the orbital and ocular axes, with the eyes in the primary position of parallel visual axes.
B and C. The ocular globe in anterior and posterior views to show conventional geometry: meridia, equator, etc. A.M.S.Q = anterior medial superior quadrant; P.L.I.Q = posterior lateral inferior quadrant.
D. The orbits from above showing the medial and lateral recti and the superior rectus (left) and inferior rectus (right), indicating turning moments primarily around the vertical axis.
E. Superior (left) and inferior (right) oblique muscles showing turning moments primarily around the vertical and also anteroposterior axes.
F. Lateral view to show the actions of the superior and inferior recti around the transverse axis.
G. Lateral view to show the action of the superior and inferior oblique muscles around the anteroposterior axis.
H. Anterior view to show the medial rotational moment of the superior and inferior recti around the vertical axis. Conventionally the 12 o'clock position indicated is said to be *intorted* (superior rectus) or *extorted* (inferior rectus) as indicated by the small arrows on the cornea.
I. Anterior view to show the torsional effects of the superior oblique (intorsion) and inferior oblique (extorsion) around the anteroposterior axis, as indicated by the small arrows on the cornea.

appreciated when it is seen that the direction of traction of the superior rectus runs *posteromedially* from its attachment *anterior* to the equator and *superior* to the cornea to its osseous attachment near the orbital apex (7.330).

The *inferior rectus* pulls in a similar direction but rotates the visual axis *downwards* about the transverse axis. It is clear, from its comparable geometry, that it also rotates the eye *medially* on a vertical axis but that its action around the anteroposterior axis *extorts* the eye, i.e. rotates it so that the corneal 12 o'clock point turns *laterally*. Superior and inferior recti, therefore, both rotate the eye medially and, since their effects around the transverse and anteroposterior axes are opposed, their combined, equal contractions could only rotate the eye medially. In binocular movements they thus assist the medial recti in converging the visual axes; and by reciprocal adjustment they can elevate or depress the visual axes. It must be added that, as the eye is rotated laterally, the lines of traction of the superior and inferior recti approach the plane of the anteroposterior ocular axis (7.330); hence their rotational effects about this and the vertical ocular axis diminish. In abduction to about 23°, they become almost purely an elevator and depressor of the visual axis. The *superior oblique* acts on the eye from the trochlea and, since the attachment of the *inferior oblique* is for practical purposes vertically below this, both muscles approach the eye at the same angle, being attached in approximately similar positions in the *superior* and *inferior posterolateral* ocular quadrants (7.330). From this geometry it is easy to understand that the superior oblique elevates the *posterior* aspect of the eye, the inferior depressing it. Hence, the former rotates the visual axis *downwards* and the latter *upwards*, both movements being around the transverse axis. But the obliquity of both is such that their traction, when the eye is in the primary position, is in a direction *posterior* to the vertical axis; both therefore rotate the eye *laterally* around this axis. With regard to the anteroposterior axis it is not difficult to deduce that in isolation the superior oblique *intorts* the eye, the inferior oblique *extorting* it. Like the superior and inferior recti, therefore, the two obliques have a common turning movement around the vertical axis but are opposed forces in respect of the other two. Acting in concert they could therefore assist the lateral rectus in abducting the visual axis, as in *divergence* of the eyes in transferring attention from near to far. Again, like the superior and inferior recti, the directions of traction of the oblique muscles also vary with ocular position; they become more nearly a pure elevator and a depressor as the eye is adducted.

In a short analysis of this kind much must be omitted and nothing can be said of the defects of ocular movement. For further information refer to Whitnall (1932), Cooper et al (1955),

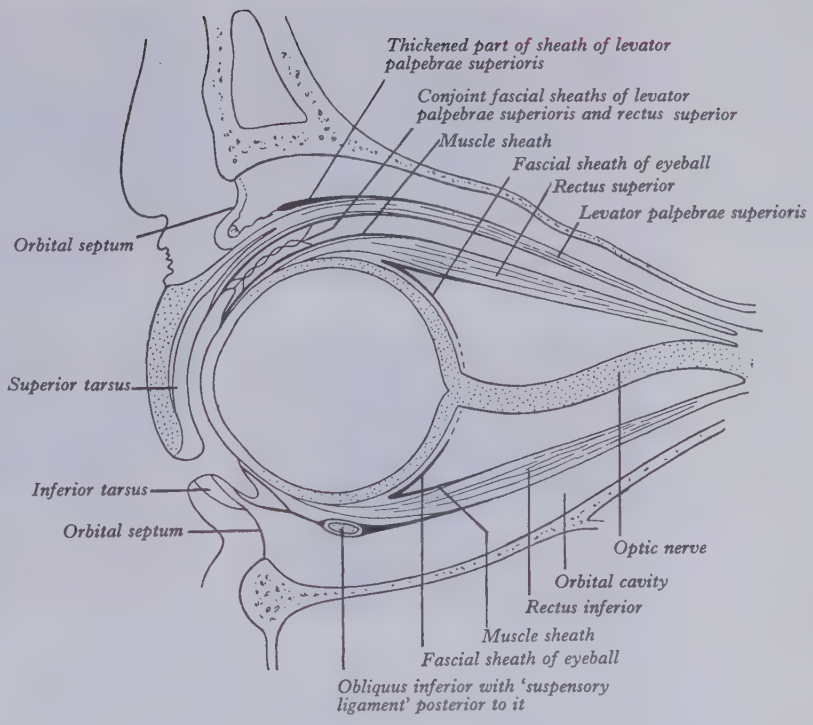
Cogan (1956), Schlossmand & Priestley (1966), Alpern (1969) and Davson (1972). For those requiring the barest data, the actions of extraocular muscles may be summarized as follows:

There is a misleading custom of linking the extraocular muscles together, usually in pairs, such as the right superior oblique and left inferior rectus, because they are supposed to deviate the visual axes down and to right, as doubtless they do. Such limited views may have a mnemonic value but they ignore the inescapable fact that in any ocular rotation *all* six muscles must change in length. Since we do not know much of the reciprocal innervational circuits of the extraocular muscles, it is impossible to dogmatize as to whether every muscle is contracted precisely in step with the progressive inhibition of an anatagonist, although the few experiments previously quoted do support such a view. However that may be, it would be more reasonable to link the superior, inferior and medial recti together as adductors or *convergence* muscles and the two obliques with the lateral recti as abductors or *divergence* muscles, a useful concept in view of the endless convergent and divergent movements of the visual axes most commonly required. Even this is an over-simplified view; convergence is usually accompanied by depression of the visual axes towards objects nearby, divergence by elevation. In these much more complex, concerted activities, the torsional effects of the muscles become much more important. Analysis shows that in simple, *cardinal* movements (adduction–abduction, elevation–depression) the torsional effects cancel out and they must also do so in all intermediate positioning of the visual axes to preserve the relation of corresponding retinal loci and hence binocular (single) vision. So far, head movements have been ignored but it is common observation that ocular movements are frequently, perhaps usually, accompanied by movements of the head, which might be likened to the *coarse* adjustment of an optical instrument such as a microscope, the *finer* adjustments being made by the ocular musculature.

It is interesting that while ocular rotations are clearly under voluntary control, *torsional* movements cannot be voluntarily initiated. But when the head is tilted relative to body, reflex torsions occur and are necessary to preserve retinal correspondence. Any small lapse in the concerted adjustment of both retinae entails diplopia. It is indeed surprising that such a complex organization of extraocular, neck and other muscles is learnt so effectively early in life that diplopia is rarely experienced; but the prize, of course, *stereoscopic vision*, is a great one.

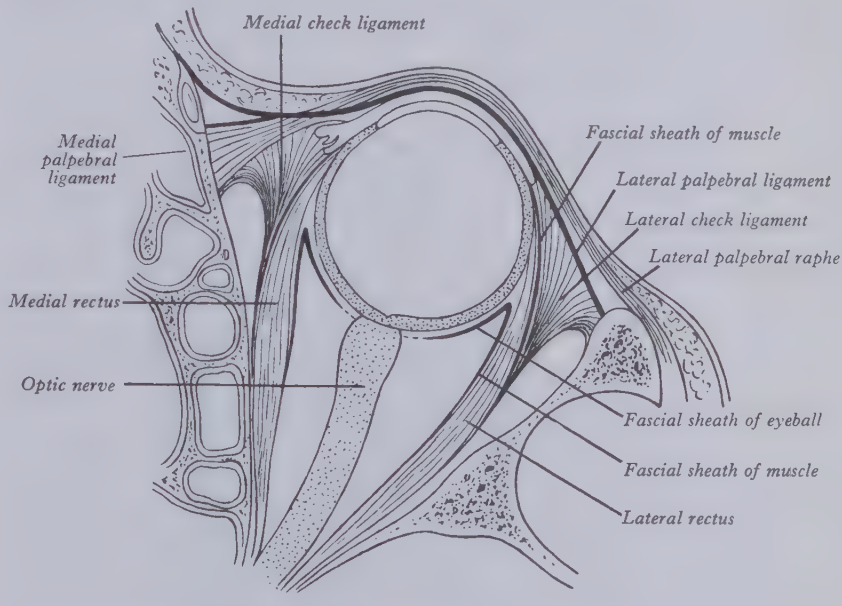
All binocular movements are either *conjugate* or *disjunctive*, the visual axes either being trained in parallel or inclined in convergence/divergence activity. While it is a necessary introductory simplification to analyse both forms of action in terms of static geometry, in reality both are dynamic and hence more complex than simple analysis suggests. In so-called 'fixation' of a focus of attention, whether uni-ocular or binocular, the visual axis is not 'fixed' in a perfectly steady manner but undergoes minute, but observable flicking (of a few minutes or even seconds of arc) across the true line of fixation. Such *micro-saccades* are rapid and surprisingly complex (see Barlow 1952, Riggs et al 1960, etc.). The term *saccade* (a French word of obscure origin meaning a 'jerk on the reins') was introduced by Dodge in 1903 for similar but much larger swings of fixation observed in subjects reading a line of print. Amplitude, velocity and reaction time in saccadic movement were first studied in detail by Westheimer (1954) and Robinson (1964) and investigations carried even further by Childress & Jones (1967), Becker & Fuchs (1969), Hallett & Lightstone (1976) and others. In general, reaction times and movements are measured in microseconds, amplitude varies from seconds to many degrees, with an accuracy of 0·2° or better, and the velocity of a large saccade may reach 500° per second. The speed of the saccades (an obvious survival factor) is assured by an initial contraction of the appropriate muscles which is slightly excessive (the 'pre-emphasis' of Robinson 1964), the necessary deceleration when the target is fixated being apparently due largely to the visco-elasticity of the extraocular muscles and orbital soft tissues, rather than to antagonistic muscular activity.

Clearly, saccadic activity is almost ever-present in human vision, and not merely in reading or the visual target practice of experimental laboratories. Not only are both visual axes endlessly and rapidly transferred to new points of interest in any part of the total visual field, but binocular gaze is very frequently made to travel routes of the most variable complexity in examining objects of some extent in the field; to this must be added the maintenance of *both* visual axes with sufficient accuracy to avoid diplopia. It is interesting to note in passing that binocular movements involving convergence are markedly slower than conjugate movements (Alpern & Wolter 1956), presumably due to the greater complexity of neural control (though the speed of contraction of the ciliaris must be a factor). Conjugate movements, indeed, might almost be 'programmed', in the current electronic jargon; but most visual human activity concerns targets of regard near enough to demand convergence and hence a neuronal intermediation of greater flexibility. Since the prime purpose is clear perception of a 'target', it is not surprising that the visual input is itself utilized in continuous feedback to the correct aiming of visual axes. Disparity in retinal images is demonstrably a strong stimulus to accurate uni-ocular fixation and binocular convergence during saccadic movement; and the sudden withdrawal of experimental stimuli interrupts corrective saccades. An interesting product of such experimentation is the observation that when a target, towards which an eye has commenced a saccade, is rapidly returned to its first position, the eye continues its saccade, as if an appraisal of the target's second position leads to a sequence of neuro-muscular events which is planned and irreversible. This has prompted some observers to liken the control to a 'sampled data system' (Young & Stark 1963) and to various other types of 'computer' apparatus. Whatever else they may achieve, such experiments do demonstrate a discontinuity in visual movement and perhaps therefore in visual perception. We are so accustomed to regarding vision as continuous, that the necessity for some kind of discontinuity, if feedback is to operate discriminantly, is overlooked. Of course, the millisecond scale of events might obscure such discontinuity; the much slower sequence in cinematography easily sustains a similar illusion of continuous vision. Much of the content of consciousness and memory can be dependent upon and evoked by visual stimuli (including the encoding of speech, mathematics and music). Hence the study of saccadic vision has a larger significance than the simpler mechanisms of visual movement. Since it is concerned with elucidating a particularly precise and intricate motor-sensory organization, it may also illumine cerebral activities on a much wider scale.



In addition to these considerations, there is much evidence that the continual movements of the eye are actually essential for vision to occur at all; the retinal and more central neural networks appear to be designed primarily to detect transient events such as movements rather than static, maintained stimuli. Indeed, images

which are essentially static, such as those due to retinal blood vessels, are not detectable unless made to move, e.g. by shifting low-angle illumination with an ophthalmoscope. This finding may be related to the complex architecture of the retina and to the presence of circuits which are specifically used to detect movements, e.g. those involving cholinergic amacrine cells (p. 1202).



Since the recti exert a *posterior* traction while the obliques pull the eyeball to some degree *anteriorly*, it is sometimes suggested that they collectively position it in the orbital cavity, preventing anteroposterior movements of the eyeball, assisted perhaps by various 'check ligaments' (vide infra).

The Fascial Sheath of the Eyeball

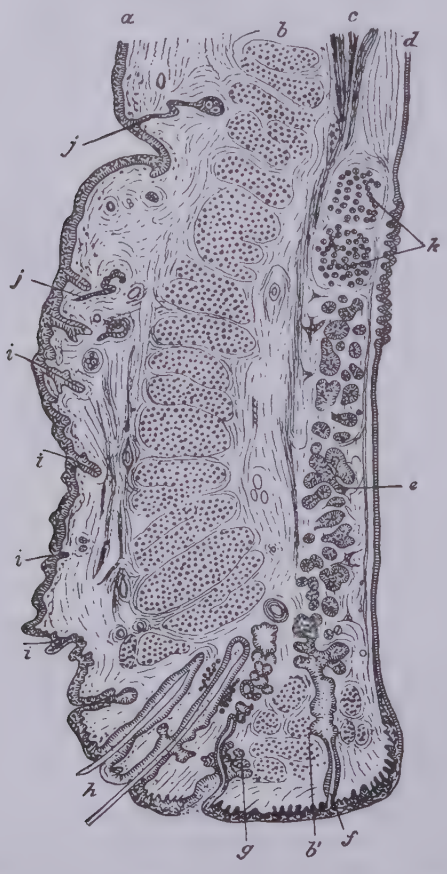
A thin fascial membrane envelops the eyeball from the optic nerve to the corneoscleral junction, separating it from the orbital fat and forming a socket for its free rotation (7.331). Its ocular aspect is smooth and separated from the sclera by an *episcleral space*, which is traversed by delicate bands of connective tissue extending between the fascia and the sclera. Posteriorly the fascia is traversed by ciliary vessels and nerves and fuses with the sheath of the optic nerve and the sclera around the nerve's entrance. It also blends with the sclera anteriorly, just behind the corneoscleral junction. It is perforated by the tendons of the extraocular muscles and is reflected on to each as a tubular sheath. The sheath of the obliquus superior reaches the fibrous trochlea of that muscle, that of the obliquus inferior the orbital floor, to which it gives off a slip. The sheaths on the recti fade into their perimysium but give off important expansions. That from the rectus superior blends with the tendon of the levator palpebrae superioris, that of the rectus inferior is attached to the inferior tarsus and the sheath of obliquus inferior. The expansions from the sheaths of recti medialis and lateralis are triangular, strong and attached respectively to the lacrimal and zygomatic bones; as they may limit the actions of the two recti, they are the *medial* and *lateral check ligaments*. An inferior thickening of the ocular fascial sheath is the *suspensory ligament of the eye* (Lockwood 1886); it is slung like a hammock below the eye, being expanded centrally and narrowing at its ends; it is formed by the union of the margins of the sheath of rectus inferior with the medial and lateral check ligaments. Anomalies of these fascial arrangements are said to interfere with normal ocular movements, causing various types of squint (Nutt 1955). However, apart from the suspensory ligament, there is no convincing evidence that any of the so-called check ligaments actually limit movement. The link between the fasciae covering the superior rectus and levator palpebrae superioris is of no known significance; it does not impede independent movements of the lid and eye. It is, however, plausible to assume that orbital connective tissue must be arranged to assist in the location of the eye within the orbit, but without obstruction to the activities of the extrinsic muscles. Its connections must also prevent the gross displacement of orbital fat, for this would interfere with the accurate positioning of the two eyes in binocular vision. A reappraisal of the disposition of orbital adipose and connective tissues by Koornneef (1977) emphasizes a series of radial septa which he describes as extending from the ocular fascial sheath to the periorbita. These could provide an excellent suspensory system. His dissections also confirm the presence of separate muscular sheaths, as here described.

7.331A Scheme of the orbital fascia in sagittal section (after Whitnall 1932).

7.331B Scheme of the orbital fascia in horizontal section (after Whitnall 1932).

The orbital fascia forms the periosteum of the orbit, or periorbita, but is only loosely connected to bone. Behind it is united with the dura mater and the sheath of the optic nerve and is continuous anteriorly with the periosteum at the orbital margin, where it gives off a stratum contributing to the orbital septum. One process of it holds the trochlea in position; another, the *lacrimal fascia*, forms the roof and lateral wall of the sulcus for the lacrimal sac (p. 346). Lang (1975) has detailed the vascularization of the orbital periosteum and fascia.

Visual Reflexes



The nerve impulses concerned with *visual reflexes* effecting movements of the eyes, head and neck in response to visual stimuli follow the optic nerves and tracts to the superior colliculi. Traversing complex connections there, they travel along the tectospinal and tectobulbar tracts to the motor neurons of spinal and cranial nerves (p. 987).

Pupillary Light Reflex

Increased illumination causes reflex meiosis (pupillary contraction), the impulses concerned travelling by the optic nerve and tract to the pretectal nuclei of both sides (p. 987), whence short axons of secondary neurons run close to the central grey matter, conveying impulses to the accessory oculomotor (Edinger–Westphal) nuclei (p. 1097); from there, preganglionic axons reach the ciliary ganglia via the oculomotor nerves and their branches to the inferior oblique muscles. Postganglionic fibres from the ganglia

7.332 In the top row of photographs the typical appearances of the living eye are compared in a Caucasian female (A), a Mongoloid male (B) and a Negroid male (C). All subjects are about 20 years of age. Note the pale sclera and grey-blue iris in A, the epicanthus overlapping the medial end of the lower eyelid in B and the dark brown pigmentation of the iris in both B and C, rendering the pupil almost invisible. Compare the size of the pupil in the same eye, photographed under steady bright light in A and by sudden exposure to the same illumination after a period of dark adaptation in D. In E the lower eyelid had been everted somewhat to exhibit the lacrimal punctum and the rich subepithelial network of blood vessels. In F note the circumcorneal pigmentation and the conjunctival blood vessels, deep to which can be seen some details of the episcleral vessels. All photographs are of the right eye. Photography by Kevin Fitzpatrick, Anatomy Department, Guy's Hospital Medical School, London.

Conjunctiva. *e*. Tarsal glands embedded in the tarsal plate. *f*. Opening of a tarsal gland. *g*. Ciliary gland. *h*. Eyelashes. *i*. Small hairs of the skin. *j*. Sweat glands. *k*. Posterior tarsal glands.

traverse the short ciliary nerves to reach the pupillary sphincters. If only one eye is stimulated both pupils nevertheless contract (the *consensual pupillary light reflex*), because fibres from each optic tract pass to *both* pretectal nuclei, decussating in the posterior commissure. The dilatator pupillae is supplied by fibres from the superior sympathetic cervical ganglion. The preganglionic fibres in this pathway arise from neurons in the lateral grey column of the first and second thoracic spinal segments, traversing the upper thoracic spinal nerves and their white rami communicantes to the sympathetic trunk, in which they ascend to the superior cervical ganglion (p. 1158). Since pupillary size results from the *balanced action* of these two innervations, the pupil dilates when the stimulus ceases. The pupil dilates also in response to painful stimulation of almost any part of the body. Presumably fibres of sensory pathways connect with the sympathetic preganglionic neurons described above. Some believe, however, that reflex pupillodilation is largely due to inhibition of the parasympathetic accessory oculomotor nuclei, though the paths involved are uncertain. One manifestation of this reflex is dilatation produced by pinching the skin of the neck, the *pupillary skin reflex*, a reminder that to the above, simplified account must be added other afferent influences, such as reticular connections with the superior collicular nuclei (pp. 987, 991).

Accommodation Reflexes

In accommodating for viewing near objects the eyes converge and at the same time the ciliares contract to modify the shape of the lens , the pupil constricting to increase the depth of focus. Pathways for reflex accommodation comprise the optic nerves and tracts, lateral geniculate bodies, optic radiations and the cortical visual areas, the latter being connected by long association fibres to the frontal cortical eye field, whence fibres descend via the internal capsule to the oculomotor nuclei. From the accessory oculomotor nuclei parasympathetic fibres pass to the ciliaris and sphincter pupillae (relaying in ciliary ganglion). From the ventral part of the oculomotor nucleus (p. 1096) other fibres supply the medial recti for the action of convergence (p. 1209). These routes have not been so clearly defined as those for the pupillary light reflex; it has been suggested (Wilkinson 1927) that contraction of the pupil in the accommodation reflex is secondary to ocular

7.334 The tarsi and their ligaments: anterior aspect.

convergence, the afferent impulses arising in proprioceptor endings in the extrinsic muscles and travelling in the oculomotor nerves directly to the accessory nuclei. In certain central nervous diseases (e.g. tabes dorsalis) the pupillary light reflex may be lost but not pupilloconstriction as part of the accommodation reflex (the Argyll Robertson pupil). A lesion producing such an effect would probably be located between the accessory oculomotor nucleus and the lateral geniculate body, where the paths for the two reflexes diverge.

Conjunctival and Corneal Reflexes

Any stimulus to conjunctiva or cornea excites blinking. Afferent impulses travel via the ophthalmic division of the trigeminal nerve and efferent impulses in branches of the facial nerve to orbicularis oculi.

Eyebrows and Eyelids

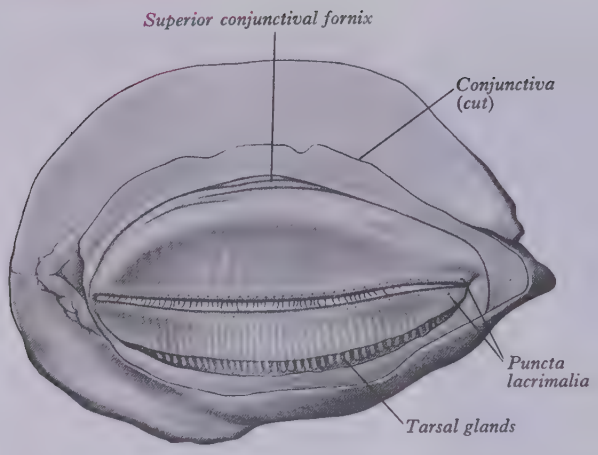
The eyebrows are arched dermal eminences surmounting the orbits, with numerous short, thick hairs set obliquely in them. Fibres of the orbicularis oculi, corrugator and the frontal part of the occipitofrontalis are attached to the dermis of the eyebrows.

The eyelids or **palpebrae** are thin, movable folds, adapted to the front of the eyes and protecting them from injury, by rapid closure. The upper eyelid is larger and more mobile, being furnished with an elevator muscle, the levator palpebrae superioris (p. 1207). The two eyelids are united at their extremities and when parted an elliptical space, the *palpebral fissure*, appears between their margins. The ends of the fissure are termed the *angles* or *canthi* of the eye.

The *lateral angle* of the eye or *lateral canthus* is more acute than the medial and is closely apposed to the eyeball. The *medial angle* or *medial canthus* is prolonged for a little towards the nose and is about 6 mm from the eyeball; the eyelids are here separated by a triangular space, the *lacus lacrimalis*, in which is a small reddish *caruncula lacrimalis* (7.332). On each palpebral margin, at the basal angles of the lacus, is a small, conical, *lacrimal papilla*, its apex pierced by the orifice of a *lacrimal canaliculus*, an aperture known as the *punctum lacrimale* (7.332).

Eyelashes grow in the palpebral margins, their distribution extending from the lateral canthus to the lacrimal papillae. They are short, thick, curved hairs, arranged in double or triple rows; the upper, which are more numerous and longer, curve upwards while those in the lower lid curve down so that upper and lower lashes do not interlace when the lids are closed. Enlarged and modified sudoriferous, *ciliary glands* are arranged in several rows near the palpebral margins, opening near the lashes (p. 93).

Structure of the Eyelids



From its facial surface inwards each eyelid consists of: skin, subcutaneous loose connective tissue, the fibres of the orbicularis oculi, the tarsus and orbital septum, tarsal glands and conjunctiva. The upper lid also contains the aponeurosis of the levator palpebrae superioris (7.333). The *skin* is extremely thin and is continuous at the palpebral margins with the conjunctiva. The *subcutaneous connective tissue* is very lax and delicate, seldom containing any adipose tissue.

The *palpebral fibres of the orbicularis oculi* are thin and pale and lie parallel with the palpebral fissure; deep to them is a layer of loose connective tissue, which in the upper lid is continuous with the scalp's subaponeurotic layer (p. 571) so that effusions of blood or pus at this level can pass down from the scalp into the upper eyelid. In this layer are the main nerves; local anaesthetics should hence be injected deep to the orbicularis oculi.

The two *tarsi* (7.334) are thin, elongate plates of dense fibrous tissue about 2·5 cm long, one in each eyelid, contributing to its form and support. The *superior tarsus*, the larger, is semi-oval, centrally about 10 mm in height and narrowing towards its ends. The lowest fibres of the superficial lamella of the aponeurosis of the levator palpebrae superioris are attached to its anterior surface, the deep lamella to its upper margin (7.325). The smaller *inferior tarsus* is narrower, about 5 mm in vertical height. The free, ciliary margins of both tarsi are thick and straight and their attached orbital edges are connected to the orbital margin by the orbital septum. Their lateral ends are attached by a band, the *lateral palpebral ligament*, to a tubercle on the zygomatic bone, just within the orbital margin; this band is separated from the more superficial *lateral palpebral raphe* (p. 571) by a few lobules of the lacrimal gland. The medial ends of the tarsi are attached by a strong tendinous band, the *medial palpebral ligament*, to the upper part of the lacrimal crest and to the adjoining maxillary frontal process in front of it; the lower edge of this ligament is separated from the lacrimal sac by some fibres of the orbicularis oculi which are attached to the ligament.

The *orbital septum* is a weak membrane attached to the orbital rim, where it is continuous with the periosteum. In the upper lid it blends with the superficial lamella of the aponeurosis of the levator palpebrae superioris, in the lower lid with the anterior tarsal surface. It is perforated by vessels and nerves passing from the orbital cavity to the face and scalp, by the aponeurosis of the levator and by the palpebral part of the lacrimal gland.

The *tarsal glands* (7.335), embedded in the tarsi, may be visible through the conjunctiva when the eyelids are everted; they are yellow and are arranged in a single row of about 30 in the upper lid and fewer in the lower. They are embedded in grooves on the posterior tarsal aspect, occupying the full tarsal height and hence being longer in the upper lid, where the tarsus is higher. Their ducts open on the free palpebral margins by minute foramina. They are modified sebaceous glands, each a straight tube with many lateral diverticula. They are supported by a basement membrane and lined at their orifices by stratified epithelium and elsewhere by a layer of polyhedral cells. Their oily secretion

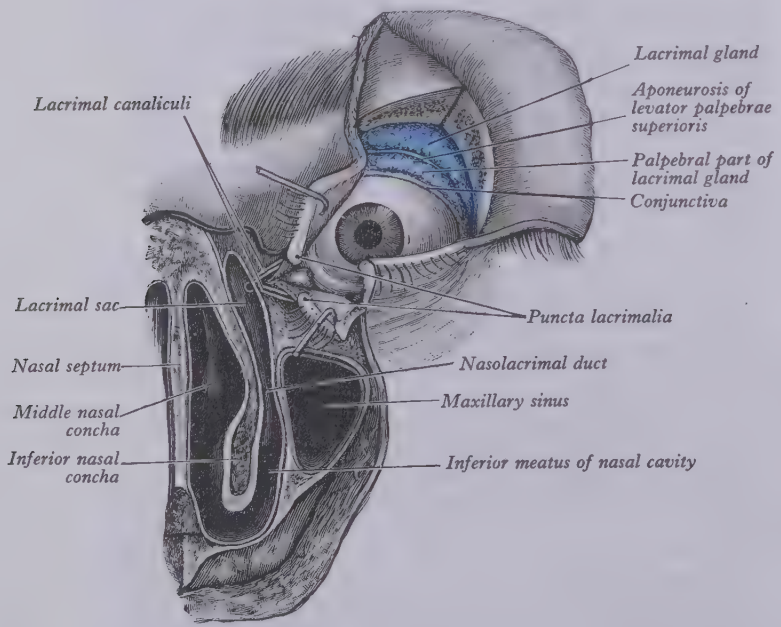
7.335 The posterior surfaces of the upper and lower eyelids of the left side. The orifices of the tarsal glands can be seen on the free margins of the lids.

spreads over the margins of the eyelids and prevents overflow of lacrimal fluid on to the cheek. It is also said to spread over the surface of the tear film to reduce evaporation.

The Conjunctiva

The conjunctiva, a transparent mucous membrane, covers the internal palpebral surfaces and folds on to the anterior sclera and cornea where it is continuous with the corneal epithelium; it is a *conjunction* between these structures.

The palpebral conjunctiva is very vascular, has numerous subepithelial connective tissue papillae and contains lymphoid tissue in its deeper parts, especially near the fornices; it is closely adherent to the tarsi. At the free palpebral margins it is continuous with the skin, with the lining epithelium of the ducts of the tarsal glands, the lacrimal canaliculi and lacrimal sac and hence with the nasolacrimal duct and nasal mucosa (an important continuity in the spread of infection). The line of reflection of the conjunctiva from the lids to the eyeball is the *conjunctival fornix*, subdivided into *superior* and *inferior fornices*, the former receiving the ducts of the lacrimal gland. Over the sclera the *ocular conjunctiva* is loosely connected to the eyeball; here it is thin, transparent, without papillae and slightly vascular. Reaching the cornea it continues as the corneal epithelium (p. 1183). The epithelium of the palpebral conjunctiva near the margins of the lids is non-keratinized stratified squamous; about 2 mm from each margin is a groove in which foreign bodies frequently lodge and here the epithelium has two layers, consisting of superficial columnar and deeper flat cells; these persist through most palpebral conjunctiva but near the fornices an intermediate layer of polygonal cells appears and this trilaminar conjunctival epithelium covers the anterior, exposed surface of the sclera. Near the corneoscleral junction the epithelium changes to stratified corneal epithelium (p. 1183). Scattered throughout the conjunctival epithelium are mucus-secreting goblet cells but there are few of these in the palpebral and circumcorneal epithelium.



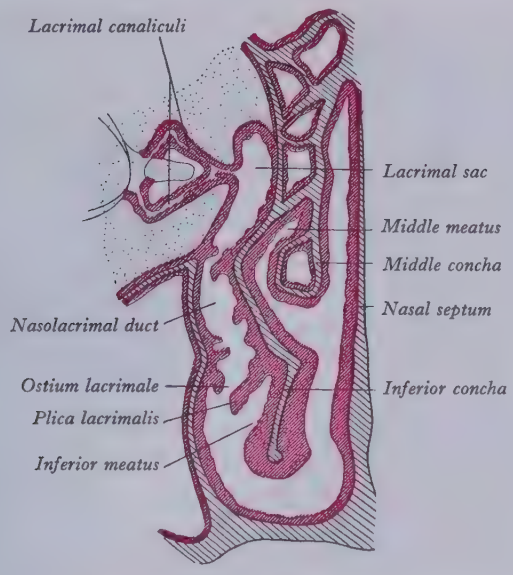
The *lacrimal caruncle* (7.332) is a small, reddish, conical body in the lacus lacrimalis at the medial canthus; it is a small island of skin, containing sebaceous and sudoriferous glands with a few slender hairs. Laterally and partly obscured by it is a fold of conjunctiva, the *plica semilunaris*, its concave free edge directed laterally towards the cornea. Its epithelium is like that of the scleral conjunctiva but contains numerous goblet cells; subjacent are some fat cells and a little non-striated muscle. The *nictitating membrane* ('third eyelid'), a conjunctival structure in some amphibians, reptiles and mammals, may be homologous with the plica semilunaris.

Vessels and Nerves

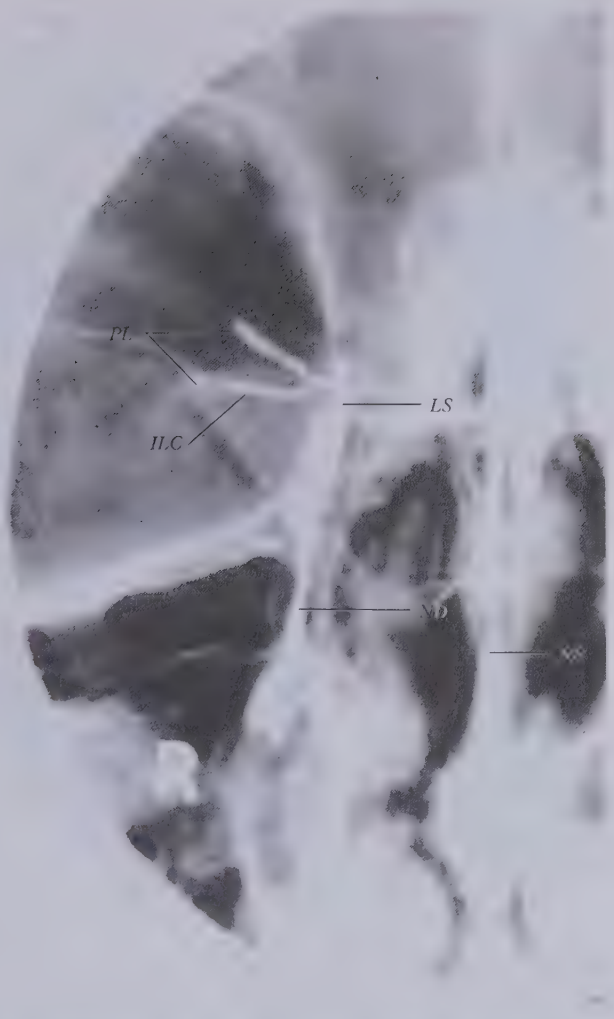
The eyelids receive their arteries from the medial palpebral branches of the ophthalmic artery and the lateral palpebral branches of the lacrimal artery (p. 746). The ocular conjunctiva is supplied by the ophthalmic division of the trigeminal nerve; the upper palpebral conjunctiva is supplied by the ophthalmic, the lower by the maxillary division. Many conjunctival nerve fibres end in bulbous corpuscles (p. 913). Lymph vessels of the eyelids and conjunctiva are described on p. 844.

Palpebral Movements

The position of the lids depends on reciprocal tone in the orbicularis oculi and levator palpebrae superioris and on the degree of ocular protrusion. In the usual opened position the margin of the inferior lid crosses the eyeball level with the lower edge of the circumference of the iris, the upper covering about half of the width of the upper iris. The eyes are closed by movements of *both* lids, produced by the contraction of the orbicularis oculi and relaxation of the levator palpebrae superioris. In looking upwards, the levator contracts and the upper lid follows the ocular movement; at the same time, the eyebrows are also usually raised by the frontal parts of the occipitofrontalis to diminish their overhang. The lower lid lags behind ocular movement, so that more sclera is exposed below the cornea and the lid is bulged a little by the lower part of the elevated eye. When the eye is depressed both lids move, the upper retaining its normal relation to the eyeball and still covering about a quarter of the iris. The lower is probably dragged downwards by the pull of the conjunctiva in the inferior fornix. In states of fear the palpebral fissures are widened by contraction of the non-striated superior and inferior tarsal muscles, due to increased sympathetic activity. Lesions of the sympathetic supply result in drooping of the upper eyelid (ptosis), as seen in Horner's syndrome. For further comments on palpebral movement see p. 1207.



7.336 The left lacrimal apparatus, dissected from the anterior aspect.



The Lacrimal Apparatus

The lacrimal apparatus (7.336, 339) comprises the lacrimal gland, which secretes a complex fluid (tears), and whose excretory ducts convey fluid to the surface of the eye, the lacrimal canaliculi, lacrimal sac and nasolacrimal duct, by which the fluid is collected and conveyed into the nasal cavity.

The lacrimal gland (7.336) is derived phylogenetically from serous secreting glands and those producing oily secretions. In primates the lacrimal (serous) element has migrated from its original position in the lower lid to the upper. The human lacrimal gland is superolateral in the orbit and has a large, upper

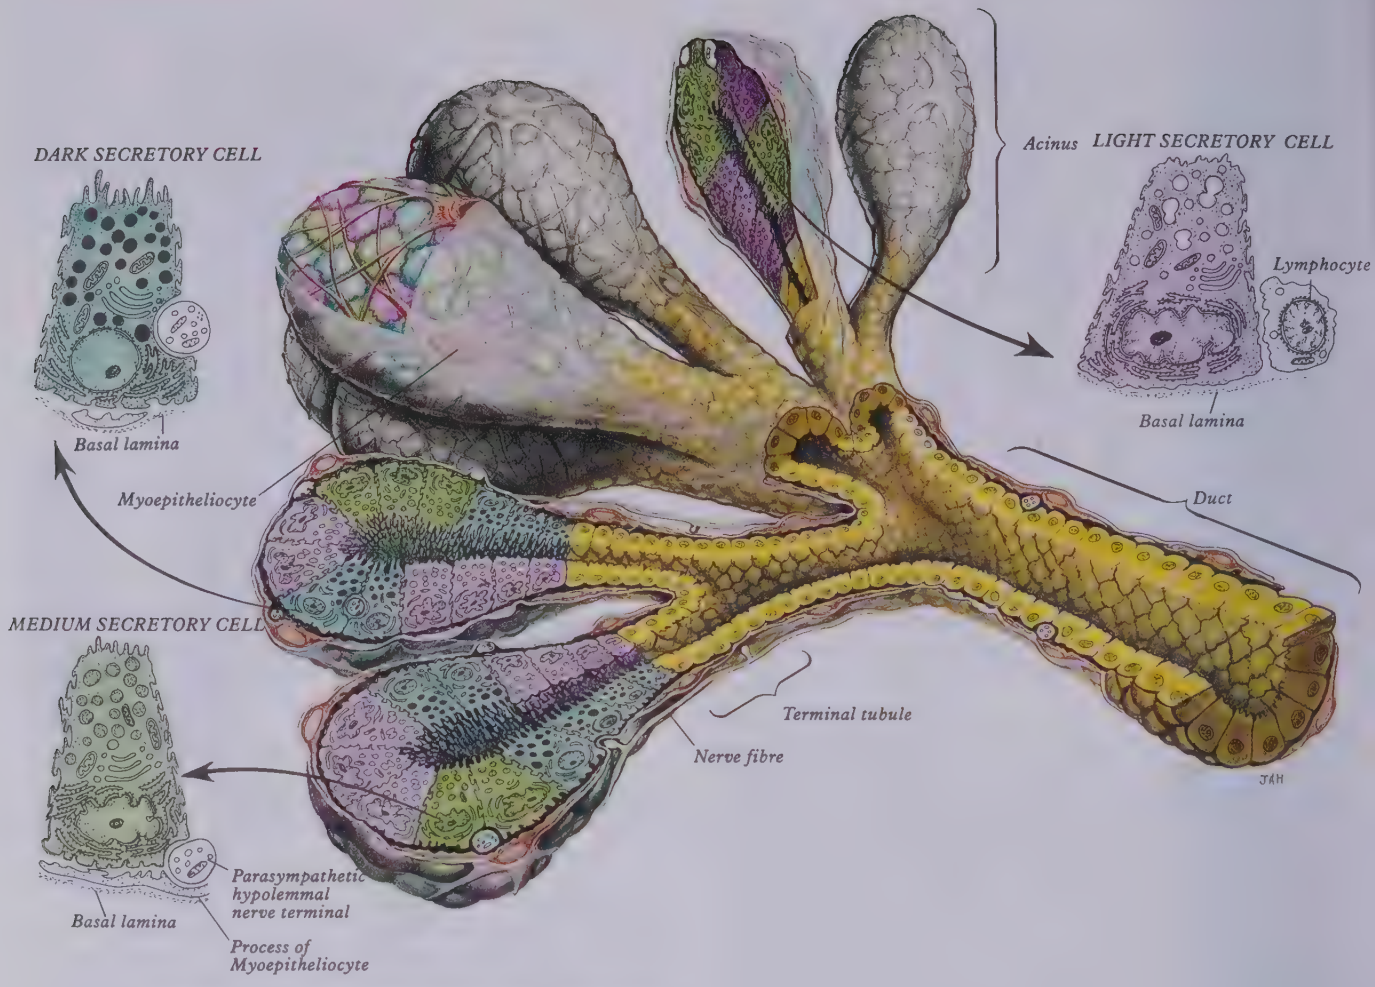
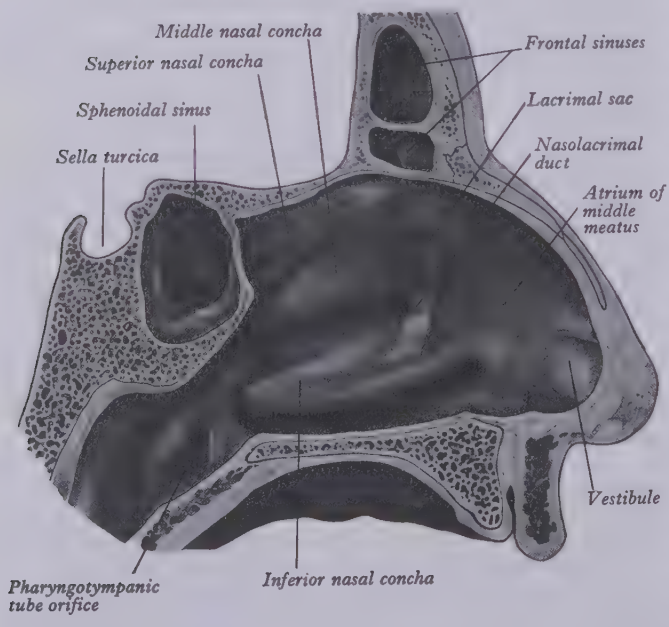
orbital and smaller, lower *palpebral part*, the two being continuous posterolaterally around the concave lateral edge of the levator aponeurosis. The orbital part, about the size and shape of an almond, lodges in the lacrimal fossa on the medial aspect of the zygomatic process of the frontal bone, just within the orbital margin. It lies above the levator palpebrae superioris and, laterally, above the lateral rectus; its inferior aspect is connected to the levator's sheath, its upper to the orbital periosteum; its anterior aspect adjoins the orbital septum and its posterior is attached to the orbital fat. The palpebral part, about one-third the size of the orbital, has two or three lobules extending inferior to the levator aponeurosis into the lateral part of the upper lid, where it is attached to the superior conjunctival fornix. It is visible through the conjunctiva when the lid is everted. Its ducts, about 12 in number, open into the superior fornix, those from the orbital part (four or five) passing through the palpebral part to join some of its ducts and the rest (six to eight) opening separately. Thus all ducts traverse the palpebral part so that excision of this part is functionally equivalent to the total removal of the gland.



Many small accessory lacrimal glands occur in or near the fornices; they are more numerous in the upper lid than in the lower. This may explain why the conjunctiva does not dry up after extirpation of the main lacrimal gland.

Structure of Lacrimal Gland (7.338)



The lacrimal gland is lobulated and tubulo-acinar in form (**8**.1A), its secretory units or 'endpieces' resembling those of salivary glands (p. 1293). The secretion is a watery fluid with an electrolyte content like plasma and containing a bacteriocidal enzyme, *lysozyme*. The primary secretion from the endpieces is modified by the ducts. Though many earlier accounts of lacrimal ultrastructure concerned rodents and lagomorphs (Obayashi 1959, Scott & Pease 1959, Ichikawa & Nakajima 1962), primate lacrimal glands have now received attention (Ruskell 1968, 1969, Egeberg & Jensen 1969, Orzalesi et al 1971, Ruskell 1975, Hirsch-Hoffmann 1976, 1978).

Its glandular cells form two categories in rhesus monkeys (Ruskell 1968, 1969, Hirsch-Hoffmann 1976), and in man two (Ito & Shibaski 1964, Kuhnel 1968), three (Ruskell 1975) or four (Hirsch-Hoffmann 1978), depending on which ultrastructural and histochemical criteria are considered to be significant. In rhesus monkeys, glandular cells with uniformly electron-dense secretory granules are described as *serous* and those with paler heterogeneous granules as *mucous* (Ruskell 1968). Ito & Shibasaki (1964) and Kuhnel (1968) propose two distinct human types of cell: one, the K cell, contains small, electron-lucent granules and stains like a mucous cell; the other, termed the G cell, contains large, electron-dense granules and stains like a serous cell. According to Allen et al (1972) and Ruskell (1975) most glandular cells are mucous, a surprising report in view of the patently serous nature of tears. Ruskell (1975) distinguishes three categories of human glandular cell, arbitrarily grouping them into 'light', 'medium' and 'dark' according to the electron density of their secretory granules; acini contain either two or all three categories and are closely associated with lymphocytes and myoepitheliocytes. Hirsch-Hoffmann (1978) proposed *four* groups of human glandular cells, distinguishable by the number and electron density of the granules and surrounding cytoplasm; the largest group have pale cytoplasm and numerous granules of varying electron density; a second group, also pale, have fewer granules; a third have darker cytoplasm and numerous granules; the remainder, also dark, have fewer, uniformly electron-dense granules. Hirsch-Hoffmann has suggested that at least some may represent different stages in the secretory activity of one or two distinct types, an interpretation supported by Egebert & Jensen (1969) and Orzalesi et al (1971).

The human lacrimal gland contains interstitial (epilemmal, p. 1297) and parenchymal (hypolemmal, **8**.52) nerve terminals (Ruskell 1975). The ultrastructure of most interstitial and all parenchymal terminals accords with cholinergic (parasympathetic) activity. A few interstitial terminals, containing small granular vesicles, may be adrenergic (sympathetic). Only 'dark' or 'serous' glandular cells have a parasympathetic, hypolemmal innervation (Ruskell 1975), as in rhesus monkeys (Ruskell 1969), in which

7.338 The structure of the lacrimal gland, showing the organization of the secretory units.

7.339 The left lateral wall of the nasal cavity viewed from the medial side. The lacrimal sac and the nasolacrimal duct of the left side have been projected on to the lateral wall of the nasal cavity to show their positions relative to the middle nasal concha, the middle meatus and the inferior concha.

ultrastructural changes after parasympathectomy suggested that serous cells are under parasympathetic control, mediated by hypolemmal terminals, while mucous cells may function autonomously. Similar parasympathetic terminals occur near the ducts and terminal tubules in the human lacrimal gland; the tubules connect secretory units and ducts, containing in their walls cells intermediate in form between glandular and ductual cells (Ruskell 1975); these cells of the terminal tubules are smaller than glandular cells and contain relatively fewer granules. Most nerve terminals of ducts and tubules are near myoepitheliocytes, perhaps inducing myoepitheliocytic contraction and assisting secretory flow. Myoepitheliocytes in secretory units appear to have no direct, hypolemmal innervation; Ruskell (1975) suggests that nearby interstitial parasympathetic terminals may control them, releasing only sufficient transmitter to induce their contraction in hypersecretion. The role of the interstitial sympathetic terminals in the control of human lacrimal gland is undetermined, as are the ultrastructure and functions of its ducts.

The lacrimal canaliculi, one in each lid, are about 10 mm long; they commence at the *puncta lacrimalia* (7.332, 336, 337). The *superior canaliculus*, smaller and shorter than the inferior, first ascends and then curves acutely inferomedially to reach the lacrimal sac. The *inferior canaliculus* first descends and turns almost horizontally to the sac. At their angles they are dilated into *ampullae*. Their lining mucosa has a non-keratinized stratified squamous epithelium on a basement membrane, beyond which is a lamina propria rich in elastic fibres (the ducts therefore being easily dilated when probed) and a layer of skeletal muscle fibres continuous with the lacrimal part of the orbicularis oculi. At the base of each lacrimal papilla these fibres are sphincteric.

The lacrimal sac (7.334, 336, 337, 339), the closed upper end of the nasolacrimal duct, lies in a fossa formed by the lacrimal bone, the frontal maxillary process and the lacrimal fascia. It is about 12 mm in length, its closed upper end is laterally flattened and its lower part rounded and merging into the duct; the lacrimal canaliculi open into its lateral wall near its upper end.

A layer of *lacrimal fascia*, continuous with the orbital periosteum, passes between the lacrimal crest of the maxilla and the lacrimal bone, forming a roof and lateral wall to the lacrimal fossa; between the fascia and the lacrimal sac is a plexus of minute veins. The fascia separates the sac from the medial palpebral ligament in front and the lacrimal part of orbicularis oculi behind. The lower half of the lacrimal fossa is related medially to the anterior part of the nasal middle meatus; the upper half to the anterior ethmoidal sinuses. (In 100 skulls Whitnall, 1911, observed that in 14 the anterior ethmoidal sinuses were related only to the fossa's posterior wall; in 32 they reached the suture between the lacrimal bone and maxilla; in 54 one irregular sinus extended to the anterior lacrimal crest.)

The lacrimal sac has a fibro-elastic wall, lined internally by mucosa continuous through the lacrimal canaliculi with the conjunctiva and through the nasolacrimal duct with the nasal mucosa.

The nasolacrimal duct (7.337, 339), about 18 mm long, descends from the lacrimal sac to open anteriorly in the inferior meatus at an expanded orifice; a mucosal *lacrimal fold* forms an imperfect valve just above this opening. The duct runs down an osseous canal formed by the maxilla, lacrimal bone and inferior nasal concha; it is narrowest in the middle and directed down, back and a little laterally. The mucosa of the lacrimal sac and the nasolacrimal duct has a bilaminar columnar epithelium, ciliated in places. A surrounding plexus of veins, forming erectile tissue, may, when engorged, obstruct the duct.

Lacrimal fluid enters the conjunctival sac at its superolateral angle and, by capillarity and blinking, is carried across the eye to the lacus lacrimalis, mainly between the lower palpebral margin and the eyeball. From the lacus it enters the lacrimal canaliculi. Contraction of the orbicularis oculi presses the puncta lacrimalia more firmly into the lacus and capillary attraction draws the secretion into the lacrimal sac. Sudden dilation of the sac, produced by the lacrimal part of the orbicularis oculi during blinking (p. 572), probably aids this. Normally the tarsal secretion prevents tear fluid from overflowing and also covers the capillary film of fluid on the cornea and sclera, perhaps delaying evaporation (Mishima & Maurice 1961, Wolff 1976).

THE AUDITORY AND VESTIBULAR APPARATUS

The peripheral auditory apparatus includes the various parts of the ear, but of particular functional importance is the *cochlear part* of its *membranous labyrinth*. Each ear is a *distance receptor* for the collection, conduction, modification, amplification and analysis of complex waves of sound reaching it. These are transduced into coded patterns of impulses in the afferent cochlear fibres of the vestibulocochlear nerve, for transmission and further analysis in the central auditory pathways of the brain (pp. 958, 960, 986, 1015, 1060).

Sound waves consist of the repetitive oscillations of the molecules constituting air; the waves vary in:

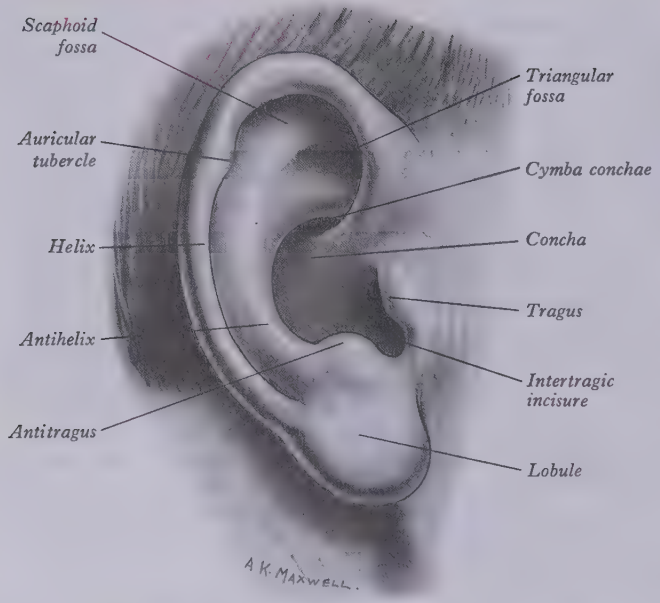
(1) the *direction* and *distance* or *location* of their source,

(2) their *intensity* or *energy content*, (3) the mixture of *frequencies* in the train of waves, and (4) the *phase* of their vibrations. The structural and functional design of ears make them, within certain ranges, extremely sensitive to differences in frequency, intensity and phase and, when used binaurally, they are very effective range and direction finders. They are also most responsive to the *rate of change* in all these parameters. Frequencies are expressed as *cycles per second* or *Hertz* (c/s or Hz), which are subjectively appreciated as *pitch*, young adult ears responding to frequencies of about 20–20 000 Hz, although higher and lower values are not uncommon in youth. *Intensity* is expressed as the *quantity of energy* transmitted per *unit time* through a *unit area* perpendicular to the direction of propagation. The subjective appreciation of sound intensity is related to the logarithm of the absolute intensity as just defined but is also dependent on frequency, the human ear being most sensitive to sounds in the range of 1500–3000 Hz; above and below this the threshold rises sharply; e.g. 10 000 times more energy is necessary for an equal perceptive effect at 15 000 Hz than at 2000 Hz. The ear's sensitivity is astounding; sounds may be discerned which involve pressure changes as small as 10^{10} atmospheres, a change equivalent to ascending or descending 1/30 000 of an inch! Because of the great variation in the intensity of sounds commonly experienced, the *decibel* has been introduced for convenience. It is defined as 10 times the logarithm of the ratio of the intensity of the sound, compared to an accepted reference level. In practice this reference level is defined as the Sound Pressure Level (SPL) and decibels are quoted as db SPL. A difference in intensity of about one decibel is usually just perceptible by the human auditory system.

The *quality* of a particular sound depends on the mixture of frequencies of which it is composed. Musical sounds usually consist of one or more fundamental frequencies each with its mathematically related series of *harmonics*. Mixtures of unrelated and *irregular* frequencies are regarded as 'noise'. Human speech has a marked content of noise. Moreover, consonants often involve higher frequencies than do vowels. Hence speech is easily obscured by concomitant noise and, with increasing age and consequent reduction of sensitivity at the high frequency range of the human ear, the elderly find speech less easy to interpret.

The elegant researches into the way in which the ear operates as a peripheral analyser of frequency and intensity and how intensity and phase differences impinging on the two ears are used in detecting the range and directions of the sound source, can merely be mentioned here. For details the reader must consult Rasmussen & Windle (1960), Whitfield (1967), De Reuck & Knight (1968), Wolstenholme & Knight (1970), etc.

The human ear can be divided, according to phylogenetic, developmental, structural and functional criteria, into *external*, *middle* and *internal* parts. Associated topographically with the cochlear, auditory part of the labyrinth, are the sensory receptors of the other major region of the inner ear, consisting of specialized sensory areas of the utricle, saccule and ampullae of the semicircular ducts which, with their contained and surrounding fluids, bony cavities and the vestibular part of the eighth cranial nerve, constitute **the peripheral vestibular apparatus**. The latter provides the central nervous system with information concerning the static position of the head in space and of its linear or angular acceleration or deceleration.

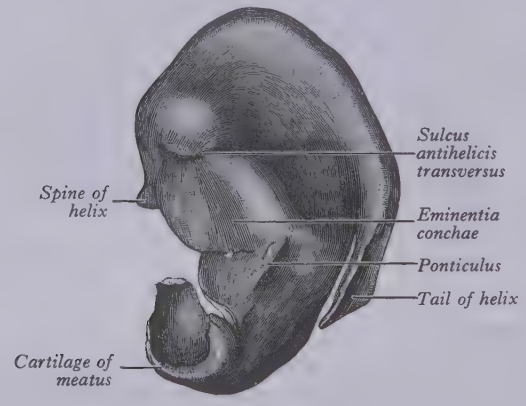


The evolution of the auditory apparatus in land vertebrates has attracted an enormous literature which cannot be even considered here; for a recent survey consult Lombard & Bolt 1977.

The External Ear

The external ear comprises the *auricle*, or *pinna*, and the *external acoustic meatus*. The auricle projects from the side of the head to collect sound waves; the meatus leads inwards from the auricle to conduct vibrations to the tympanic membrane; not that they act solely as an inert ear-trumpet, for they are the first of a series of *stimulus modifiers* in the auditory apparatus, as will become apparent.

THE AURICLE



The lateral surface of the auricle (7.340) is irregularly concave, turns slightly forwards and displays numerous eminences and depressions. Its prominent curved rim, or *helix*, usually bears

7.340 The right auricle: lateral aspect.

postero-superiorly a small *auricular tubercle* (of Darwin), a structure which is quite pronounced around the sixth month of intrauterine life, when the auricle closely resembles that of some adult monkeys. Another curved prominence, parallel and anterior to the posterior part of the helix, is the *antihelix*, dividing above into two *crura* flanking a depressed *triangular fossa*. The curved depression between the helix and antihelix is the *scaphoid fossa*. The antihelix encircles the deep, capacious *concha* of the auricle, which is incompletely divided by the *crus* or anterior end of the helix; the conchal area above this, the *cymba conchae*, overlies the supermeatal triangle of the temporal bone, which can be felt through it (pp. 352, 355), deep to which is the mastoid antrum. Below the crus of the helix and in front of the concha is a small curved flap, the *tragus*, which projects posteriorly, partly overlapping the meatal orifice. Opposite the tragus and separated from it by the *intertragic incisure*, is a small tubercle, the *antitragus*. Below this is the *lobule*; composed of fibrous and adipose tissues, this is soft, unlike the majority which, being supported by elastic cartilage, is firm. The cranial surface of the auricle presents elevations corresponding to the depressions on its lateral surface, after which they are named, e.g. the eminentia conchae, eminentia fossae triangularis, etc.

Though primarily collecting 'trumpets' for sound waves, the auricles, by their asymmetry and variations in thickness, probably introduce *variable delay paths* in sound transmission, which may be important in the efficient binaural (and also the cruder monaural) localization of sources of sound.

7.341 The medial surface of the right auricular cartilage.

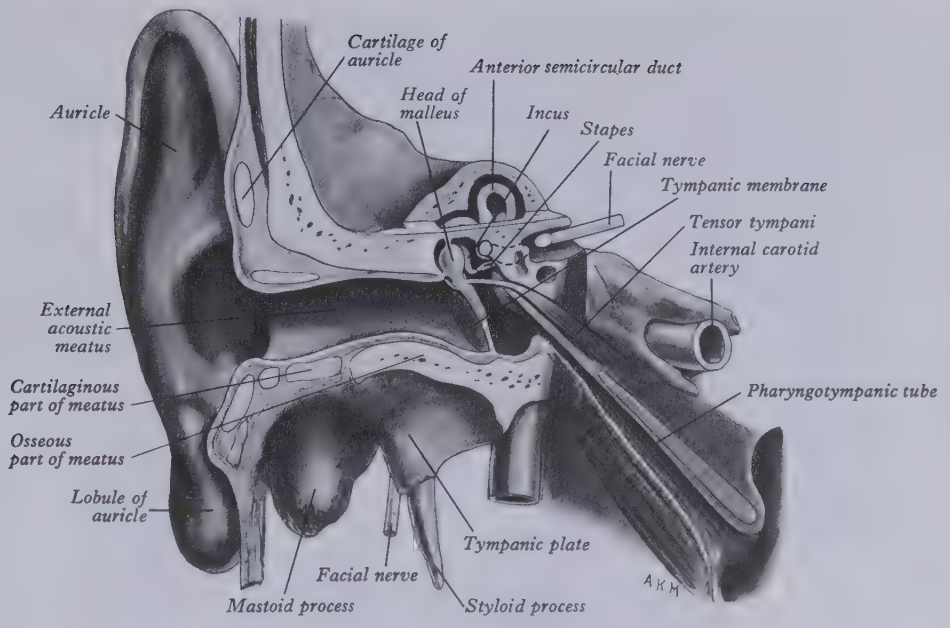
In its **structure** the auricle is a thin plate of *elastic fibrocartilage* covered by skin and connected to the surrounding parts by ligaments and muscles; it is continuous with the cartilage of the external acoustic meatus, which is joined to the margins of the bony meatus by fibrous tissue. Its *skin* is thin, adherent to the cartilage and bears fine hairs furnished with sebaceous glands which are most numerous in the concha and scaphoid fossa. On the tragus, antitragus and intertragic incisure the hairs are strong and numerous, especially in elderly males. The skin is continuous with that of the external acoustic meatus.

The auricular cartilage (7.341) is a single piece of elastic fibrocartilage, its surface moulded by eminences and depressions as described above; it is absent from the lobule and between the tragus and the crus of helix, the gap being filled by dense fibrous tissue. Anteriorly, where the helix curves upwards, is a small cartilaginous projection, the *spine of the helix*, its other extremity being prolonged inferiorly as the *tail of the helix* and separated from the antihelix by the *fissura antitragohelicina*. The cartilage's cranial aspect bears the *eminentia conchae* and *eminentia triangularis*, corresponding to the depressions on the lateral surface. A transverse furrow, the *sulcus antihelicis transversus*, corresponding to the inferior crus of the antihelix on the lateral surface, separates the two eminences. The eminentia conchae is crossed by an oblique ridge, the *ponticulus*, for the attachment of the auricularis posterior muscle. There are two fissures in the auricular cartilage, one behind the crus helicis and another in the tragus.

The ligaments of the auricle form two sets: (1) the extrinsic, connecting it to temporal bone; (2) the intrinsic, interconnecting various parts of its cartilage. There are two *extrinsic ligaments*, anterior and posterior, the *anterior* extending from the tragus and the spine of the helix to the root of the zygomatic process of the temporal bone; and the *posterior ligament* passes from the posterior surface of the concha to the lateral surface of the mastoid process. The chief *intrinsic ligaments are: (a)* a strong fibrous band from the tragus to the helix, completing the meatus anteriorly and forming part of the concha's boundary; (*b*) a band between the antihelix and the tail of the helix. Less prominent bands also exist on the cranial aspect of the auricle.

THE AURICULAR MUSCLES

These are two sets: the *extrinsic*, connecting the auricle to the skull and scalp and moving the auricle as a whole; and the *intrinsic*, connecting the different parts of the auricle.



The extrinsic muscles are the auriculares anterior, superior and posterior. The *auricularis anterior*, the smallest of the three, is a thin fan of pale fibres, arising from the lateral edge of the epicranial aponeurosis, its fibres converging to insert into the spine of the helix. The *auricularis superior*, the largest of the three, is also thin and fan-shaped and converges from the epicranial aponeurosis via a thin, flat tendon to attach to the upper part of the cranial surface of the auricle. The *auricularis posterior* consists of two or three fleshy fasciculi arising by short aponeurotic fibres from the mastoid part of the temporal bone and inserted into the ponticulus on the eminentia conchae.

Nerve supply. Auriculares anterior and superior are supplied by temporal branches of the facial nerve and auricularis posterior by the posterior auricular branch of the same nerve.

Actions. In man these muscles have very little obvious effect: the auricularis anterior draws the auricle forwards and up; the auricularis superior elevates it slightly; and the auricularis posterior draws it back. Despite the paucity of auricular movement, auditory stimuli may evoke patterned responses from these small muscles and electromyography can detect the 'crossed acoustic response' elicited by this means in investigative clinical neurology.

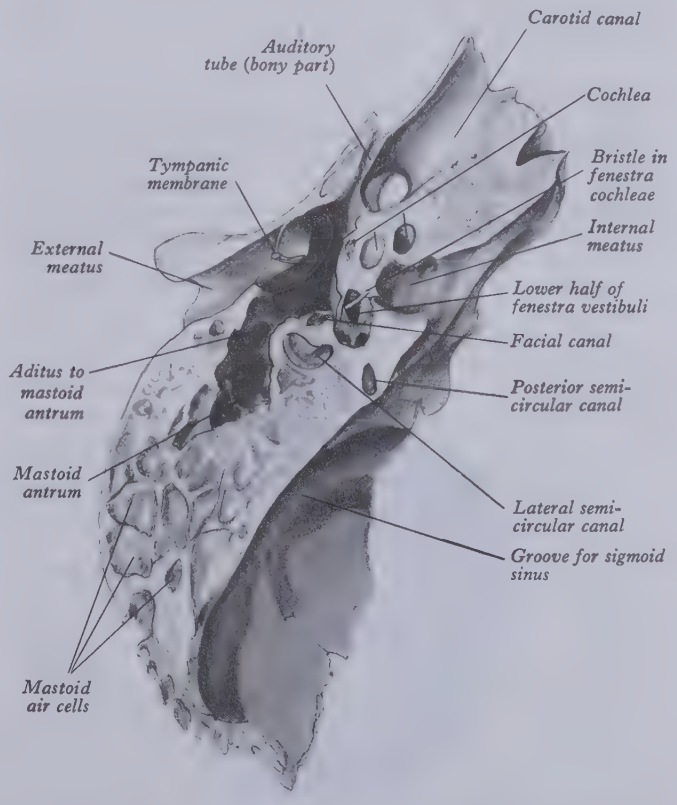
The intrinsic muscles are: helicis major and minor, tragicus, antitragicus, transversus auriculae and obliquus auriculae. They modify auricular shape minimally, if at all, in most human ears. Occasional individuals can, however, modify the shape and position of their external ears.

Helicis major is a narrow vertical band on the anterior margin of the helix, passing from its spine to its anterior border, where the helix is about to curve back. *Helicis minor* is an oblique fasciculus,

7.342 The external and middle regions of the right ear: anterior aspect.

covering the crus helicis. *Tragicus* is a short, flattened, vertical band on the lateral aspect of the tragus. The *antitragicus* (muscle) passes from the outer part of the antitragus (prominence) to the tail of the helix and the antihelix. The *transversus auriculae*, on the cranial aspect of the auricle, consists of scattered fibres, partly tendinous, partly muscular, extending between the eminentia conchae and the eminentia scaphae. The *obliquus auriculae*, also on the cranial aspect of the auricle, comprises a few fibres extending from the upper and posterior parts of the eminentia conchae to the eminentia triangularis.

The nerve supply to the intrinsic muscles on the lateral aspect is from the temporal branches of the facial and to those on the cranial aspect from the facial's posterior auricular branch.



The arteries of the auricle are: (1) the posterior auricular branch of the external carotid, supplying three or four rami to its cranial surface; twigs from these reach the lateral surface, some through fissures in the cartilage, others round the margin of the helix; (2) the anterior auricular branches of the superficial temporal artery, distributed to the lateral surface; (3) a branch from the occipital artery. **Veins** correspond to the arteries of the auricle. Arteriovenous anastomoses are numerous in the skin of the auricle.

Lymphatics of the auricle drain into: (1) the parotid lymph nodes, especially the node in front of the tragus, (2) the upper deep cervical lymph nodes, (3) the mastoid lymph nodes.

The sensory nerves of the auricle are: (1) the great auricular nerve, supplying most of the cranial surface and the posterior part of the lateral surface (helix, antihelix, lobule); (2) the lesser occipital nerve, supplying the upper part of the cranial surface; (3) the auricular branch of the vagus, supplying the concavity of the concha and posterior part of the eminentia; (4) the auriculotemporal nerve, supplying the tragus, crus of the helix and the adjacent part of the helix; (5) the facial nerve, which with the vagal auricular branch probably supplies small areas on both aspects of the auricle in the depression of the concha and over its eminence. The details of facial cutaneous innervation and whether the facial fibres reach the external acoustic meatus and tympanic membrane require further clarification.

THE EXTERNAL ACOUSTIC MEATUS

This extends from the concha to the tympanic membrane (7.342, 343). Its length, from the floor of the concha, is approximately 2·5 cm and from the tragus about 4 cm. It has two structurally different parts, the lateral third being *cartilaginous* and the medial two-thirds *osseous*. It forms an S-shaped curve, directed at first medially, anteriorly and slightly up (*pars externa*), then posteromedially and up (*pars media*) and lastly again anteromedially and slightly down (*pars interna*). It is oval in section, its greatest diameter being obliquely inclined postero-inferiorly at the external orifice but nearly horizontal at its medial end. There are two constrictions, one near the medial end of the cartilaginous part, the other, the *isthmus*, in the osseous part about 2 cm from the bottom of the concha. The tympanic membrane, which closes

7.343 Oblique section through the left temporal bone viewed from above. From a section prepared by P F Milling. Compare with 7.345 and 7.348.

its medial end, is obliquely set and so the floor and the anterior wall of the meatus are longer than its roof and posterior wall.

The lateral, *cartilaginous part* is about 8 mm long: it is continuous with the auricular cartilage and attached by fibrous tissue to the circumference of the osseous part. This meatal cartilage is deficient postero-superiorly, the gap being occupied by a sheet of collagen; two or three deep fissures exist in its anterior part.

The *osseus part* is about 16 mm long, and is narrower than the cartilaginous part. It is directed anteromedially and slightly downwards, with a slight posterosuperior convexity. Its medial end is smaller than the lateral end and is obliquely placed, the anterior wall projecting medially about 4 mm beyond the posterior and marked, except above, by a narrow *tympanic sulcus*, to which the perimeter of the tympanic membrane is attached. Its lateral end is dilated and mostly rough for the attachment of the meatal cartilage.

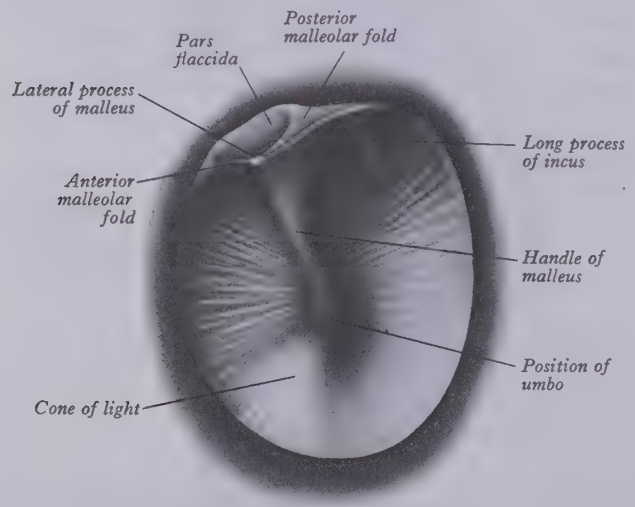
The anterior, inferior and most of the posterior parts of the osseous meatus are formed by the tympanic element of the temporal bone, which in the fetus is only a *tympanic ring* (p. 380); the posterosuperior region is formed by temporal squamous bone.

The auricular skin continues into the external acoustic meatus and covers the tympanic membrane's external surface. It is thin, with no dermal papillae, and is closely adherent to the cartilaginous and osseous parts of the tube; inflammation is very painful owing to increased tension in these tissues. In the thick subcutaneous tissue of the cartilaginous part of the meatus numerous *ceruminous glands* secrete ear wax or *cerumen*, their coiled tubular structure resembling that of sweat glands (p. 93). When active the secretory cells are columnar but cuboidal when quiescent; they are covered externally by myoepithelial cells. Ducts open either on to the epithelial surface or into a nearby sebaceous gland of a hair follicle. Cerumen prevents the maceration of meatal skin by trapped water and may discourage invasion by insects. Over-production or accumulation of wax may completely block the meatus or obstruct the vibration of the tympanic membrane. Ceruminous glands and hair follicles are largely limited to the cartilaginous meatus, but a few small glands and fine hairs occur in the roof of the lateral part of the osseous meatus. In addition to the protection given by the cerumen and meatal hairs, the warm humid environment of the relatively enclosed meatal air aids the mechanical responses of the tympanic membrane.

Relations of the Meatus

The mandible's condyloid process is anterior to the meatus and partially separated from its cartilaginous part by a small part of the parotid gland. A blow on the chin may cause the condyle to break into the meatus. Mandibular movements affect the size of the cartilaginous lumen. The middle cranial fossa lies above the osseous meatus and the mastoid air cells are posterior to it, separated from the meatus by a thin layer of bone. Its deepest part is below the epitympanic recess (p. 1223) and antero-inferior to the mastoid antrum, the lamina of bone separating it from the antrum being only 1–2 mm thick and providing the 'transmeatal approach' of aural surgery.

The meatal arteries are: the posterior auricular branch of the external carotid, the deep auricular branch of the maxillary and the auricular branches of the superficial temporal. The *veins* drain into: the external jugular and maxillary veins and the pterygoid plexus. The *lymphatics* drain with those of the auricle (p. 844). The *meatal nerves* are derived from the auriculotemporal branch of the mandibular, which supplies the anterior and superior walls of the meatus and the auricular branch of the vagus, supplying the posterior and inferior walls.

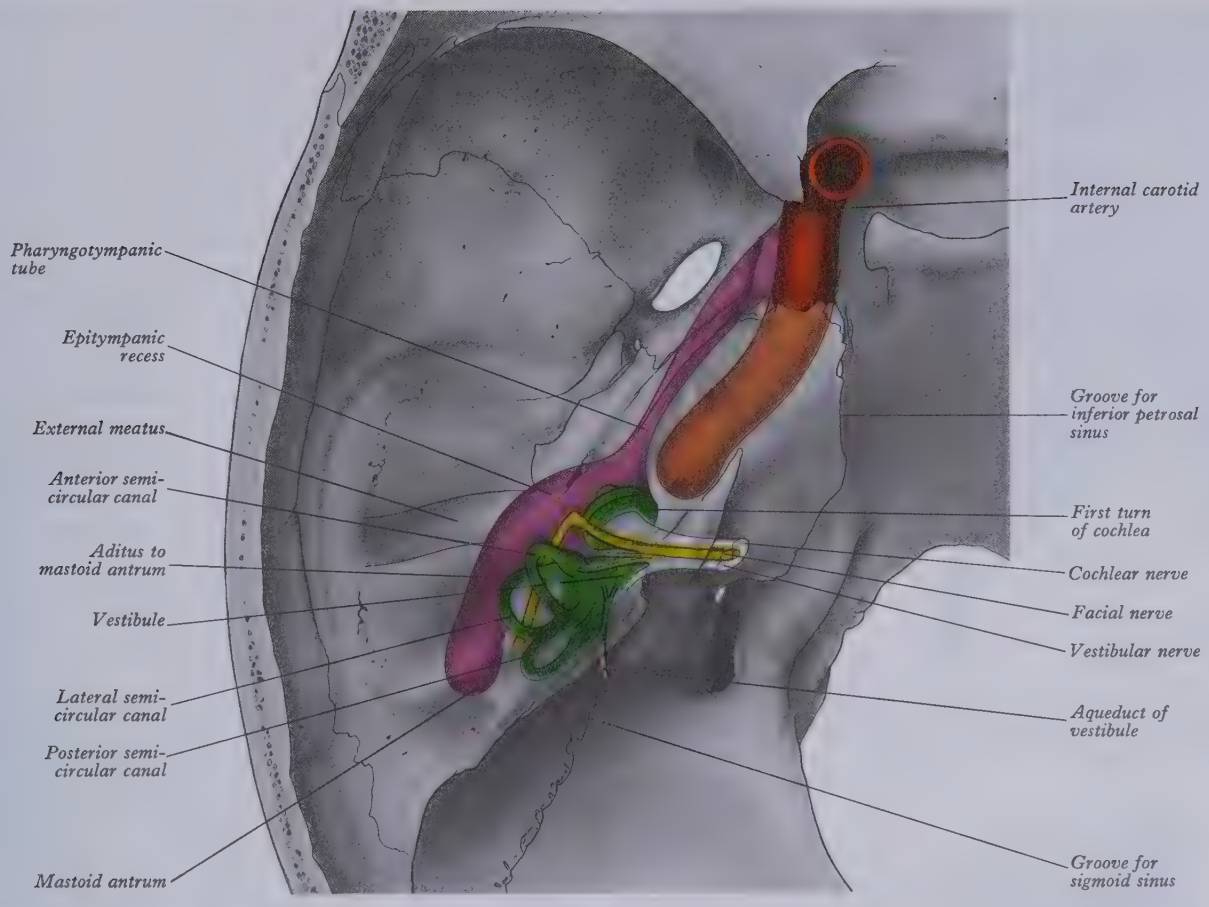


Clinical Examination of the Meatus

To inspect the meatus and tympanic membrane satisfactorily with light reflected down a speculum, the former's sinuosity can be to some extent straightened by pulling the auricle upwards, back and a little laterally. In this way, most of the meatus and tympanic membrane can be viewed.

At the junction of the osseous and cartilaginous parts the forward bend in the meatus constricts it, a point of importance in attempts to remove a foreign body lodged in the meatus. The shortness of the meatus in children also exposes the tympanic membrane to the danger of damage when an aural speculum is used. Even in adults a speculum should not be inserted beyond the constricted junction of the cartilaginous and osseous parts. Immediately anterolateral to the tympanic membrane is a depression on the meatal floor, bounded laterally by a prominent ridge, where foreign bodies may be impacted. Most of the tympanic membrane is visible through a speculum (7.344). It is pearly-grey, slightly glistening and placed at an acute angle of about 55° with the floor of the meatus and an obtuse angle with the roof. At birth it lies almost in the plane of the cranial base.

A reddish-yellow streak midway between the anterior and posterior margins extends from the centre obliquely upwards and forwards, marking the handle of the malleus, which is attached internally. At the upper part of this streak, near the roof of the meatus, a small, white round prominence marks the position of the lateral process of the malleus, projecting against the membrane. The tympanic membrane is not planar but is drawn in at its centre, or *umbo* (p. 1224), by the handle of the malleus. A bright reflected 'cone of light' appears in the antero-inferior quadrant. Anterior and posterior to the short process of the malleus, the variably prominent *anterior* and *posterior malleolar folds* appear, with the flaccid part of the membrane (p. 1224) between them. Posterior and parallel to the upper part of the handle of the malleus, the long process of the incus is often visible as a whitish streak, sometimes ending below near a round spot, the head of the stapes.



Applied Anatomy. Imperfect development of the external parts, a supernumerary auricle, preauricular cysts, fistulae and sinuses, or the absence of the meatus occasionally occur. In a child up to an age of four or five years a gap exists in the antero-inferior osseous wall of the meatus, the *foramen of Huschke* (pp. 381, 395) which is filled by a membrane; it may persist in the adult. The sources of the meatal innervation, which include the vagus, account for the occurrence of reflex coughing and sneezing when there is irritation of the meatus and the vomiting which may follow syringing the ears in children and the occasional heart failure induced by this process in the elderly. The association of earache with toothache or with lingual carcinoma is due to the involvement of the mandibular branch of the trigeminal, which supplies the teeth and tongue as well as the meatus. The upper half of the tympanic membrane is more vascular: for this reason and to avoid the chorda tympani and ossicles, incisions of this membrane should be postero-inferior.

7.344 The left tympanic membrane: external aspect as seen through a speculum.

The Tympanic Cavity (Tympanum)

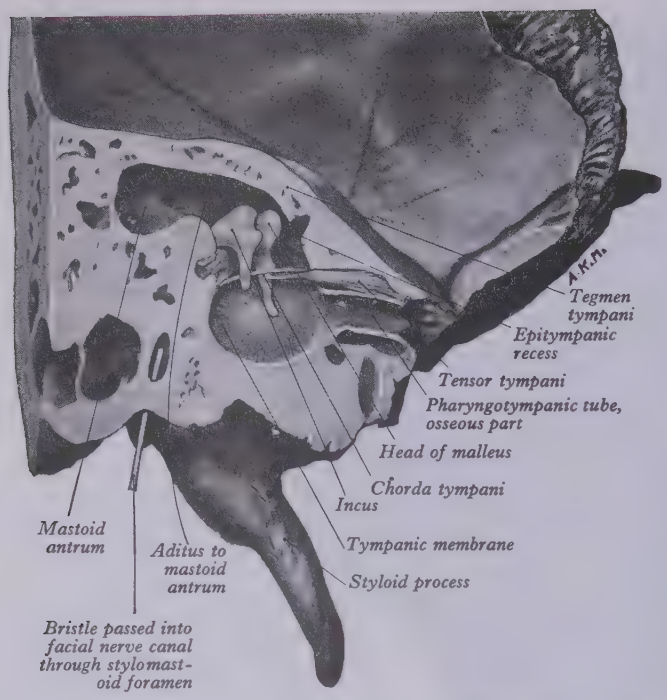
The tympanic cavity or *middle ear* (7.343, 345, 347, 348) is an irregular, laterally compressed space in the temporal bone, lined

7.345 Scheme showing the parts of the left auditory apparatus as if viewed through a semi-transparent temporal bone. Compare with 7.343 and 7.348.

by mucoperiosteum (p. 1226) and containing air derived from the nasopharynx via the auditory tube. It contains a train of movable ossicles, which connect the lateral to the medial wall to transmit vibrations of the tympanic membrane across the cavity of the middle ear to the cochlea; its essential function is to transfer energy efficiently from the relatively weak vibrations in the elastic, compressible *air* in the external acoustic meatus to overcome the inertia of the incompressible *fluids* around the delicate receptors in the cochlea. Mechanical coupling between the two systems must match their resistance to deformation or 'flow', i.e. their *impedance*, as closely as possible. Thus aerial waves of low amplitude and *low force* per unit area arrive at the tympanic membrane, which has 15–20 times the area of the *stapedial footplate* in contact with perilymph. In this manner, the force per unit area generated by the footplate is increased by a similar amount, while the amplitude of vibration is almost unchanged.

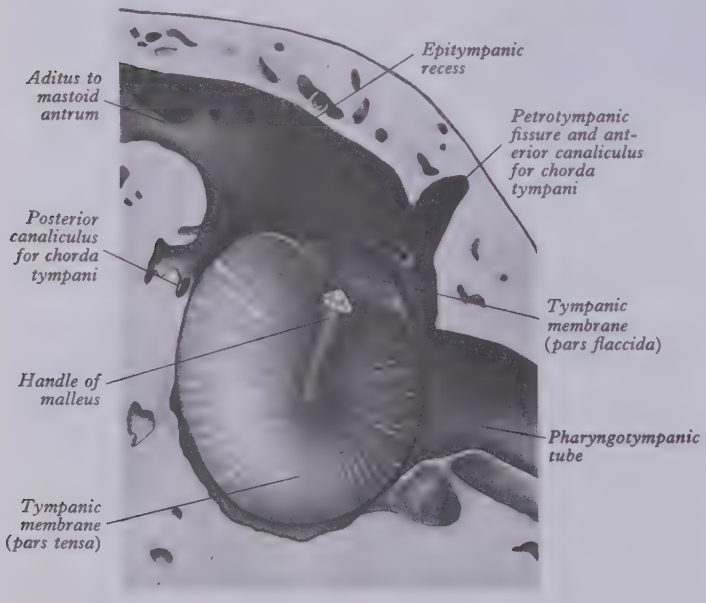
Protective mechanisms are also incorporated into the tympanic cavity's design, including the auditory (pharyngotympanic) tube to equalize pressure on both sides of the delicate tympanic membrane, the protective shape of articulations between the ossicles and the reflex contractions of the stapedius and tensor tympani muscles preventing damage due to sudden or excessive excursions of the ossicles.

The cavity has two parts: the *tympanic cavity proper*, opposite the membrane, and an *epitympanic recess*, above its level. The latter contains the upper half of the malleus and most of the incus. Including the recess, the vertical and anteroposterior diameters of the cavity are each about 15 mm; the transverse is about 6 mm above and 4 mm below but opposite the umbo it is only 2 mm. The cavity is bounded *laterally* by the tympanic membrane and *medially* by the lateral wall of the internal ear. It communicates posteriorly with the mastoid antrum and via this with the mastoid air cells and anteriorly with the pharyngotympanic tube (7.345).



BOUNDARIES OF THE TYMPANIC CAVITY

The roof of the tympanic cavity (7.346), is a thin plate of compact bone, the *tegmen tympani*. This separates the cranial and tympanic cavities, forming much of the anterior surface of the petrous temporal bone; it is prolonged posteriorly to roof the mastoid antrum and anteriorly to cover the canal for the tensor tympani. In youth, the unossified petrosquamosal suture (p. 379) may allow the spread of infection from the tympanic cavity to the meninges. In adults, veins from the tympanic cavity traverse this suture to the superior petrosal or petrosquamous sinus (p. 803) and may also transmit infection to these structures.



The floor is a narrow, thin, convex plate of bone separating the cavity from the superior bulb of the internal jugular vein (7.348); bone may be patchily deficient here and the tympanic cavity and vein are then separated only by mucous membrane and fibrous tissue. Near the medial wall is a small aperture for the tympanic branch of the glossopharyngeal nerve. The floor is sometimes thick and may contain some accessory mastoid air cells.

The lateral wall (7.346, 347) consists mainly of the tympanic membrane but is partly also the ring of bone to which the membrane is attached. The ring is deficient or notched above and near this region are the openings of the anterior and posterior canaliculi for the chorda tympani and also the petrotympanic fissure.

The *posterior canaliculus for the chorda tympani nerve* is situated in the angle between the posterior and lateral walls of the tympanic cavity just behind the tympanic membrane and level with the upper end of the handle of the malleus; it leads into a minute canal which descends in front of the facial canal and ends in it about 6 mm above the stylomastoid foramen. Through it the chorda tympani nerve and a branch of the stylomastoid artery enter the tympanic cavity.

7.346 Oblique vertical section through the left temporal bone, to show the lateral wall of the middle ear and the mastoid antrum.

7.347 The lateral wall of the left tympanic cavity.

The *petrotympanic fissure* opens just above and in front of the ring of bone to which the tympanic membrane is attached; it is a mere slit about 2 mm in length, containing the anterior process and anterior ligament of the malleus and it transmits to the tympanic cavity the maxillary artery's anterior tympanic branch.

The *anterior canaliculus for the chorda tympani* opens at the medial end of the petrotympanic fissure; through it the chorda tympani leaves the tympanic cavity.

The tympanic membrane (7.346, 347) separates the tympanic cavity from the external meatus. It is thin and semi-transparent, almost oval, though somewhat broader above than below, and is placed at an angle of about 55° with the meatal floor. Its longest, antero-inferior diameter is from 9–10 mm and its shortest is from 8–9 mm. Most of its circumference is a thickened *fibrocartilaginous ring* attached to the *tympanic sulcus* at the medial end of the meatus; this sulcus is deficient superiorly and here, as noted above, the *anterior* and *posterior malleolar folds* pass to the lateral process of the malleus, leaving between them the triangular *pars flaccida*, a thin, lax part of the membrane; a small perforation may occur in this sometimes. The membrane is elsewhere taut, the *pars tensa*. The handle of the malleus is firmly attached to the membrane's internal surface as far as its centre, the *umbo*, which projects towards the tympanic cavity. Though this membrane as a whole is convex medially, its radiating fibres (vide infra) are curved with their concavities directed upwards.

Histologically, the tympanic membrane has three strata: an outer cuticular, an intermediate fibrous and an inner mucous. The *cuticular stratum* is continuous with the thin skin of the meatus and is keratinized, stratified squamous in type, devoid of dermal papillae and hairless. Its subepithelial tissue is vascularized and may develop a few peripheral papillae. The *fibrous stratum* has an external layer of radiating fibres diverging from the handle of the malleus and a deep layer of circular fibres, peripherally plentiful but sparse and scattered centrally in the membrane. Marginally and centrally a fine network of elastic fibres is said to be mixed with the collagen (but vide infra). The *mucous stratum* is a part of the mucosa of the tympanic cavity; it is thickest near the tympanic membrane's upper part and is covered, it has been claimed, by a layer of ciliated columnar epithelial cells. However, cilia occur only in patches or are entirely absent and then replaced by a low cuboidal or simple squamous epithelium.

These appearances, based on light microscopy, have been much amplified by electron microscopy and other techniques: first in guinea-pigs (Johnson et al 1968), in which the *external* epithelium is approximately 10 cells thick and has two zones, a superficial of non-nucleated squames and a deep zone like the epidermal stratum spinosum, with numerous desmosomes between cells, the deepest of which lie on a continuous basal lamina but lack epithelial pegs and hemidesmosomes. The *internal* epithelium is a single layer of very flat cells, with overlapping or interdigitating boundaries carrying desmosomes and tight junctions between cells. Their cytoplasm contains only a few organelles, the luminal surfaces of these apparently metabolically inert cells have a few irregular microvilli and are covered by an amorphous electron-dense material. Ciliated columnar cells are absent. Most interestingly the intermediate stratum contains filaments about 10 μm in diameter, with links between filaments at 25 nm intervals. The filaments are disposed in outer radial and inner non-radial zones, the former more numerous; neither resemble collagen or elastin. In amino acid composition, also, the filaments are distinctive and may consist of a protein peculiar to the tympanic membrane. McMinn & Taylor 1978, reporting on the development of the fibrillar component in guinea-pig and human embryos and fetuses, have confirmed the findings in guinea-pigs mentioned above, but in human fetuses small groups of collagen fibrils were apparent at eleven weeks in utero, with small bundles of elastin microfibrils. Older specimens showed more typically cross-banded collagen fibrils and the development of an amorphous elastin component. Large fibroblasts occur between the external radial fibres and basal lamina of the *external* epithelium, while blood capillaries and their basement membranes lie just deep to the basal lamina of the *internal* epithelium. In the pars flaccida the fibrous stratum is replaced by loose connective tissue.

The *arteries* of the tympanic membrane are from: the maxillary artery's deep auricular branch (to the outer, cuticular stratum) and the stylomastoid branch of the occipital or the posterior auricular artery and the tympanic branch of the maxillary to the internal mucosa. The *superficial veins* drain to the external jugular; those in the *deep surface* drain partly to the transverse sinus and dural veins and partly to the venous plexus of the pharyngotympanic tube. The *nerve supply* is from: the auriculotemporal branch of the mandibular nerve, the auricular branch of the vagus, the tympanic branch of the glossopharyngeal and possibly from the facial nerve.

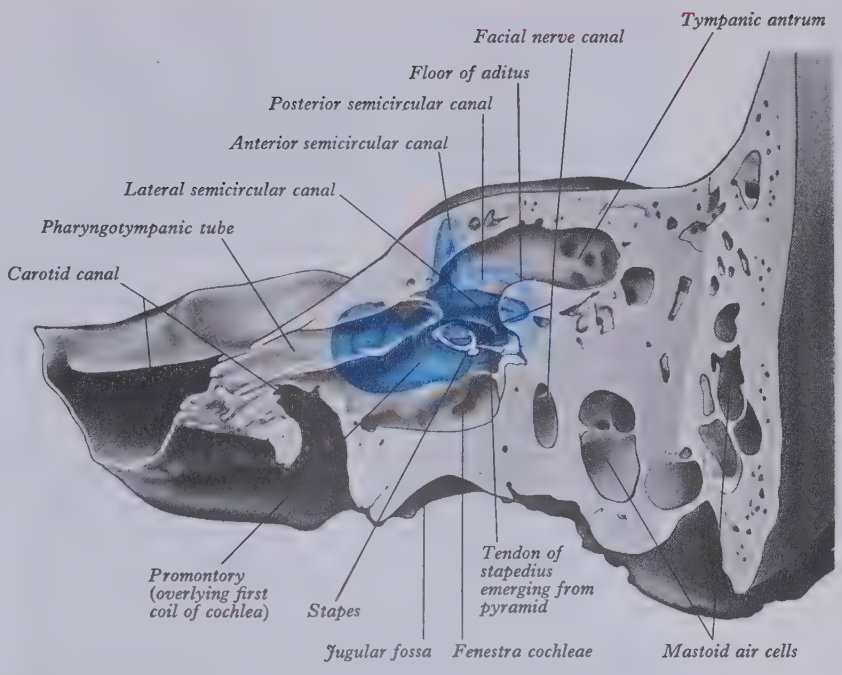
The medial wall of the tympanic cavity (7.348, 349) is also the lateral boundary of the internal ear. Its features are the promontory, fenestra vestibuli, fenestra cochleae and the facial prominence.

The rounded *promontory*, minutely grooved by the nerves of the tympanic plexus, overlies the lateral projection of the basal turn of the cochlea; a minute spicule of bone frequently connects the promontory to the pyramidal eminence of the posterior wall. Anterior to the promontory the apex of the cochlea is near the medial wall of the tympanum (7.342, 343). Behind the promontory the *sinus tympani* indicates the position of the ampulla of the posterior semicircular canal.

The *fenestra vestibuli* (*f. ovalis*) is a reniform opening posterosuperior to the promontory, connecting the tympanic cavity to the vestibule; its long diameter is horizontal and its convex border directed superiorly. It is occupied by the base of the stapes, the circumference of which is attached to the fenestral margin by an annular ligament.

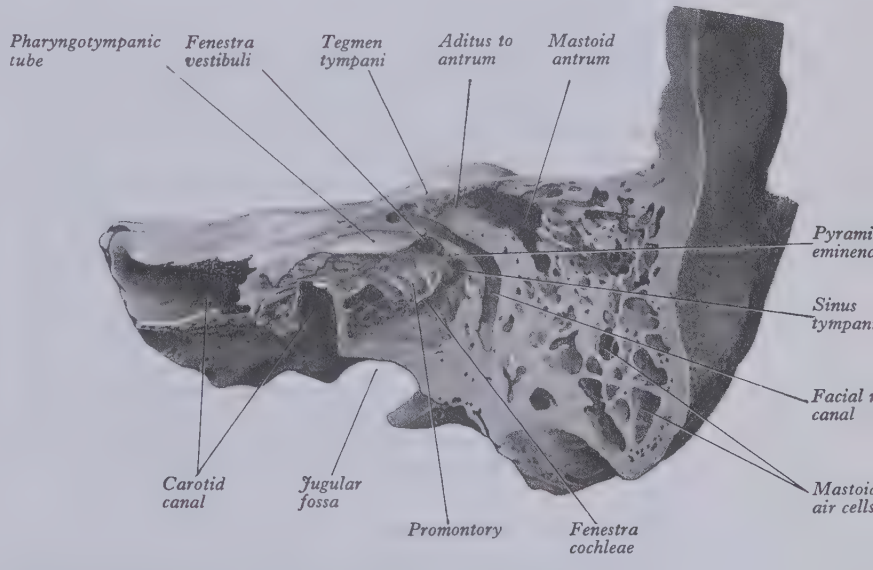
The *fenestra cochleae* (*f. rotunda*) is postero-inferior to the fenestra vestibuli and separated from it by the posterior part of the promontory. It lies completely under the overhanging edge of the promontory in a deep hollow or niche. It is placed very obliquely; in dried specimens it opens anterosuperiorly from the tympani cavity into the scala tympani of the cochlea. It is closed by the *secondary tympanic membrane*, which is somewhat concave towards the tympanic cavity and convex towards the cochlea, the membrane being bent so that its posterosuperior one-third is at an angle to its antero-inferior two-thirds. The membrane has three layers: an external derived from the tympanic mucosa, an internal from the cochlear lining membrane and a middle, fibrous layer.

The *prominence of the facial nerve canal* indicates the position of the upper part of a bony canal for the facial nerve. The canal, its lateral wall sometimes being partly deficient, traverses the medial tympanic wall from before backwards, just above the fenestra vestibuli, then curves down into the posterior wall of the cavity.



The posterior wall (7.348) is wider above than below, its main features being the aditus to the mastoid antrum, the pyramid and the fossa incudis.

The *aditus to the mastoid antrum*, a large irregular aperture, leads back from the epitympanic recess into the upper part of the *mastoid antrum*. On the medial wall of the aditus is a rounded eminence, above and behind the prominence of the facial nerve canal, due to the underlying lateral semicircular canal.



The *pyramidal eminence* is just behind the fenestra vestibuli and anterior to the vertical part of the facial nerve canal; it contains the stapedius muscle, its summit projecting towards the fenestra vestibuli; a small apical aperture transmits the muscle's tendon. Its cavity is prolonged down and back in front of the facial nerve canal and communicates with the latter by an aperture through which a small branch of the facial nerve passes to the stapedius (p. 1110).

The *fossa incudis*, a small depression low and posterior in the epitympanic recess, contains the short process of the incus, fixed to the fossa by ligamentous fibres.

The mastoid antrum (7.343, 345–349) is an air sinus in the petrous temporal bone and has relations of considerable surgical importance, being often infected. In its upper *anterior wall* is an opening, the aditus to the mastoid antrum, leading back from the epitympanic recess, with the lateral semicircular canal medial to it. The antrum's *medial wall* is related to the posterior semicircular canal (7.345). *Posterior* is the sigmoid sinus; some mastoid air cells may intervene between this and the antrum. The *roof*, formed by the tegmen tympani, lies below the middle cranial fossa and temporal lobe of the brain. The floor has several openings communicating with the mastoid air cells. *Antero-inferior* is the descending part of the facial nerve canal. The *lateral wall* of the antrum, the usual surgical approach to the cavity, is formed by the postmeatal process of the squamous temporal bone. This is only 2 mm thick at birth but increases at a rate of approximately 1 mm a year to attain a final thickness of 12–15 mm. In adults the lateral wall of the antrum corresponds to the *suprameatal triangle* on the outer surface of the skull (pp. 352, 355), palpable through the cymba conchae (p. 1220). The triangle's superior side, the supramastoid crest, is level with the floor of the middle cranial fossa; the antero-inferior side, forming the posterosuperior margin of the external acoustic meatus, indicates approximately the position of the descending part of the facial nerve canal; and the posterior side, formed by a posterior vertical tangent to the posterior margin of the external acoustic meatus, is just anterior to the sigmoid sinus. The adult capacity of the antrum is about 1 ml and its general diameter about 10 mm. Unlike other air sinuses, it is present at birth and is indeed then almost adult in size, although it is at a higher level relative to the external acoustic meatus than in adults. In the very young, owing to the thinness of the lateral antral wall and the absence of the mastoid process, the stylomastoid foramen and emerging facial nerve are very superficially situated.

7.348 Oblique section through the left temporal bone, to show the medial wall of the middle ear. The cochlea and the semicircular canals are in blue. Note the relationship of the first coil of the cochlea to the promontory and the closeness of the facial nerve canal and the lateral semicircular canal to the medial wall of the aditus.

7.349 Oblique section through the left temporal bone, showing the medial wall of the middle ear. Compare with 7.348.

The mastoid air cells (7.343, 348, 349) vary considerably in number, form and size. Usually they interconnect and are lined by a mucosa with squamous non-ciliated epithelium, continuous with that in the mastoid antrum and tympanic cavity. They may fill the mastoid process, even to its tip, and some may be separated

from the sigmoid sinus and posterior cranial fossa only by extremely thin bone, which is occasionally deficient. Some may lie superficial to, or even behind the sigmoid sinus and others may occur in the posterior wall of the descending part of the facial nerve canal. Those in the squamous temporal bone may be separated from deeper cells in the petrous part by a plate of bone in the line of the squamomastoid suture. Sometimes they extend very little into the mastoid, this process consisting largely of dense bone or trabecular bone containing bone marrow. Varieties of the mastoid process occur (3.135) and three types are commonly described: *pneumatic*, with many air cells, *sclerotic*, with few or none, and *mixed*, containing both air cells and bone marrow. Pannoer (1970) proposed a more elaborate scheme, dependent on the degree of pneumatization and the relation of air cells to the lateral sinus; in a series of 100 mastoid processes, the cells most distant from the antrum were largest. Air cells may extend beyond the mastoid process into the squamous temporal bone above the supramastoid crest, into the posterior root of the zygomatic process of the temporal, into the osseous roof of the external acoustic meatus just below the middle cranial fossa and into the floor of the tympanic cavity very close to the superior jugular bulb. Rarely, a few may excavate the jugular process of the occipital bone. An important group may extend medially into the petrous temporal bone, even to its apex, related to the pharyngotympanic tube, carotid canal, labyrinth and abducent nerve; some investigators maintain that these are not continuous with the mastoid cells but grow independently from the tympanic cavity. The extensions of the mastoid air cells described above are pathologically important since infection may spread to the structures around them. Though the antrum is well developed at birth, the mastoid air cells are merely minute antral diverticula at this stage. As the mastoid develops in the second year, the cells gradually extend into it and by the fourth year they are well formed, although their greatest growth occurs at puberty. In about 20% of skulls the mastoid process has no air cells at all.

The anterior tympanic wall is narrowed by the approximation of the medial and lateral walls of the cavity. Its inferior, larger area is a thin lamina forming the posterior wall of the carotid canal, perforated by the superior and inferior caroticotympanic nerves and the tympanic branch or branches of the internal carotid. Opening above on the anterior wall are two parallel canals; superior is the *canal for the tensor tympani* and inferiorly the *osseous part of the pharyngotympanic tube*. These canals incline downwards and anteromedially to open in the angle between the squamous and petrous parts of the temporal bone; they are separated by a thin, osseous septum. The canal for the tensor tympani and the bony septum runs posterolaterally on the medial tympanic wall, ending immediately above the fenestra vestibuli, where the posterior end of the septum is curved laterally to form a pulley, the *processus trochleariformis* (*cochleariformis*), over which the tendon of the tensor tympani is turned laterally to its attachment on the upper part of the handle of the malleus.

THE PHARYNGOTYMPANIC (AUDITORY) TUBE

The *pharyngotympanic* or *auditory* tube (7.342, 345, 346), connecting the tympanic cavity to the nasopharynx, allows the passage of air between these spaces to equalize the air pressure on both aspects of the tympanic membrane. It is about 36 mm long and descends anteromedially at an angle of about 45° with the sagittal plane and 30° with the horizontal. It is formed partly by bone and partly by cartilage and fibrous tissue.

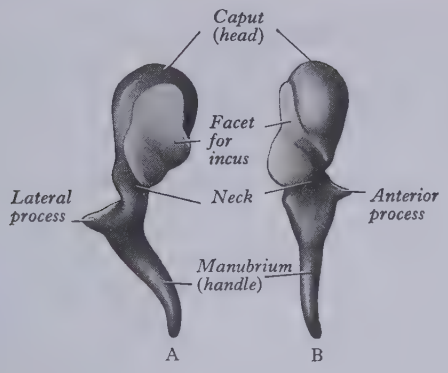
The osseous *part*, about 12 mm long, starts from the anterior tympanic wall and gradually narrows to end at the junction of the squamous and petrous parts of the temporal bone, where it has a jagged margin for the attachment of the cartilaginous part; the carotid canal lies medially. It is oblong in transverse section, with its greater dimension horizontal.

The *fibrocartilaginous part*, about 24 mm long, is formed by a triangular plate of cartilage, mostly in the posteromedial wall of the tube. Its apex is attached by fibrous tissue to the circumference of the jagged rim of the osseous tube and its base is directly under the mucosa of the lateral nasopharyngeal wall, forming a *tubal elevation* behind the pharyngeal orifice of the tube. The cartilage's upper part is bent laterally and downwards, producing a broad *medial* and narrow *lateral lamina*. In transverse section it is hook-like and incomplete below and laterally, where the canal is composed of fibrous tissue. The cartilage is tied to the cranial base in the groove between the petrous temporal bone and the greater wing of the sphenoid, ending near the root of the medial pterygoid plate. The cartilaginous and osseous parts of the tube are not in the same plane, the former descending more steeply than the latter. The diameter is greatest at the pharyngeal orifice, least at the junction of the two parts (the *isthmus*) and increasing again towards the tympanic cavity.

The mucosa of the tube is continuous with the nasopharyngeal and tympanic mucosae; it is lined by a ciliated columnar epithelium and is thin in the osseous part but thickened by mucous glands in the cartilaginous part; near the pharyngeal orifice is a variable, but sometimes considerable lymphoid mass, the *tubal tonsil*.

Relations of the pharyngotympanic tube. *Anterolaterally* the tensor veli palatini separates the tube from the otic ganglion, the mandibular nerve and its branches, the chorda tympani and the middle meningeal artery. Some fibres of the tensor are attached to the lateral cartilaginous lamina and to the fibrous part, forming the *dilatator tubae*. The salpingopharyngeus (p. 1328) is attached to the inferior part of the cartilage near its pharyngeal opening. *Posteromedially* are the petrous temporal bone and the levator veli palatini which arises partly from its medial lamina. The pharyngeal orifice is described with the nasopharynx (p. 1323).

The tube is opened during deglutition but the mechanism is uncertain. The dilatator tubae, aided by the salpinopharyngeus, may be responsible, though some deny the muscle's existence. The levator veli palatini, by elevating the cartilaginous tube, might allow passive opening by releasing tension on the cartilage.

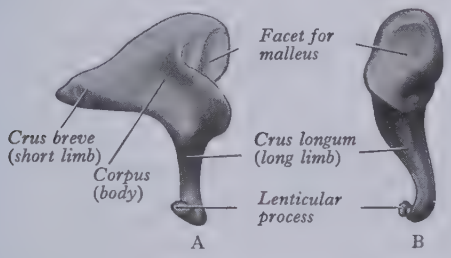


At birth the auditory tube is about half its adult length, its direction being more horizontal and its bony part relatively shorter but much wider. Its pharyngeal orifice is a narrow slit, level with the palate and without a tubal elevation.

Arteries of the auditory tube arise from the ascending pharyngeal branch of the external carotid and from the middle meningeal and the artery of the pterygoid canal (both branches of the maxillary artery). *Veins* drain to the pterygoid venous plexus. *The nerves* are from the tympanic plexus (p. 1228) and from the pharyngeal branch of the pterygopalatine ganglion. The precise contribution from the nerves forming the plexus, i.e. the glossopharyngeal, the cervical sympathetic and possibly the facial, remains uncertain in man.

THE AUDITORY OSSICLES

A chain of mobile ossicles, the *malleus*, *incus* and *stapes*, transfers sound waves across the tympanic cavity from its membrane to the fenestra vestibuli. The malleus is attached to the tympanic membrane and the base of the stapes to the rim of the fenestra vestibuli, while the incus is suspended between them, articulating with both bones.

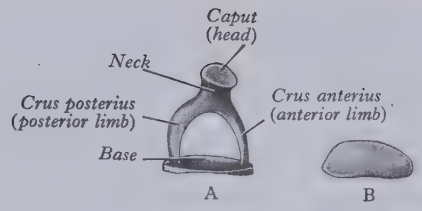


The malleus (7.350), shaped like a mallet, is 8–9 mm long and is the largest of the ossicles; it has a head, neck, manubrium and anterior and lateral processes. The *head*, its enlarged, ovoid upper end, is situated in the epitympanic recess; it articulates posteriorly with the incus, being covered elsewhere by mucosa. The cartilaginous articular facet for the incus is narrowed near its middle and consists of a larger upper part and a smaller, lower part, orientated almost at right angles to each other. Opposite the constriction the lower margin of the facet projects as the *spur* (*cog-tooth*) of the malleus. The neck is the narrowed part below the head and inferior to this is an enlargement from which the processes project. The *manubrium mallei* (*handle of the malleus*) is connected by its lateral margin with the tympanic membrane. It descends posteromedially, diminishing towards its free end which curves slightly forwards and is transversely flat. High on its medial surface a small projection receives the tendon of the tensor tympani. The *anterior process* is a delicate bony spicule, directed forwards from the enlargement below the neck and connected with the petrotympanic fissure by ligamentous fibres (vide infra);

7.350 The left malleus: A. posterior aspect; B. medial aspect.

in fetal life this is the longest process of the malleus and is continuous in front with Meckel's cartilage (p. 172). The *lateral process*, a conical projection from the root of the manubrium, is directed laterally and is attached to the upper part of the tympanic membrane and via the anterior and posterior malleolar folds to the sides of the notch in the upper part of the tympanic sulcus.

Ossification. The cartilaginous precursor of the malleus originates as part of the dorsal end of Meckel's cartilage. Excepting its anterior process, it ossifies from a single endochondral centre which appears near the future neck of the bone in the fourth month in utero. The anterior process ossifies separately in dense connective tissue and joins the rest at about the sixth month of fetal life.



7.351 The left incus: A. medial aspect; B. anterior aspect.

The incus (7.351) is shaped less like an anvil (from which it is named) than a premolar tooth, with its two diverging roots. It has a body and two processes. The *body* is somewhat cubical but laterally compressed; it has an anterior, cartilage-covered, saddle-shaped facet for articulation with the head of the malleus. The *long process*, rather more than half the length of the handle of the malleus, descends almost vertically, behind and parallel to the handle; its lower end bends medially and ends in a rounded *lenticular process*, the medial surface of which is a cartilaginous facet for the head of the stapes. The *short process*, somewhat conical, projects posteriorly and is attached by ligamentous fibres to the fossa incudis in the postero-inferior part of the epitympanic recess.

Ossification. The incus has a cartilaginous precursor continuous with the dorsal extremity of Meckel's cartilage (p. 172). Ossification often spreads from a single centre in the upper part of its long process in the fourth fetal month; the lenticular process, however, may have a separate centre.

The stapes (7.352), or stirrup, has a head, neck two limbs and a base. The *head* (*caput*) is directed laterally and has a small cartilaginous facet for the lenticular process of the incus. To the constricted *neck* is attached posteriorly the tendon of the stapedius. The *limbs* (*crura*) curve away from the neck and merge with a flattened oval or reniform *base* forming the footplate of the stapes and attached to the margin of the fenestra vestibuli by an annular ligament. The anterior limb is shorter and less curved than the posterior.

Ossification. The stapes is preformed in the perforated dorsal moiety of the hyoid arch cartilage of the fetus. Ossification starts

7.352 The left stapes: A. superior aspect; B. basal aspect.

from a single endochondral centre, appearing in the base in the fourth fetal month.

At birth the auditory ossicles have reached an advanced state of maturity.

The Articulations of Auditory Ossicles

These are typical synovial joints. The incudomalleolar joint is saddle-shaped, the incudostapedial is a ball and socket articulation. Their articular surfaces are covered with hyaline cartilage and each joint is enveloped by a capsule containing much elastic tissue and lined by synovial membrane.

The Ligaments of the Auditory Ossicles

The ossicles are connected to the tympanic walls by ligaments: three for the malleus and one each for the incus and stapes. Some of these are mere mucosal folds carrying blood vessels and nerves to and from the ossicles and their articulations; others contain a central, strong band of collagen fibres.

The *anterior ligament of the malleus* stretches from the mallear neck, just above the anterior process, to the anterior wall of the tympanic cavity near the petrotympanic fissure, some of its collagen fibres traversing the fissure to the spine of the sphenoid; others continue into the sphenomandibular ligament which, like the anterior malleolar, is derived from the perichondrial sheath of Meckel's cartilage (p. 172). The ligament may contain muscle fibres (*laxator tympani* or *musculus externus mallei*).

The *lateral ligament of the malleus* is a triangular band stretching from the posterior part of the tympanic incisure's border to the head of the malleus. The *superior ligament of the malleus* connects the head of the malleus to the roof of the epitympanic recess. The *posterior ligament of the incus* connects the end of its short process to the fossa incudis. The *superior ligament of the incus* is little more than a mucosal fold passing from the body of the incus to the roof of the epitympanic recess.

The vestibular surface and the rim of the stapedial base are covered with hyaline cartilage; the rim is attached to the margin of the fenestra vestibuli by an elastic *annular ligament of the base of the stapes*, parts of which are much narrower, acting as a kind of hinge on which the stapedial base moves when the stapedius muscle contracts and during acoustic oscillation (vide infra).

THE MUSCLES OF THE TYMPANIC CAVITY

The tensor tympani (7.342, 346), a long slender muscle, occupies the bony canal above the osseous pharyngotympanic tube, from which it is separated by a thin bony septum. It arises from the cartilaginous part of the pharyngotympanic tube and the adjoining region of the greater wing of the sphenoid, as well as from its own canal. It passes back within its canal, ending in a slim tendon which bends laterally round the pulley-like processus trochleariformis and finally attaches to the handle of the malleus, near its root.

The nerve supply is a branch of the nerve to the medial pterygoid (a ramus of the mandibular nerve), traversing the otic ganglion without interruption (p. 1113). The muscle receives both motor and proprioceptive fibres (Candiollo 1965).

The stapedius extends from the wall of a conical cavity in the pyramidal eminence (and its continuation anterior to the descending part of the facial nerve canal, p. 1110), its minute tendon emerging from the orifice at the pyramid's apex to pass forwards to attach to the posterior surface of the neck of the stapes (7.348). The muscle is of an asymmetrical bipennate form,

containing numerous small motor units, each of only six to nine muscle fibres. A few neuromuscular spindles exist near the myotendinous junction.

The nerve supply is a branch of the facial nerve (for details see Blevins 1967).

Actions. The tensor tympani and stapedius usually contract together in reflex response to sounds of fairly high intensity, exerting a 'protective damping effect before vibrations reach the internal ear' (Hallpike 1935). The tensor pulls the tympanic membrane inwards to tense it and also pushes the stapes more tightly into the fenestra vestibuli. The strapedius muscle opposes the tensor in the latter action. Paralysis of the stapedius results in hyperacusis.

MOVEMENTS OF THE AUDITORY OSSICLES

The malleolar manubrium faithfully follows all movements of the tympanic membrane, while the malleus and incus rotate together around an axis running from the short process and posterior ligament of the incus to the anterior ligament of the malleus. When the tympanic membrane and manubrium move medially the long process of the incus moves in the same direction, pushing the stapedial base towards the labyrinth and perilymph (p. 1202). This causes a compensatory outward bulging of the secondary tympanic membrane of the fenestra cochleae. These events are reversed when the membrane moves outwards, but if its movement is large the incus does not follow the full outward excursion of the malleus, merely gliding on it at the incudomalleolar joint and thus preventing a dislocation of the stapedial base from the fenestra vestibuli. When the manubrium moves medially, the spur at the lower margin of the malleolar head locks the incudomalleolar joint, forcing a medial movement of the long process of the incus; the joint is unlocked again when the manubrium moves outwards. The three bones together act as a bent lever so that the stapedial base does not move in the fenestra vestibuli like a piston but rocks on a fulcrum at its antero-inferior border, where the annular ligament is thick. More complex stapedial movements have been described (Békésy 1960). The rocking movement around a vertical axis, which is like a swinging door, is said to occur only at moderate intensities of sound. With loud, low-pitched sounds, the axis becomes horizontal, the upper and lower margins of the stapedial base oscillating in opposite directions around this central axis, thus preventing excessive displacement of the perilymph.

THE TYMPANIC MUCOSA

The mucosa of tympanic cavity is continuous with that of the pharynx, via the pharyngotympanic tube; it covers the ossicles, muscles and nerves in the cavity, forming the inner layer of the tympanic membrane and the outer layer of the secondary tympanic membrane; it also spreads into the mastoid antrum and air cells. It forms several vascular folds extending from the tympanic walls to the ossicles: of these, one descends from the roof of the cavity to the head of the malleus and the upper margin of the body of the incus and a second surrounds the stapedius, others investing the chorda tympani nerve and the tensor tympani muscle. These folds separate off saccular recesses and give the interior of the tympanic cavity a somewhat honeycombed appearance. One such *superior recess of the tympanic membrane* lies between the neck of the malleus and the pars flaccida. Two others, the *anterior* and *posterior recesses of the tympanic membrane*, are formed by the mucosa around the chorda tympani and lie, respectively, anterior and posterior to the manubrium of the malleus. The tympanic mucosa is pale, thin and slightly vascular. It has a ciliated columnar epithelium except over the posterior part of the medial wall, the posterior wall, often parts of tympanic membrane and the auditory ossicles, the cells of these surfaces being flatter and non-ciliated. Near the pharyngotympanic tube goblet cells are numerous; otherwise there are no mucous glands. The mastoid antrum and air cells are lined by flat, non-ciliated epithelium. Undoubtedly there are considerable mucosal variations in the middle ear, which include squamous, cuboidal, columnar and ciliated columnar epithelia. No systematic ultrastructural study has yet been made in this field (Kawabata & Paparella 1969).

It must be re-emphasized that the tympanic cavity and mastoid antrum, auditory ossicles and structures of the internal ear are almost fully developed at birth and subsequently alter little. In fetuses the cavity contains a gelatinous tissue which has practically disappeared by birth, when it is filled by a fluid which is absorbed when air enters via the auditory tube.

THE VASCULATURE OF THE TYMPANIC CAVITY

Six *arteries* supply the walls and contents of the tympanic cavity. Two are larger than the others: the *anterior tympanic* branch of the *maxillary*, supplying the tympanic membrane, and the *stylomastoid* branch of the *occipital* or *posterior auricular* arteries, supplying the posterior tympanic cavity and mastoid air cells. The smaller arteries include: the *petrosal* branch of the *middle meningeal*, entering through the hiatus for the greater petrosal nerve; the *superior tympanic* branch of the *middle meningeal*, traversing the canal for the tensor tympani; a branch from the *ascending pharyngeal* and from the *artery of the pterygoid canal*, accompanying the pharyngotympanic tube; and a *tympanic branch* or branches from the *internal carotid*, arising in the carotid canal and perforating the thin anterior wall of the tympanic cavity. In early fetal life a *stapedial artery* traverses the stapes (p. 217) (a feature which persists in some other mammals). *Veins* terminate in the pterygoid venous plexus and the superior petrosal sinus. From the mucosa of the mastoid antrum a small group of veins runs medially through the arch formed by the anterior semicircular canal, emerging on the posterior surface of the petrous temporal bone at the subarcuate fossa to drain into the superior petrosal sinus; these are the remains of the large *subarcuate veins* of childhood, a route for the spread of infection from the mastoid antrum to the meninges. *Lymph vessels* are described on p. 844.

THE NERVES OF THE TYMPANIC CAVITY

The nerves constitute the *tympanic plexus*, ramifying on the surface of the promontory. They arise from the tympanic branch of the glossopharyngeal nerve and the caroticotympanic nerves of sympathetic origin (Arslan 1960). The former enters the cavity by the tympanic *canaliculus for the tympanic nerve*, ramifying to join the plexus; the *superior* and *inferior caroticotympanic nerves* (from the carotid sympathetic plexus) traverse the carotid canal's wall and also join the plexus. The tympanic plexus supplies: (1) branches to the mucosa of the tympanic cavity, pharyngotympanic tube and mastoid air cells; (2) a branch traversing an opening anterior to the fenestra vestibuli and joining the greater petrosal nerve; (3) the *lesser petrosal nerve*, which may be regarded as the continuation of the tympanic branch of the glossopharyngeal fibres traversing the tympanic plexus. The lesser petrosal nerve occupies a small canal below that for the tensor tympani; it runs past and receives a connecting branch from the facial nerve's genicular ganglion, emerges from the anterior surface of the temporal bone via a small opening lateral to the hiatus for the greater petrosal nerve and then traverses the foramen ovale or the small canaliculus innominatus to join the otic ganglion. Postganglionic secretomotor fibres leave this ganglion in the auriculotemporal nerve to supply the parotid gland.

The *chorda tympani* leaves the facial nerve about 6 mm above the stylomastoid foramen and runs anterosuperiorly in a canal to enter the tympanic cavity via the *posterior canaliculus*. It then curves anteriorly in the substance of the tympanic membrane between its mucous and fibrous layers (p. 1223), crosses medial to the upper part of the manubrium of the malleus to the anterior wall, finally entering the *anterior canaliculus*. (For its further course see p. 1110.) The other nerves which are closely related topographically to the tympanic cavity include: the facial and its genicular ganglion and the stapedial and greater petrosal branches; the auricular branch of the vagus; afferent and efferent terminals of the vestibulocochlear nerve; and the internal carotid sympathetic plexus (all detailed elsewhere in this section). The *meningeal branch* (p. 1106) of the mandibular nerve supplies branches to the mastoid air cells.

Applied Anatomy. Fractures of the middle cranial fossa almost always involve the tympanic roof, accompanied by the rupture of the tympanic membrane or a fractured roof of the osseous external acoustic meatus. Such injuries usually entail prolonged bleeding

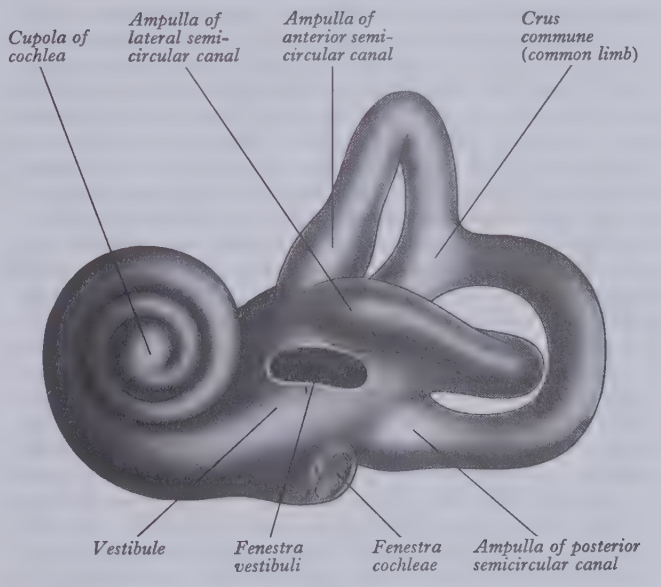
from the ear, with escape of cerebrospinal fluid if the dura mater has been torn.

The tympanic cavity is a common site of infection, usually spreading to it from the nose and pharynx along the pharyngotympanic tube, which usually becomes occluded because of the inflammatory swelling of its mucosa. The products of inflammation, thus confined to the tympanic cavity, may spread into the mastoid antrum, their only escape then being by the rupture of the tympanic membrane, either spontaneous or surgically induced, followed by the free discharge of pus. If the swelling of the pharyngotympanic tube then subsides, normal drainage of the cavity returns and perforations in the tympanic membrane heal; but, if the tube is occluded by enlarged lymphatic tissue, pus may continue to gather and discharge through the perforations as a chronic otorrhoea. Intracranial complications may follow: an abscess may form between the bone and the dura mater, above the tympanic cavity, beneath the dura of the temporal lobe or between the deep aspect of the mastoid process and the sigmoid sinus, possibly extending widely and surrounding the sinus, in which thrombosis may ensue; an infected clot may be detached into the general circulation, causing metastatic abscesses, e.g. in the lungs. Bone disease of the tympanic cavity or mastoid antrum may lead to severe and fatal septic meningitis or to the formation of brain abscesses, particularly in the temporal lobe of the cerebrum and the cerebellar hemisphere. In chronic bone disease in the tympanic cavity, the facial nerve may be exposed in its canal, its inflammation leading to facial paralysis of the infranuclear type (p. 1111).

THE INTERNAL EAR

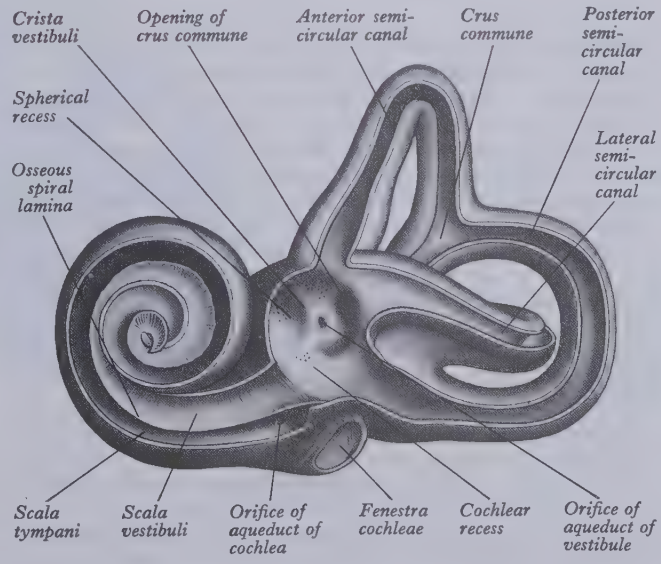
The internal ear includes the *osseus labyrinth*, a complex series of cavities in the petrous temporal bone, and the contained *membranous labyrinth*, a corresponding complex set of interconnected membranous sacs and ducts.

The Osseous Labyrinth



This (7.345, 353, 354) has three regions: the *vestibule*, *semicircular canals* and *cochlea*. These are all cavities within bone, lined by periosteum and containing a clear fluid, the *perilymph*, within which is the membranous labyrinth. The osseous labyrinth lies in denser, harder bone than that in other parts of the petrous bone; it is hence possible, particularly in young skulls, to dissect out the labyrinth from the petrous temporal.

THE VESTIBULE



The vestibule is the central part of the osseous labyrinth and lies medial to the tympanic cavity, posterior to the cochlea and anterior to the semicircular canals. Somewhat ovoid in shape but transversely narrow, it measures about 5 mm from front to back, the same from above below and about 3 mm across. Its *lateral wall* bears the fenestra vestibuli, closed by the stapedial base and its annular ligament. Anteriorly, on the *medial wall* is a small *spherical recess* containing the *saccule* and perforated by several minute holes, the *macula cribrosa media*; the recess adjoins the inferior vestibular area at the medial end of the internal acoustic meatus (7.354); the foramina transmit twigs of the vestibular nerve to the saccule. Behind the recess is an oblique *vestibular crest*, its anterior end being the *vestibular pyramid*; this ridge divides below to enclose a small depression, the *cochlear recess*, perforated by vestibulocochlear fascicles passing to the cochlear duct's vestibular end. Posterosuperior to the vestibular crest, in the roof and medial wall of the vestibule, is the *elliptical recess* which contains the *utricle*. The pyramid and adjoining part of the ellipitical recess are perforated by a number of holes, forming the *macula cribrosa superior*; the holes in the pyramid transmit the nerves to the utricle and those in the recess the nerves to the ampullae of the superior and lateral semicircular ducts. The region of the pyramid and elliptical recess corresponds to the superior vestibular area in the internal acoustic meatus (7.354). The opening of the vestibular *aqueduct* is below the elliptical recess; the aqueduct reaches the posterior surface of the petrous bone, containing one or more small veins and part of the membranous labyrinth, the *endolymphatic duct*. In the posterior part of the vestibule are the five *orifices of the semicircular canals*; in its anterior wall is an elliptical opening leading into the *scala vestibuli* of the cochlea.

THE SEMICIRCULAR CANALS

There are three semicircular canals: anterior (superior), posterior and lateral (horizontal); they lie posterosuperior to the vestibule. They are compressed from side to side and each describes about two-thirds of a circle; they are unequal in length but all are about 0·8 mm in diameter; each has a terminal swelling, an *ampulla* which is almost twice the diameter of the canal. They open into the vestibule by five openings, one of which is shared by two of the canals.

7.353 The left osseous labyrinth: lateral aspect.

7.354 The interior of the left osseous labyrinth.

The *anterior (superior) semicircular canal*, 15–20 mm in length, is vertical and placed transverse to the long axis of the petrous temporal bone, lying under the anterior surface of its arcuate eminence (p. 379). Some maintain, however, that the eminence does not accurately coincide with this semicircular canal, but is adapted to the occipitotemporal sulcus on the inferior surface of the temporal lobe of the brain. The canal's anterior end is ampullated, opening into the upper and lateral part of the vestibule; its other end unites with the posterior canal's upper end to form the *crus commune*, about 4 mm long, which opens into the medial part of the vestibule.

The *posterior semicircular canal*, also vertical, curves backwards almost parallel with the posterior surface of the petrous bone; it is 18–22 mm long; its ampullated end opens low in the vestibule, where the *macula cribrosa inferior* transmits nerves to the ampulla; this corresponds in position to the *foramen singulare* in the internal acoustic meatus (7.354). The canal's upper end joins the crus commune.

The *lateral (horizontal) canal* is 12–15 mm long, its arch directed horizontally and posterolaterally. Its anterior, ampullated end opens into the upper and lateral angle of the vestibule, above the fenestra vestibuli and just below the superior canal's ampullated end; its posterior end opens below the orifice of the crus commune.

It is often said that the two lateral semicircular canals are in the same plane and that the anterior canal of one side is almost parallel with the opposite posterior canal. Blanks et al (1975) measured the angular relations of the planes of the semicircular osseous canals in 10 human skulls. Although the planes of the three ipsilateral canals were almost perpendicular to each other, some variation was apparent, the angles being as follows: horizontal/anterior $111{\cdot}76 \pm 7{\cdot}55°$; anterior/posterior $86{\cdot}16 \pm 4{\cdot}72°$; posterior/horizontal $95{\cdot}75 \pm 4{\cdot}66°$. The planes of similarly orientated canals of the two sides showed marked departure from being parallel: left anterior/right posterior $24{\cdot}50 \pm 7{\cdot}19°$, left posterior/right anterior $23{\cdot}73 \pm 6{\cdot}71°$, left horizontal/right horizontal $19{\cdot}82 \pm 14{\cdot}93°$. The same observers (Curthoys et al 1977) have also measured the dimensions and radii of the canals; means for the radii of the osseous canals were as follows: horizontal 3·25 mm, anterior 3·74 mm, and posterior 3·79 mm. The functional implications of these data are still speculative. In diameter the osseous canals are about 1 mm (minor axis) and 1·4 mm (major axis). The membranous ducts within them are much smaller but are also elliptical in transverse section, with major and minor axes of 0·23 and 0·46 mm. Representative means for ampullary dimensions are as follows: length 1·94 mm, height 1·55 mm. Curthoys and collaborators have recorded many other labyrinthine dimensions. They attempt to equate the metrical data with theories of labyrinthine mechanics.

THE COCHLEA

The cochlea (7.345, 353, 354, 355), shaped like a conical snail-shell, is the most anterior part of the labyrinth, lying anterior to the vestibule. It is about 5 mm from base to apex and 9 mm across its base. Its apex, or *cupula*, points towards the anterosuperior area of the tympanic cavity's medial wall (7.345); its base faces the bottom of the internal acoustic meatus and is perforated by numerous apertures for the cochlear nerve. The cochlea has a central conical axis, the *modiolus*, with a spiral canal of about two and three-quarter turns around it; a delicate *osseus spiral lamina* projects from the modiolus, partially dividing the canal. Within this bony spiral lies the membranous cochlear duct, attached to the modiolus and to the outer cochlear wall by its other edge. There are thus formed three longitudinal channels within the cochlea, the middle one (the cochlear duct) being blind, ending at the apex of the cochlea and its flanking channels communicating with each other at the modiolar apex at a narrow slit, the *helicotrema* (vide infra). The cochlear duct bears on one of its walls the sensory receptors responsible for audition (p. 1235). The perilymphatic channels on either side of it are the *scala vestibuli* and *scala tympani*. The former is in continuity with the vestibule and the latter is separated from the tympanic cavity by the secondary tympanic membrane at the fenestra cochleae.

The modiolus, the central cochlear pillar, has a broad base near the lateral end of the internal acoustic meatus, where it corresponds to the *tractus spiralis foraminosus*, the multiple foramina of which transmit the fascicles of the cochlear nerve; those for the first turn and a half traverse the small foramina of the tractus spiralis, those for the apical turn traverse the *foramen centrale* in the tract's centre. Canals from the tractus traverse the modiolus and issue centrifugally in sequence into the base of the osseous spiral lamina. Here the small canals enlarge and fuse together to form the *spiral canal of the modiolus* (Rosenthal's canal) which follows the course of the osseous spiral lamina and contains the *spiral ganglion*. The foramen centrale continues as a canal through the modiolar centre to its apex.

The osseous cochlear canal, at its first turn, bulges towards the tympanic cavity where it underlies the promontory (p. 1225). It is about 35 mm long, diminishing in diameter from the base to the summit and ending at the *cupula*, which forms the cochlea's apex; at its start the canal is about 3 mm in diameter. It has three openings at its base: the *fenestra cochleae* (round window) facing the tympanic cavity and closed by the *secondary tympanic membrane*; the *fenestra vestibuli* (oval window) occupied by the base of the stapes (p. 1225); and the *cochlear canaliculus*, a minute funnel-shaped canal opening on the inferior surface of the petrous temporal bone (p. 379), transmitting a small vein to the inferior petrosal sinus and connecting the subarachnoid space to the scala tympani (vide infra).

The osseous spiral lamina is a ledge projecting from the modiolus like the thread of a screw; it reaches about halfway across the cochlear canal, partly dividing it into an upper *scala vestibuli* and a lower *scala tympani*. Its width decreases progressively towards its apex, ending in a hook-shaped *hamulus* partly bounding the *helicotrema*, through which the scalae are continuous. From the spiral modiolar canal many canaliculi radiate through the osseous lamina to its rim, carrying the cochlear nerves. In the lower part of the first turn a *secondary spiral lamina* projects *inwards* from the *outer* cochlear wall but does not reach the osseous spiral lamina, leaving a narrow *vestibular fissure* between them.

The osseous labyrinth was long regarded as lined by a thin fibroserous membrane adherent to the periosteum, its flat epithelium bounding the *perilymphatic space* which is filled with *perilymph* bathing the exterior of the membranous labyrinth. But electron microscopy shows that the perilymphatic space is bounded by fibroblast-like *perilymphatic cells*, with strands of extracellular fibres, the detailed form of the cells varying in different parts of the labyrinth. Where the perilymphatic space is narrow, the cells are essentially *reticular* or *stellate* in form, their sheet-like cytoplasmic extensions crossing and dividing the space into connected intercellular clefts of variable shape and size. This tissue and its spaces occupies the cochlear canaliculus; but where the space is wider, as in the scalae vestibuli and tympani and much of the vestibule, the perilymphatic cells on the periosteum and the external surface of the membranous labyrinth are extremely flat, with a rather featureless cytoplasm; apart from a few projections into the perilymph the arrangement approaches that of a true squamous epithelium. Elsewhere, on parts of the perilymphatic surface of the basilar membrane (p. 1235), the cells are cuboidal. Closely related to the periosteal and labyrinthine aspects of these cells are bundles of collagen fibres, which the cells may form. In some species fibres with a helical substructure, differing from collagen, have been described but their status in mankind is uncertain.

The perilymph resembles the cerebrospinal fluid in its composition but minor differences have been described (Ormerod 1960). Many regard it as an ultrafiltrate of plasma, with perhaps some addition from the cerebrospinal fluid. Its source, rate of production, circulation and absorption are as yet not fully known. The supposed connection between the perilymphatic and subarachnoid spaces via the *cochlear canaliculus* is controversial. The canaliculus was often described as containing a simple, epithelial duct connecting the two spaces, a view rejected by some (Waltner 1948, Mygind 1948, Young 1952, 1953), who surmised that the connective tissue blocked the canaliculus, thus separating the two fluid compartments. However it seems likely that

intercellular crevices persist in the canal; electron-dense tracers such as thorotrast, introduced into the subarachnoid space, readily appear in the perilymphatic spaces (Duvall & Quick 1969). Others (Silverstein et al 1969) point out that, in cats, even india ink or avian erythrocytes pass into the perilymphatic spaces via the cochlear canaliculus within 24 hours of their introduction into the subarachnoid space of the posterior cranial fossa. The latter authors regard perilymph as probably derived from: (1) blood vessels surrounding the spaces, (2) fluid spaces surrounding the sheaths of the vestibulocochlear nerve fibres and (3) cerebrospinal fluid arriving along the cochlear canaliculus. The mechanism of removal of perilymph is uncertain.

In summary, the organization of the perilymphatic spaces as follows: the vestibular perilymphatic space connects posteriorly with that around the semicircular canals and opens anteriorly into the cochlear scala vestibuli, which in turn opens into the scala tympani via the helicotrema; the latter scala is separated from the tympanic cavity by the secondary tympanic membrane but is continuous with the subarachnoid space through the cochlear canaliculus (vide supra).

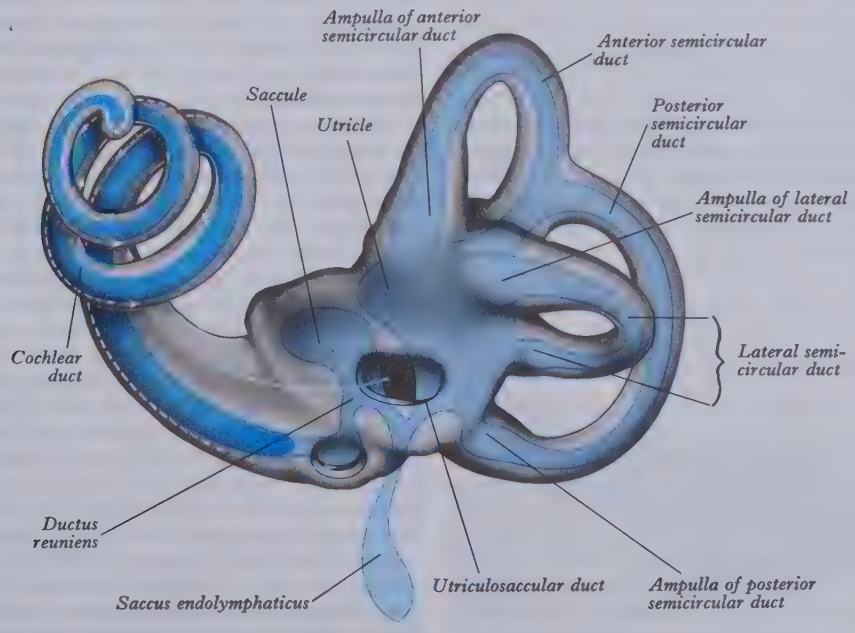
During development, the petrous bone adjoining the labyrinth is developed from the cartilaginous otic capsule by endochondral ossification; it is denser than petrous bone elsewhere, with interglobular spaces containing cartilage cells (7.356). The cochlear modiolus, however, is formed from trabecular dermal bone (Fraser & Dickie 1914).

The Membranous Labyrinth

The membranous labyrinth (7.355), lying within the osseous labyrinth, is much narrower and is filled with *endolymph*, a fluid of unique composition; in its walls the terminal fibres of the vestibulocochlear branches are distributed. It includes: (1) the *utricle* and *saccule*, two small sacs occupying the vestibule, (2) three *semicircular ducts* in the semicircular canals, (3) the *cochlear duct* in the osseous cochlea. These parts form a closed system of channels which communicate freely with one another. The semicircular ducts open into the utricle and this opens into the saccule via the ductus utriculosaccularis, which also joins the ductus endolymphaticus; the saccule opens into the cochlear duct through the ductus reuniens.

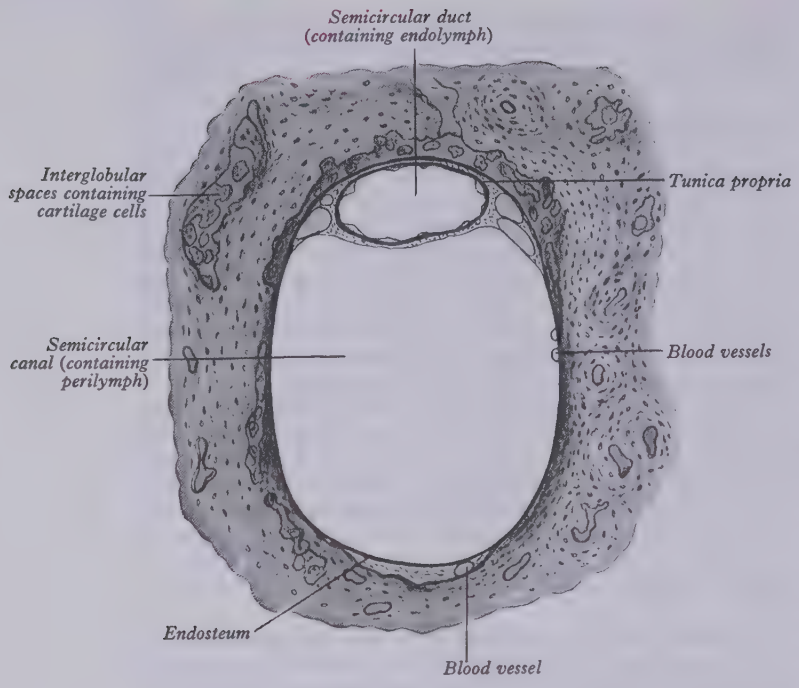
The membranous labyrinth is attached to the wall of the osseous labyrinth at certain points, but is separated from the greater part of it by a perilymphatic space. For the ultrastructure of the membranous labyrinth consult Wersall (1956), Engstrom & Wersall (1958), Iurato (1967), Kimura (1969), Babel et al (1970).

THE UTRICLE



The utricle, the larger of the vestibular sacs, is irregularly oblong and occupies the posterosuperior region of the osseous vestibule, in contact with the elliptical recess and the area inferior to it. The part of the utricle in the recess is a pouch or cul-de-sac. The lateral half of its floor and adjoining lateral wall is thickened over an area of about 3 mm by 2 mm as the *utricular macula* (p. 1232), innervated by the utricular fibres of the vestibular nerve. The ampullae of the anterior and lateral semicircular ducts open into its lateral part; the ampulla of the posterior duct, the crus commune and the posterior end of the lateral duct open into its medial part. The lateral duct's posterior end widens into a flattened cone joining the utricle's medial end at a right angle. From the anteromedial part of the saccule the *ductus utriculosaccularis* is given off and gives a side branch opening into the ductus endolymphaticus, the main duct passing on to the saccule.

THE SACCULE



The saccule lies in the spherical recess near the opening of the cochlear scala vestibuli. Viewed from the anterior aspect, it appears almost globular but it is prolonged postero-inferiorly as a cone, the upper surface of which is partly in contact with the under-surface of the utricle, both sharing a common wall. In the saccule's anterior wall is an oval thickening, the *macula of the saccule* (pp. 1232, 1233), in a plane set at right angles to the utricular macula and innervated by the saccular fibres of the vestibulocochlear nerve. Its cavity is connected via a Y-shaped tube with the utricle. The *ductus endolymphaticus* leaves it posteriorly to join the ductus utriculosaccularis, passing inferomedially along the vestibular aqueduct to end in the *saccus endolymphaticus* under the dura mater on the posterior surface of the petrous bone. From the saccule's lower part a short *ductus reuniens* passes inferiorly, widening into the basal end of the cochlear duct (7.355).

THE SEMICIRCULAR DUCTS

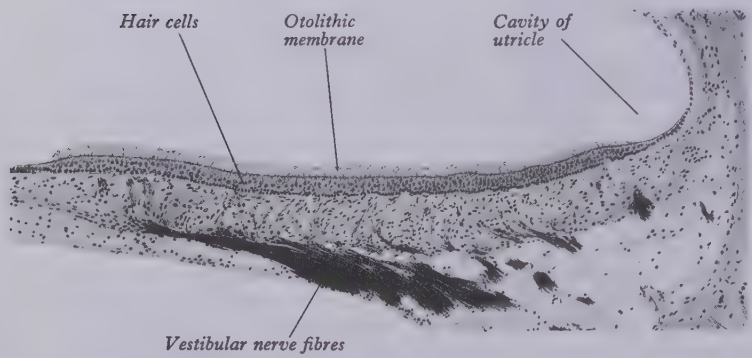
The semicircular ducts (7.355, 356) are about one-quarter of the diameter of their osseous canals but are similar in general shape.

7.355 Scheme of the membranous labyrinth (blue) projected on to the osseous labyrinth. The arrows indicate the direction of sound waves in the cochlea.

7.356 Transverse section through the left posterior semicircular canal and duct of an adult man (after J K Milne Dickie). Magnification × 50.

Each has an ampulla at one end within the ampulla of its bony canal. The semicircular ducts open into the utricle by five orifices, one being common to the medial end of the anterior and the superior end of the posterior duct. In each ampulla the wall is thickened, projecting inwards as a transverse elevation shaped like an hour glass, the *septum transversum*, its most prominent part being the *ampullary crest*; this projects from the ampullary wall most distant from the concavity of its duct, an arrangement by which 'any movement of endolymph would be caught by the crista to greatest advantage' (Dickie 1920).

The utricle, saccule and semicircular ducts are suspended by fibrocellular bands across the perilymphatic space which stretch from the osseous wall to the membranous labyrinth within; through much of the course of the semicircular ducts, the membranous duct is securely attached by much of its circumference to the osseous wall (7.356).



STRUCTURE OF THE UTRICLE, SACCULE AND SEMICIRCULAR DUCTS

The walls of the utricle, saccule and semicircular ducts are generally described as being trilaminar. The *external* layer is largely fibrous and vascular; its superficial fibres are often covered by flat perilymphatic cells and this outer surface sometimes blends with the labyrinthine periosteum. The *middle* layer, composed of more delicate vascular connective tissue, has on its internal surface, especially in the semicircular ducts, a number of papilliform projections. The *internal* layer is usually a simple epithelium varying from squamous to cuboidal or polygonal, with a basement membrane. The cells have a *specialized* arrangement in the ampullary crests and maculae (7.357, 358); here the middle layer is also thicker. Flanking each crest, between it and the ampullary wall, is an area of tall epithelium, which appears crescentic in section, known as the *planum semilunatum*.

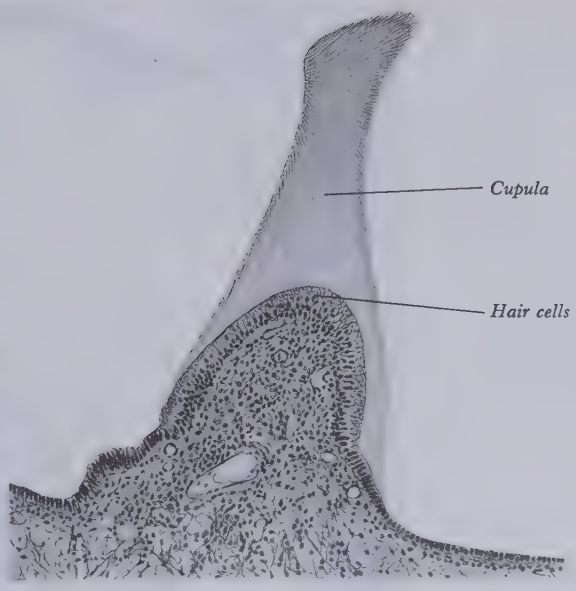
In the so-called 'non-specialized' areas of the membranous labyrinth, the general epithelium (whose cells vary from squamous to tall columnar) shows ultrastructurally (Kimura 1969) *light* and *dark* cells which are quite dissimilar in their cytology. In many regions the epithelium resembles simple non-secretory epithelia elsewhere. The *light cells* of such areas contain elliptical or crenated heterochromatic nuclei, few mitochondria, occasional ribosomes and micropinocytotic vesicles and show a few microvilli on their luminal aspect. Junctional complexes occur near their luminal borders, with some interdigitation of the cell surfaces. Infolding of the basal plasma membrane is minimal. In contrast, some patches or strips of epithelium in the utricle and the semicircular ducts, including the ampullae, consist of *dark cells*. Their luminal surfaces carry occasional microvilli and show endocytic vesicles; junctional complexes and interdigitations occur; their irregular nuclei are central or near the luminal surface; their dense supranuclear cytoplasm contains: numerous coated vesicles, larger smooth-walled vesicles and mitochondria, free and attached polysomes, lipid droplets, lysosomes, lipofuscin granules, microfilaments and microtubules and an obvious Golgi apparatus. The infranuclear region consists of many long cytoplasmic processes projecting towards the basal lamina. Each process has an elongate, fusiform enlargement, completely occupied by a mitochondrion. The plasma membrane of these processes is covered by basal lamina. Such cells are obviously highly active and their structural similarity to cells in other ion-transporting epithelia (e.g. renal tubules, p. 1401, the ciliary body of the eye, parotid duct, salt-secreting glands of various submammalian forms) suggests an involvement in the control of the ionic composition of endolymph (vide infra).

In *ampullary crests* the epithelium contains sensory *hair cells* and *supporting cells*. **Hair cells** are of two types. *Type I* is piriform with a rounded base and a short neck. Except at its free end it is surrounded by a large goblet-shaped nerve terminal or *calix*, the apposed plasma membranes being separated by a gap of about 20–30 nm but at some points the interval is about 5 nm. The nucleus is basal and surrounded by mitochondria, with a concentration of these organelles near the free surface of the cell. Occasional cisternae of granular endoplasmic reticulum, free polysomes, microfilaments and microtubules, many smooth vesicles of about 20 nm and supranuclear Golgi apparatus all occur. The *type II* hair cell is cylindrical, its nucleus lying at various levels but usually more central than in type I cells. Its cytoplasm contains similar organelles, but the smooth-walled vesicles are more abundant and a supranuclear Golgi apparatus more prominent. The basal part of type II cells is in contact with a number of synaptic end-bulbs, of two varieties, both containing mitochondria and many small vesicles; in *non-granulated terminals* the vesicles are clear, in *granulated endings* they contain electron-dense cores. Non-granular terminals are *afferent* nerve fibres; granular terminals are regarded as rami of *efferent* fibres innervating type II hair cells, probably modifying the effective threshold of the hair cells. Thus, both types of terminal are probably the sites of neurochemical transmission, but are oppositely directed. However, the details remain uncertain. The calix of type I hair cells is regarded as the terminal of an afferent vestibular fibre but whether it is neurochemical or 'electrical' is still to be determined. A number of granular end-bulbs are often applied to the external calicial aspect and these are probably *efferent*, presynaptically modifying transmission by the calix.

Type I hair cells may be regarded as the more 'discriminative' of the two types. Calices are derived from larger and therefore faster vestibular nerve fibres, each innervating a small group of type I cells. But type II cells contact the end-bulbs from several

7.357 Section of the macula of the utricle of the cat. Weigert–Pal and iron haematoxylin stain. (For source see 7.358.) Magnification × 112.

thin vestibular nerve fibres, each innervating many type II cells, distributed over a substantial area of membrane.



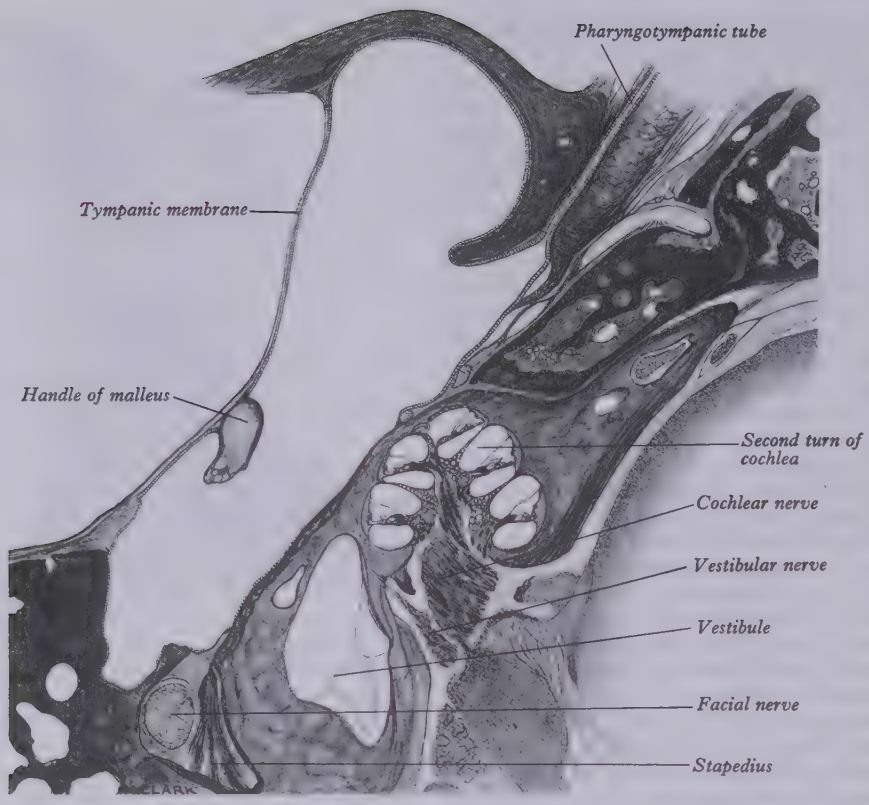
The apical surfaces of both types are similar, carrying 40–100 'hairs', stereocilia or modified microvilli of varying length and arranged in a regular hexagonal array and polarized with respect to a long *kinocilium* attached to one border of the cell. This kinocilium has a typical basal body within the cell's apical cytoplasm and its shaft contains a ring of nine double microtubules, but the central pair (as in most cilia) is sometimes absent. Despite its name, its motility is uncertain. The stereocilia are non-motile, constricted at their attachment to the hair cell; each contains a longitudinal array of microfilaments. On cell borders opposite the kinocilium, stereocilia are about 1 μm in length but lengthen towards the cilium, reaching about 100 μm close to it. Stereocilia are also interconnected by lateral links which probably ensure that they move together as a unit when deflected during stimulation (Ernstrom 1985).

In each vestibular receptor site the hair cells are arranged in a *precise pattern* of considerable functional significance (vide infra). In the ampullae of the lateral semicircular ducts, the sides of hair cells with a kinocilium are all directed towards the utricular cavity, but in the ampullae of the anterior and posterior ducts they are directed away from it. In the two maculae there is a sinuous '*parting line*' across the central region; structural polarization of the hair cells is reversed on the opposite sides of this line. In the utricle, hair cells are set in curved contours, with the kinocilium of each cell *nearer* to the parting line but in the saccule *remote* from it. For details of the orientation of these arrays consult Iurato (1967), Babel et al (1970), Ades & Engstrom (1974).

The supporting cells are elongate and of variable diameter; each has a basally positioned nucleus and rests on the basal lamina of the epithelium. They have microvilli; their cytoplasm contains large osmiophilic granules, possibly secretory, a well developed Golgi apparatus and vertical microtubules and microfilaments entering a prominent subapical terminal web; mitochondria are abundant. Whether these cells are mainly nutritive or modify the composition of the endolymph remains uncertain. Junctional complexes exist around the subapical parts of the hair and supporting cells; in the ampullae, the processes of both project into a dome-shaped gelatinous protein-polysaccharide mass, the cupula; its precise composition is as yet undetermined. The cupular apex almost reaches the opposite ampullary wall but can swing in response to currents in the endolymph. When the current ceases, its elastic recoil returns the cupula to the intermediate vertical position, but it may overshoot and oscillate before coming to rest.

Epithelial cells of the *planum semilunatum* (Iurato 1967) lie adjacent to the crista on one side and gradually change to ampullary cuboidal epithelium on the other; they have a few microvilli, containing basally abundant parallel, smooth-walled double membranes, arranged perpendicular to the basement membrane. The basal plasma membrane has invaginations ending in vesicular enlargements in the cytoplasm. Between the folds are vesicles and mitochondria in lines. The nucleus is apical with abundant mitochondria, endoplasmic reticulum, well developed Golgi apparatus, polyribosomes and vesicles, some containing granules. In these features the cells of the planum resemble *dark cells* (vide supra) elsewhere in the labyrinth (vide supra). The planum semilunatum may secrete endolymph. *Supporting* and *hair cells* of the *utricular* and *saccular maculae* are like those in the ampullary crests; but the gelatinous mass into which their stereocilia and kinocilia are inserted is the flatter *otolithic membrane* (*membrana statoconiorum*), containing many minute crystalline *otoliths*, *otoconia* or *stataconia*, which consist of calcite (Carlström et al 1953) and associated protein, giving the maculae an opaque white appearance.

The ampullary crests and the maculae are concerned with equilibratory reflexes influencing ocular position relative to *movements* of the head, by vestibular connections via the medial longitudinal fasciculus (p. 985) with the nuclei of the third to sixth cranial nerves and affecting cervical movements through the descending fibres of the same fasciculus (p. 986). They also influence the general body musculature through the vestibulospinal tracts (p. 932) and other central pathways. (For central vestibular and cerebellar connections see pp. 957, 966, 967, 975.) Muscle activity is also influenced by the *position* of the head; macular otoliths, under the influence of gravity, pull on the apical processes of the hair cells in varying positions and are therefore referred to as organs of *static balance* (*statotonic reflexes*); ampullary crests are organs of *kinetic balance*, stimulated by movement or pressure changes in the endolymph due to *angular accelerations* of the head (*statokinetic reflexes*), producing deviation of cupulae. But the maculae may also be involved in *linear acceleration*. The terms static and kinetic are hence not wholly appropriate. The saccular macula, though histologically the same as the utricular, is believed by some to be concerned not in vestibular reflexes but with the cochlea in the reception of low frequency sound.



7.358 Section of an ampullary crest of a six-month-old human fetus. Stained with haematoxylin and eosin. From a section lent by E W Walls, Professor Emeritus, Middlesex Hospital Medical School, University of London. Magnification × 75.

How deformation of the stereocilia by the movement of the cupulae or otoliths alters the ionic conductance of hair cell membranes is uncertain. Electrophysiological recordings suggest that most vestibular nerve fibres show a continuous basal discharge of afferent impulses when the hair cells are not stimulated. Bending the stereocilia towards the kinocilium raises this frequency and bending in the opposite direction lowers it. Head position, or linear or angular acceleration, is signalled by the balance or imbalance in the patterns of impulses from pairs of receptor sites in the membranous labyrinths of the two sides; e.g. a horizontal swing to the right raises the discharge rate from the ampulla of the right lateral semicircular duct but decreases it in the left. The inertia of the endolymph gives it relative movement to the left in both labyrinths. The positions of the ampullary kinocilia and stereocilia result in compression on the right and decompression on the left ampulla of any bilateral pair of semicircular ducts. (For further discussion see Fischer 1956.)

THE ENDOLYMPHATIC DUCT AND SAC

Throughout the whole endolymphatic duct the surface cells resemble those lining the non-specialized parts of the membranous labyrinth. Where the saccus endolymphaticus expands under the dura mater it is surrounded by a well-vascularized connective tissue, its epithelium changing to tall columnar cells consisting of two main types: one with dense cytoplasm, but otherwise unspecialized; the other less dense, with abundant long microvilli on its luminal surface, its cytoplasm containing numerous mitochondria, pinocytotic invaginations and vesicles and larger smooth-walled vacuoles.

The endolymph filling the membranous labyrinth contrasts in its composition with the perilymph outside it, the latter being

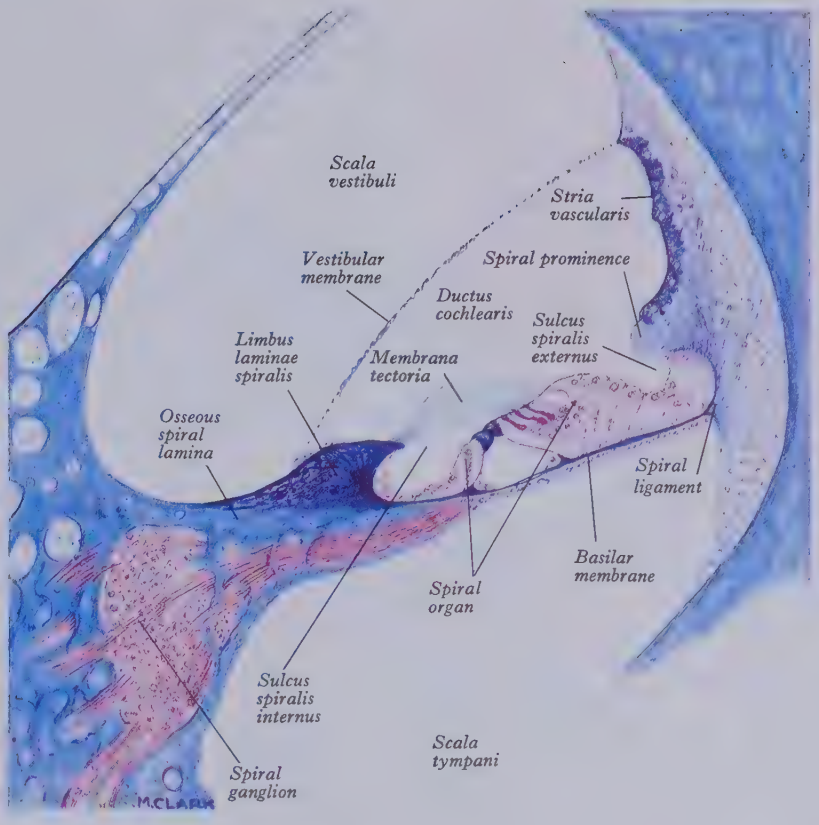
7.359 Horizontal section through the left temporal bone. Drawn from a section prepared at the Ferens Institute and lent by the late J Kirk.

comparable to extracellular tissue fluid or cerebrospinal fluid, while endolymph resembles intracellular fluid in its ionic composition, being rich in potassium and poor in sodium ions. It is accepted that endolymph is a secretion from a source still unknown. Structures involved in its production may include the *dark cells* of the utricle and semicircular ducts, the columnar cells of the *planum semilunatum* and specialized epithelial cells and related blood vessels of the *stria vascularis* of the cochlear duct (vide infra). Whatever their relative contributions, endolymph probably circulates in the labyrinth, entering the ductus endolymphaticus for removal by the specialized epithelium of its sac into the adjacent vascular plexus. Pinocytotic removal of fluid may also occur in other labyrinthine regions.

A unique positive electrical potential exists in the endolymphatic spaces, varying from +77 millivolts in the cochlear duct near the stria vascularis to about +44 millivolts in the utricle, while it is absent or even negative in the ampullae. Thus, a difference of as much as 150 millivolts exists across the membranes of cochlear hair cells, between the cochlear endolymph and the cell interior. This may assist in creating the extreme sensitivity to mechanical deformation found in *auditory* hair cells (vide infra).

THE COCHLEAR DUCT

The cochlear duct (7.359, 360) is a spiral tube running along the outer wall of the osseous cochlea. The osseous spiral lamina (p. 1230) projects for only part of the distance between the modiolus and the outer cochlear wall, the *basilar membrane* completing the roof of the scala tympani. The endosteum of the outer wall is thickened into a *spiral cochlear ligament* projecting inwards and attached to the outer edge of the basilar membrane. A second, thinner *vestibular membrane* (*Reissner's membrane*) extends from the thickened endosteum on the osseous spiral lamina to the outer wall, attached well above the outer edge of the basilar membrane. The canal thus enclosed, between the scala tympani below and the scala vestibuli above, is the *cochlear duct* (7.360). It is triangular in section, its roof the vestibular membrane, its outer wall the endosteum, its floor the basilar membrane and the outer part of the osseous spiral lamina. Its closed upper end, the *lagaena*, is attached to the cupola (p. 1230). The duct's lower end turns medially, narrowing into the *ductus reuniens*, to connect with the saccule (7.355). The spiral organ (of Corti), comprising the sensory area of the cochlea, is set on the basilar membrane. The thin vestibular membrane is covered on both surfaces by flat epithelium. The endosteum of the outer wall is greatly thickened to form a *spiral ligament*, which projects inferiorly as a triangular *crista basilaris*, to which the rim of the basilar membrane is attached; immediately above this is a concavity, the *sulcus spiralis externus*, above which the thick, highly vascular periosteum projects as a *spiral prominence*, above which again is a specialized, thick epithelial layer, the *stria vascularis*. (For ultrastructural details see Babel et al 1970.)



THE VESTIBULAR MEMBRANE

The vestibular membrane (of Reissner) has two layers of squamous epithelial cells separated by a basal lamina. The aspect facing the scala vestibuli bears perilymphatic cells, thick in their central perinuclear zone but elsewhere extremely thin; zonulae occludentes occur between them, creating a diffusion barrier. The endolymphatic aspect has typical squamous epithelial cells, also joined by zonulae occludentes and containing mitochondria and many vesicles; their basal surfaces are sometimes smooth but often complexly invaginated; the surface carries numerous, short, irregular microvilli. These cells may be involved in fluid transport.

THE STRIA VASCULARIS

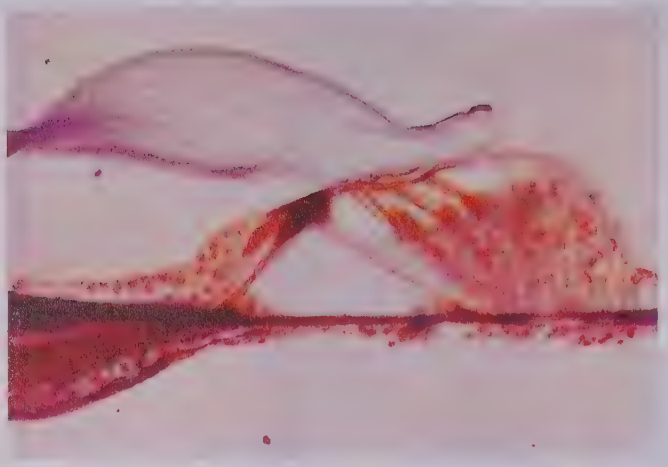
As noted above this is on the cochlear duct's outer wall above the spiral eminence. It has a special stratified epithelium continuing a dense *intra-epithelial capillary plexus* and three cell types: (1) superficial *marginal*, *dark* or *chromophil cells*, (2) *intermediate*, *light*, or *chromophobe cells*, (3) *basal cells*.

The endolymphatic surface contains only dark cells; the intermediate and basal cells are cytologically similar, differing in their

7.360 Section through the second turn of the cochlea indicated in the previous figure. The modiolus is to the left. Mallory's stain.

position, their pale cytoplasm containing scattered mitochondria, many endocytic vesicles and some melanin granules; they send cytoplasmic processes towards the surface, insinuated between the deeper parts of the marginal cells. Marginal dark cells have dense granular cytoplasm with many mitochondria and endocytic vesicles. Their deep parts consist of long cytoplasmic processes separated by deep invaginations of plasmalemma, each containing many mitochondria. Intra-epithelial capillaries are enveloped by the descending processes of dark cells and ascending processes from intermediate and basal cells. The stria vascularis is considered to be ion-transporting, assisting to maintain the unusual ionic composition of endolymph. But other regions of the membranous labyrinth may also be involved in this activity. Exploration of the stria by micro-electrodes shows it to be the source of the large positive endocochlear electrical potential, the maintenance of which is directly dependent upon adequate oxygenation of the epithelial cells, provided by the intra-epithelial capillary plexus.

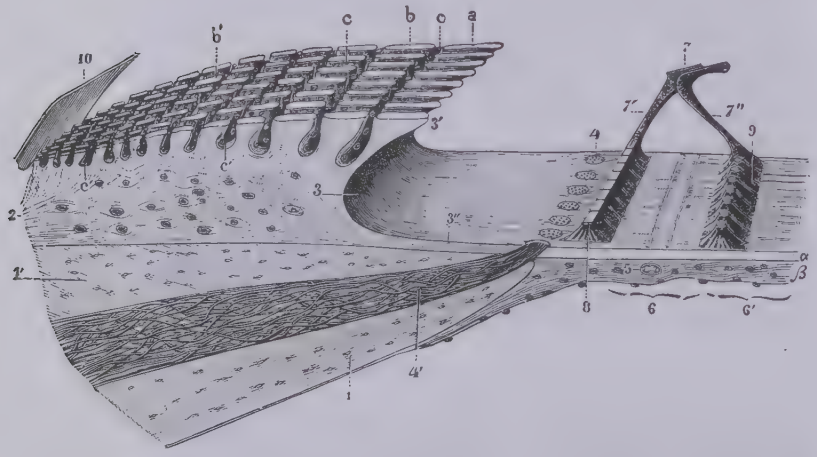
THE OSSEOUS SPIRAL LAMINA



This consists of two plates of bone, between which are canals for the cochlear nerve filaments. On the upper plate, within the duct of the cochlea, the periosteum is thickened as the *limbus laminae spiralis* (7.360, 362), ending externally in the *sulcus spiralis internus*, which in section is shaped like a C; its upper part, the overhanging limbic edge, is the *vestibular labium* and the lower tapering part is the *tympanic labium*, perforated by foramina for branches of the cochlear nerve. The upper surface of the vestibular labium is crossed at right angles by furrows, separated by numerous elevations, the *auditory teeth* (*dentes acoustici*) (7.362). The limbus is covered by a layer appearing superficially as squamous epithelium, but only the cells over the 'teeth' are flat, those in the furrows (7.363) being columnar (*interdental cells*) and occupying the intervals between the elevations. This epithelium is continuous with that in the sulcus spiralis internus and on the inferior surface of the vestibular membrane. It is considered by some that during development the interdental cells secrete material forming the tectorial membrane (vide infra).

THE BASILAR MEMBRANE

This stretches from the tympanic lip of the osseous spiral lamina to the crista basilaris (7.360, 362). It consists of two zones, a thin *zona arcuata* stretching from the limbus spiralis to the bases of the outer rods and supporting the organ of Corti, and an outer thicker *zona pectinata*, commencing beneath the bases of the outer rods and attached laterally to the crista basilaris. The zona arcuata is composed of compact bundles of small collagenoid filaments 8–10 nm in diameter, mainly radial in orientation. In the zona pectinata the basilar membrane is trilaminar, its upper layer a homogeneous network of transverse fibres, the lower composed of compact bundles of longitudinal fibres with an intermediate structureless layer containing few cells. At its attachment to the crista basilaris the upper and lower layers fuse. The length of the basilar membrane is about 35 mm; its width *increases* from 0·21 mm basally to 0·36 mm at its apex, accompanied by corresponding narrowing of the osseous spiral lamina and a decrease in the thickness of the crista basilaris. Its inferior surface is covered by a layer of vascular connective tissue and elongated perilymphatic cells; one vessel is larger and termed the *vas spirale*; it lies immediately below the tunnel of Corti (*cuniculum internum*).



THE SPIRAL ORGAN OF CORTI

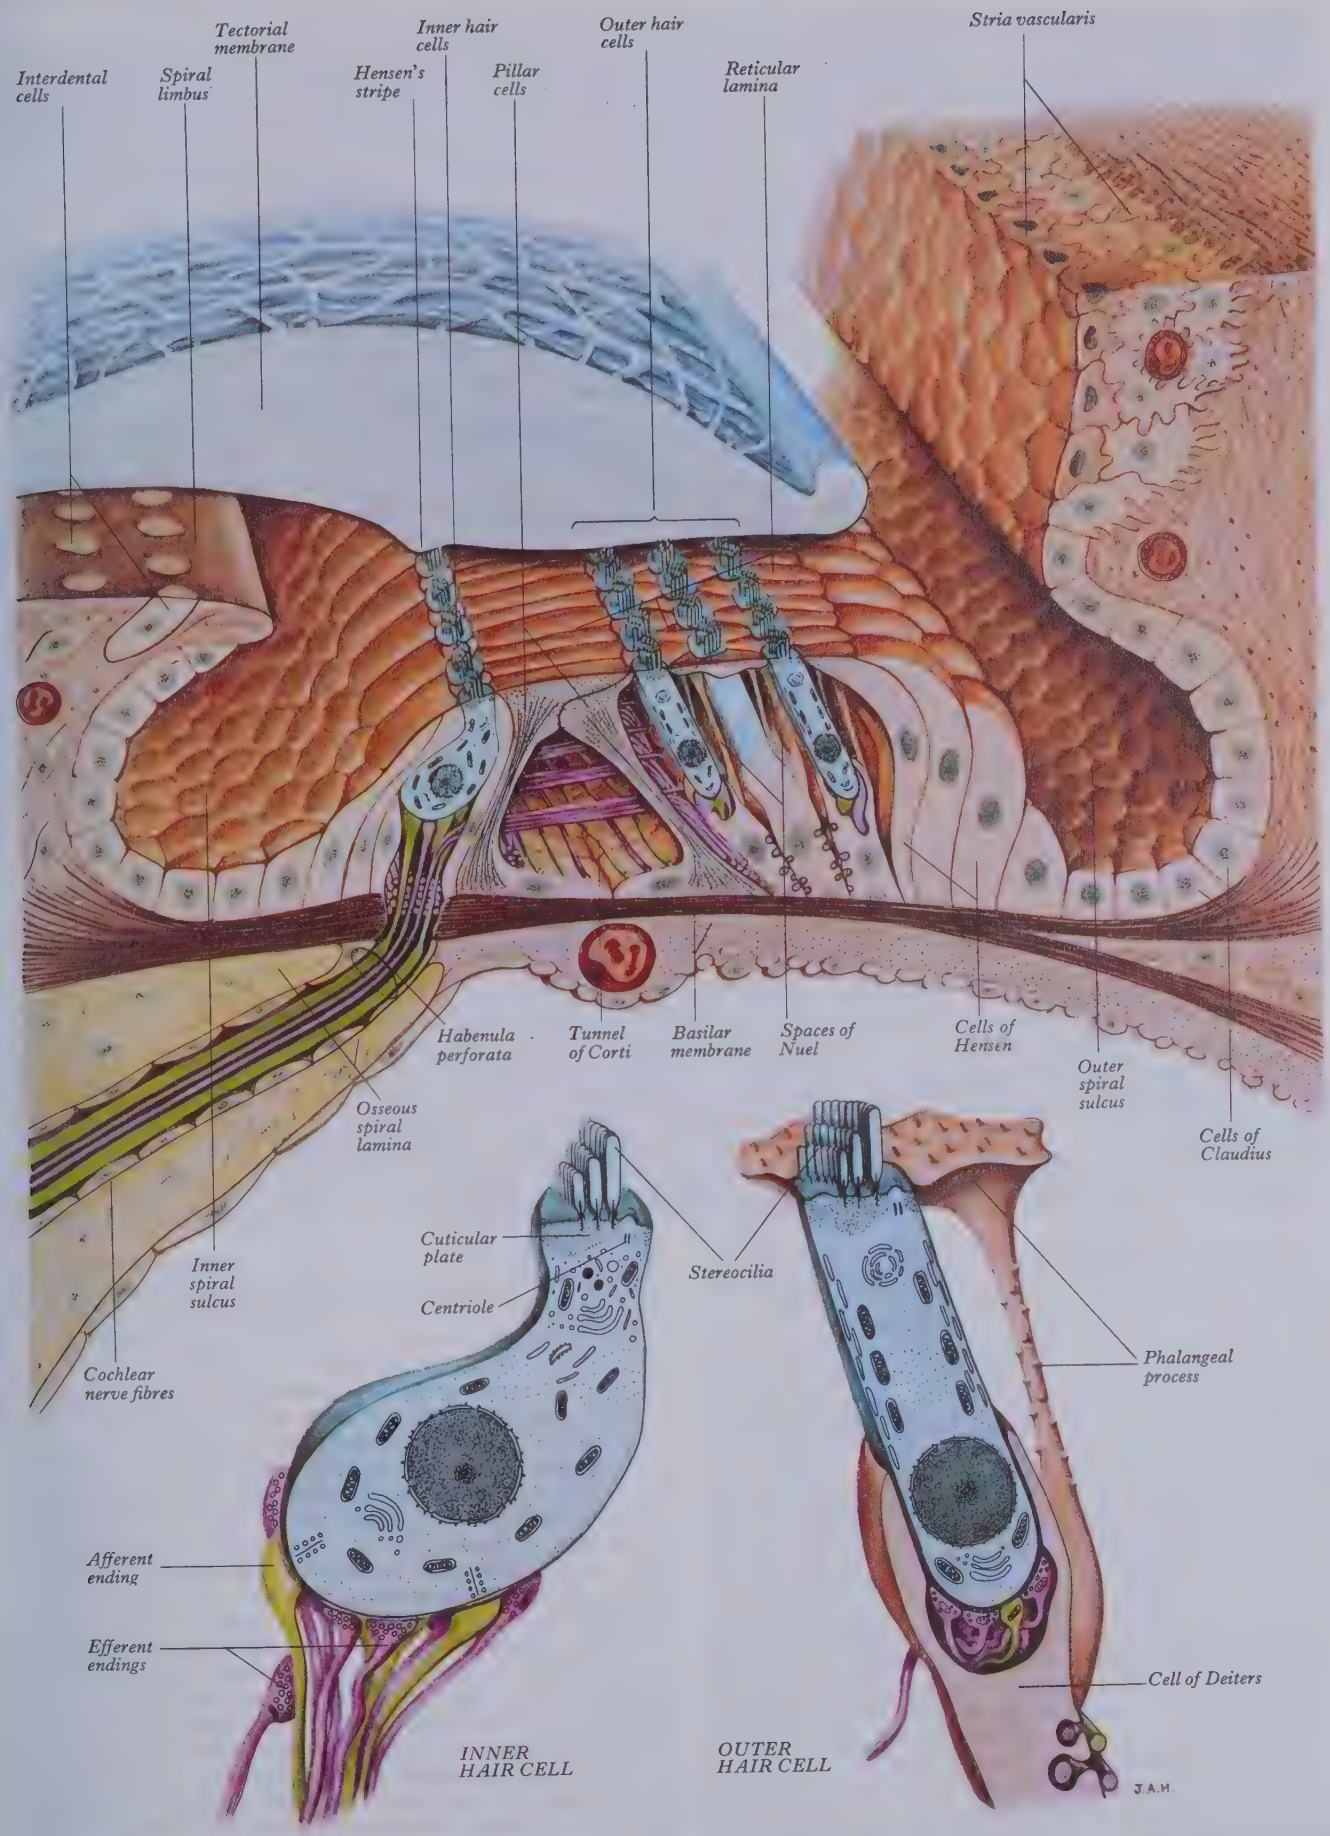
The spiral organ (of Corti) (Smith & Dempsey 1957, Engström & Wersall 1958, Babel et al 1970, Ades & Engström 1974) consists of a series of epithelial structures lying on the zona arcuata of the basilar membrane (7.360–365). The more central of these structures are two rows of cells, the *internal and external rod cells* (*of Corti*) or *pillar cells*. The bases or *foot plates* (*crura*) of the rod cells are expanded, resting contiguously on the basilar membrane but apically widely separated; the two rows incline to each other and come into contact above at the *heads of the pillars*, enclosing between them and the basilar membrane is the *cuniculum internum* (tunnel of Corti) (7.363), which has a triangular cross-section. Internal to the inner rods is a single row of *inner hair cells* and external to the outer rods three or four rows of *outer hair cells*,

7.361 Transverse section of the spiral organ of Corti (cat), stained with the Mallory trichrome method to show the inner and outer hair cells (orange), the basilar membrane (dark blue) and tectorial membrane (light blue) and various supporting cells, including those surrounding the tunnel of Corti. Magnification × 400.

with supporting cells, *phalangeal cells (of Deiters)* and cellulae limitans externae (cells of Hensen). The free ends of the external hair cells and apical processes of phalangeal cells form a regular mosaic termed collectively the *reticular lamina* or *membrane* (Engström et al 1966). The organ is covered by the *tectorial membrane*, a shelf of stiff gelatinous proteinaceous material; a narrow gap separates this from the reticular lamina except where the apical stereocilia of the external hair cells project to make contact with it. In addition to the *inner tunnel* (*cuniculum internum* or tunnel of Corti), other intercommunicating spaces exist around the outer hair cells also connected with the inner tunnel, including an *outer tunnel* (*cuniculum externum*) between the outermost hair cells and inner cells (of Hensen), under the reticular lamina, and also a cuniculum medium (space of Nuel) between the outer pillar (of Corti) and the external hair cells. The latter tunnel is continuous with the extracellular spaces around the apical two-thirds of the external hair cells. This complex of intercommunicating spaces is filled with perilymph which diffuses into it through the matrix of the basilar membrane. The fluid in these spaces is also sometimes called the *cortilymph* and it is possible that minor alterations in perilymphatic composition occur within it, as it is exposed to the activities of synaptic endings and specialized excitable cells.

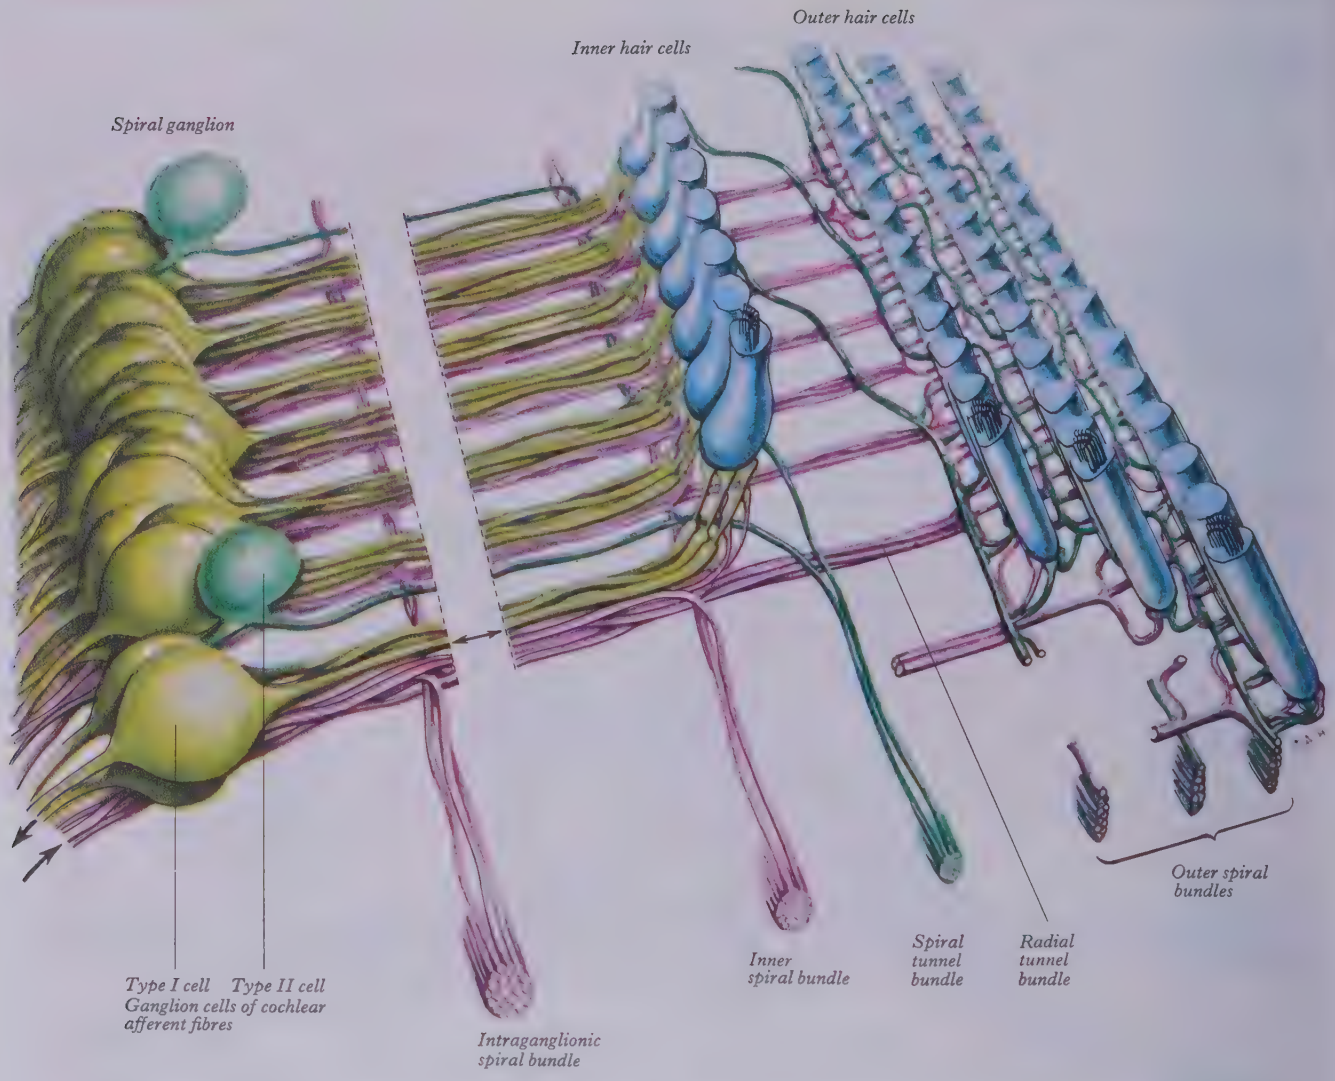
7.362 The limbus laminae spiralis and the basilar membrane (schematic, after Testut). 1, 1′. Lower and upper lamellae of the lamina spiralis ossea. 2. Limbus laminae spiralis, with a, the auditory teeth of the first row; b, b′, the teeth of the other rows; c, c′, the grooves between the auditory teeth and the cells which are lodged in them. 3. Sulcus spiralis internus, with 3′, its labium vestibulare, and 3″, its labium tympanicum. 4. Foramina nervosa, giving passage to the nerves from the spiral ganglion. 5. Vas spirale. 6. Zona arcuata, 6′. zona pectinata of the basilar membrane, with α, its hyaline layer, β, its connective tissue layer. 7. Summit of the tunnel of Corti, with 7′, its inner rod, and 7″, its outer rod. 8. Bases of the inner rods, from which the cells are removed. 9. Bases of the outer rod. 10. Part of the vestibular membrane.

The pillar cells (rods of Corti) have a base or *crus*, an elongated *scapus* (rod) and an upper end or *caput*; each crus and caput are in contact but the scapi are separated by the inner (Corti's) tunnel. The nucleus is in the triangular crus of each cell. The scapus is finely striated but an oval non-striated part of the caput stains deeply with carmine. Electron microscopy shows many microtubules 30 nm in diameter, arranged in linked parallel bundles of 2000 or more in the scapus and diverging above to terminate in superficial dense granular cytoplasm, the *cuticle*, in the head. Microtubules start in a wide area of limiting membrane in dense cytoplasmic material in the crus. In the body transverse sections show microtubules often arranged in a rectangular lattice with adjacent individuals linked to actin filaments lying parallel to them; many of them curve into the reticular lamina (vide infra) to end near the junctional complexes, with similar expansions from phalangeal cells (supporting cells of Deiters) and the subapical lateral surfaces of outer hair cells. Although the 'rod', as originally interpreted, corresponds only to the cytoskeletal structures and adjacent cytoplasmic densities, this term has now come to include the whole cell which forms these organelles. Their nuclei are situated in the foot-like expansion resting on the basal lamina.



Internal pillar cells (rods) number almost 6000, their bases resting on the basilar membrane near the tympanic lip of the sulcus spiralis internus. Their bodies form an angle of about 60° with the basilar membrane, their heads resembling the ulna's proximal end, with deep concavities for the heads of the outer pillar cells. Their heads overhang those of the latter.

External pillar cells (*rods*), almost 4000 in number, are longer and more oblique, forming with the basilar membrane an angle of only 40°. Their heads, convex internally, fit into the concavities on the heads of the inner pillar cells and project externally as thin, *phalangeal processes*, which unite with the phalangeal processes of the phalangeal (Deiters') cells to form the *reticular lamina* or *membrane* (vide infra).

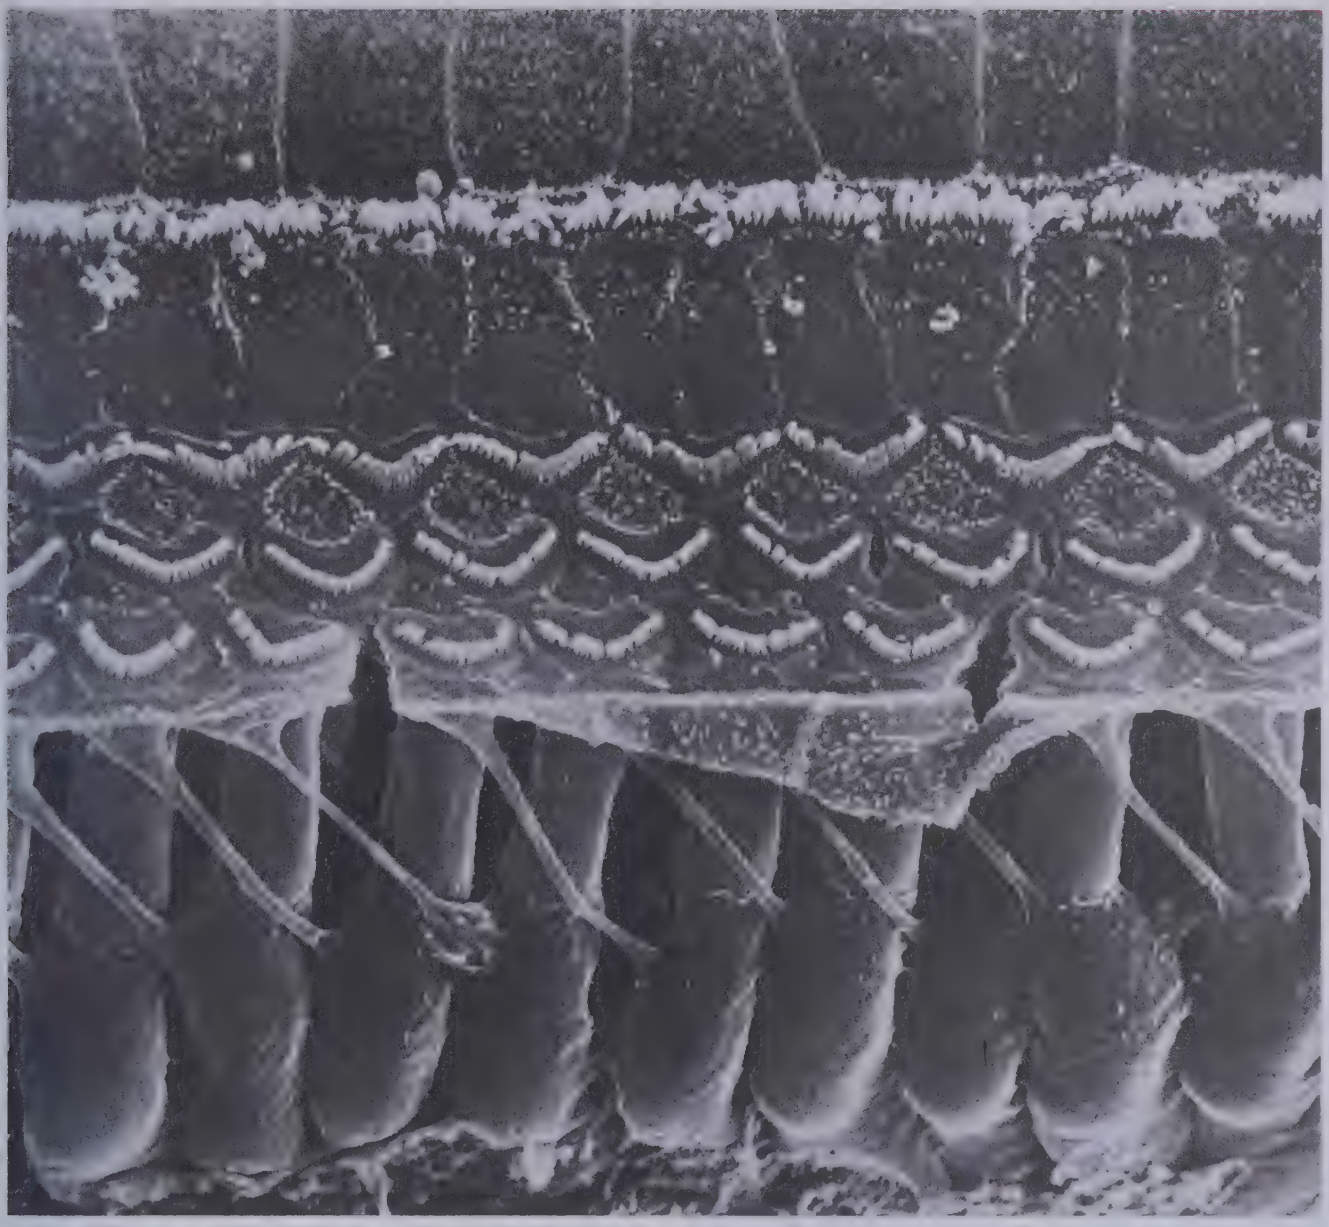


The distances between the bases of the internal and external pillar cells increase from the cochlear base to its apex but the angles between them and the basilar membrane diminish.

Hair cells (epitheliocyti pilosi) are columnar or slightly piriform, depending on their position in the cochlea. Their apices are level with the heads of the pillar cells, each surmounted by about 50–100 'hairs' or stereocilia. Their bases reach about halfway down the thickness of the spiral organ and each has a large, basally placed euchromatic nucleus. The basal plasma membrane forms synaptic contacts with the cochlear nerve fibres. They are arranged as inner and outer groups, tilted at an angle to each other and differing in detailed structure and innervation. *Inner* hair cells, about 3500 in number, form a single row internal to the inner pillar cells; since they exceed the rods in diameter, each inner hair cell contacts more than one. Their free (apical) ends are encircled by a cuticular membrane formed by surrounding supporting (inner phalangeal) cells, fixed to the heads of the inner pillar cells (vide infra). The neighbouring supporting cells continue towards the modiolus as columnar, then cuboidal cells lining the sulcus spiralis internus (*border cells*). The *outer hair cells* number about 12 000 and are nearly twice as tall as the internal. In the basal cochlea they are arranged in three regular rows, to which, in the human cochlea (although not in many other species), is added variably a fourth and sometimes a fifth, less regular in arrangement, near its apex.

Electron microscopy has shown much detail in cochlear hair cells and supporting structures (e.g. Babel et al 1970). **Inner hair cells** resemble type I vestibular hair cells (p. 1232); each has a short piriform body, the basal expansion containing a large euchromatic nucleus (7.363, 364), surmounted by a narrower apex which bears on its surface 50–60 stereocilia but no kinocilium. Cytoplasm contains an abundance of organelles, indicative of the high metabolic rate, including many mitochondria in the apical region, free polyribosome groups, agranular endoplasmic reticulum, various vesicles and lysosomes.

7.363 Three-dimensional schema of the structure of the cochlear spiral organ and stria vascularis, showing the arrangement of the various types of cell and their overall innervation. The organization of the inner and outer hair cells and their synaptic connections are depicted below. Sensory nerve terminals are coloured green and efferent fibres purple. See text for variant terminology.



7.364 The innervation of the spiral organ, showing the distribution of afferent and efferent fibres. The ganglion cells of the sensory nerve fibres include those related to the inner hair cells (dark green) and others innervating the outer hair cells (light green). Efferent fibres are depicted in purple. Note the great contrast between the multiple, convergent afferent innervation of the inner hair cells (about 10 fibres to each cell) and the divergent supply of the outer hair cells (one afferent fibre to about 10 cells).

Microtubules and microfilaments occur, especially in the basal cytoplasm. Under the apical surface a thick layer of filamentous, granular material, the *cuticular plate*, forms a continuous cap except at the apical region nearest the inner tunnel (of Corti) where a centriole is present. The plate is attached around its perimeter by intercellular junctions to the nearby phalangeal and pillar cells.

The sterocilia resemble those of the vestibular hair cells, being very narrow at their base but expanding to a cylindrical process maximally 6 μm long and 0·2 μm across. They are like other microvilli in being enclosed by an apical plasma membrane and they contain numerous longitudinal microfilaments of actin. However, internally they have a highly ordered structure (see e.g. Tilney 1985). Basally an additional dense central axial rootlet penetrates the cuticular plate as an anchorage. Stereocilia are able to yield, at these narrow basal ends, to fluid movements or other mechanical disturbances resulting from auditory stimuli (vide infra). Unlike the vestibular hair cells, a kinocilium is absent from mature cochlear hair cells, though it occurs in early development. In its place is a centriole beneath the apical membrane in the cuticle-free gap, probably a functionless remnant although possibly concerned with microtubule formation.

From the surface, groups of stereocilia appear arranged in a shallow U, its base towards the centriole and thus also the inner tunnel. Each stereocilial cluster has three or four rows, each successively taller towards the tunnel; the tallest may possibly touch the tectorial membrane. The basal plasma membrane synapses with two types of terminal bulbs derived from cochlear nerve fibres. (1) *Afferent* terminals contain few mitochondria or microtubules and clear vesicles of varying size. Both the presynaptic (hair cell) and postsynaptic bulbar membranes are thickened by cytoplasmic densities, the latter more so, and the presynaptic cytoplasm contains clear and dense-cored synaptic vesicles. *Accessory synaptic structures* are electron-dense rods, rings or lamellae around which synaptic vesicles cluster. (2) *Efferent* terminal bulbs contain more mitochondria, microtubules and abundant synaptic vesicles, most being small, spherical and clear but some larger, with dense cores. Although often described as synapsing with cell bases, efferent terminals are never seen to make such contacts in feline and infrequently in rodent and human material. More numerous are the contacts between efferent terminals and the lateral aspect of *afferent* bulbs. The efferent fibre presumably modifies transmission in the afferent fibre terminal. Inner hair cells are, apart from these synapses, wholly surrounded by the cytoplasm of internal phalangeal sustentocytes, whose superficial rims encircle the lateral margins of the apical surfaces of hair cells and form occluding junctions with them. Similar junctions exist between the outer aspect of the rim of phalangeal cells and expansions from the inner pillar cells. These specializations form the inner area of the 'cuticular membrane' of light microscopy.

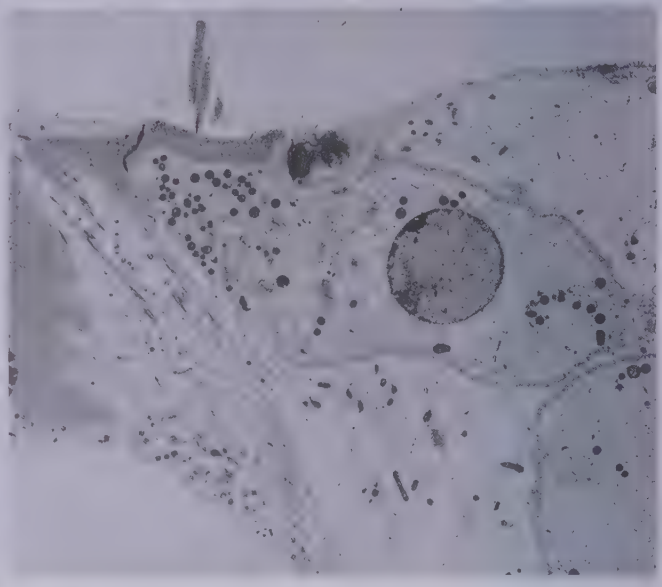
Outer hair cells are more specialized but have features in common with the inner type. They are longer, more cylindrical

7.365 Scanning electron micrograph of a portion of the spiral organ of Corti (guinea pig) dissected to expose the outer row of outer hair cells and their attendant Deiters' cells with narrow phalangeal processes. The apices of three rows of outer hair cells with their stereocilia are visible in the foreground and behind them are the apices of the rod cells and a row of inner hair cells and their stereocilia. Magnification × 2500.

and have a large basal euchromatic nucleus. Many mitochondria occur near their lateral plasma membranes and in the basal cytoplasm below the nucleus. Otherwise the cell has far fewer organelles than inner hair cells; most notable are the complexes of flat membranous cisternae attached by filaments to the lateral walls or, in the apical cytoplasm, taking the form of concentric whorls (Hensen bodies) and probably precursors of the cisternae. These membranes may help to retain the cell's cylindrical shape but may also be metabolic. Other inclusions are microtubules, microfilaments, polyribosomes, vesicles, lysosomes and glycogen; but most of the cytoplasm is a pale matrix containing fine filaments and granules of unknown composition. A cuticular plate, as in the internal hair cells, caps the cytoplasm and anchors the rootlets of sterocilia, which are arranged in the form of a V or W with its base away from the inner tunnel and towards a centriole in the apical cuticle-free gap. Up to 100 stereocilia have been counted in a single group, arrayed in ranks of graded length (7.365, 366); stereocilia in apical cochlea are taller than those in the basal parts of the cochlear coil but in all groups the longest stereocilia project into corresponding recesses in the tectorial membrane (Hunter-Duvar 1976). It is significant that both inner and outer hair cells are arranged on the basilar membrane with their centrioles remote from the modiolus (i.e. external), a point of functional interest, indicating a structural polarity which is related to the direction and phase of deformation occurring during auditory stimulation (vide infra). Stereocilia are linked laterally to each other by numerous extracellular filaments; of particular interest are thin strands connecting the apices of short stereocilia to the sides of taller ones ('tip links' Pickles et al 1983, Furness & Hackney 1985) which may be important in sensory transduction.

The base of each external hair cell is cupped in the apex of an external phalangeal cell, except at the synapses. But here afferent *and* efferent terminals, the latter being particularly numerous, are related directly to the plasma membrane of the hair cell (Engström et al 1965).

The external phalangeal cells (of Deiters) (7.363) lie between the rows of outer hair cells, their expanded bases lying on the basilar membrane and their apical ends partially enveloping the bases of hair cells with a finger-like *phalangeal process* extending up diagonally between the hair cells to the reticular membrane, there forming a plate-like expansion completing the gaps



7.366A Scanning electron micrograph of a group of outer hair cells arranged in three rows, showing the arrangement of their stereocilia and related phalangeal processes of the Deiters' cells, collectively forming the reticular lamina (see text). Short microvilli are visible on the surfaces of the non-sensory cells. Magnification × 3000.

between hair cell apices (vide infra). Their cytoplasm contains bundles of microtubules arising from the cell base and continuing up into the phalangeal process; other microtubules reinforce the cup supporting the base of the hair cell. External to them are five or six rows of columnar *supporting cells (of Hensen)* or *external limiting cells* (7.363), beyond which are the *external supporting cells* (of Claudius). Their surfaces bear microvilli. Near the lagaena they contain fat globules decreasing in number and size down the cochlear duct. Hallpike (1931) suggested that these provide a graduated load tuning the lagaena to low tones.

Near the base of the cochlea, another group of small cells is present among the bases of the phalangeal cells; these are termed Boetschli cells and their functions are unknown.

The reticular lamina (7.363), as seen by light microscopy, is a delicate framework perforated by circular holes occupied by the apices of outer hair cells, extending from the heads of the external rods to the outer row of outer hair cells and completed by several rows of minute cuticular *phalanges*. The innermost row of phalanges are the phalangeal processes of external rods. Ultrastructurally the reticular lamina consists of the horizontal expansions of the outer rods and phalangeal cells carrying bundles of microtubules in an attenuated film of dense cytoplasm. The expansions encircle the apical rims of the hair cells, where occluding zones and desmosomes are formed and the microtubules end. Between adjacent supporting cells are occluding junctions, most apically desmosomes and extensive gap junctions which couple them electrically. Under this delicate support the apical two-thirds of the lateral surfaces of the external hair cells are free and bathed by cortilymph (vide supra). The significance of this arrangement is twofold: the reticular lamina creates a highly impermeable barrier to the passage of ions except through cell membranes during sensory activity; it also forms a rigid support between the apices of the hair cells, coupling them mechanically to the movements of the underlying basilar membrane which causes lateral shearing movements between the cells and the overlying, static tectorial membrane.

7.367 Electron micrograph of an inner hair cell (guinea pig) showing the apical stereocilia with bases embedded in the dense cuticular plate. Note the centrally placed nucleus and numerous cytoplasmic organelles. The apex of a rod cell is visible on the left and below it the cavity of the tunnel of Corti. Magnification × 3000.

If hair cells are lost through trauma by sound or drugs, phalangeal processes rapidly fill the gap, disturbing the regular laminal pattern (*phalangeal scars*) but restoring its function.

The membrana tectoria (7.361, 363), overlying the sulcus spiralis internus and spiral organ, is composed of a stiff, gelatinous plate of proteinaceous composition and fine fibres invisibly embedded in a gelatinous matrix (Iurato 1967, Steel 1978). By electron microscopy filaments of 4 nm in diameter appear, consisting of a collagen-like protein and mucopolysaccharides. In transverse section it has a characteristic shape, the underside being nearly flat and the upper surface convex; it is thin on the modiolar side where it is attached to the vestibular lip of the limbus laminae spiralis, extending centrally as far as the vestibular membrane. Its outer part forms a thickened ridge,

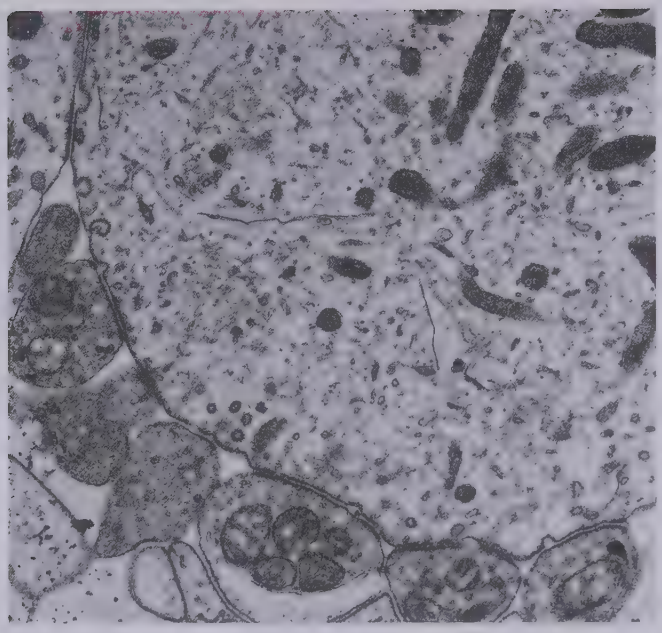
7.366B Scanning electron micrograph of the apices of two outer hair cells showing the different lengths of the stereocilia in the three ranks which constitute each group. Microvilli are also seen on the surface of the Deiters' cells (right). The innermost row of outer hair cells is shown; the tunnel of Corti, roofed by rod cell processes, is on the left. Magnification × 5000. Figs 7.365–369 supplied by Hilary C Dodson and 7.366A, B photographed by Michael Crowder, Guy's Hospital Medical School, London.

7.368 Scanning electron micrograph of the surface of Reissner's membrane, viewed from the cochlear duct aspect, showing the regular pattern of simple squamous epithelial cells. Magnification × 2500.

overhanging the edge of the reticular lamina. Scanning electron microscopy shows a network of fine ridges on the upper surface, the lower surface being relatively smooth, except where the stereocilia of the outer hair cells leave a pattern of W- or V-shaped impressions. Another feature, in some species, is a longitudinal ridge along its under surface near the inner tunnel, visible by light microscopy as *Hensen's stripe*. The *interdental cells* of the vestibular labium, to which the membrane is attached, have a well developed Golgi apparatus, many mitochondria and free polysomes; they may secrete the membrane. The lips of the stereocilia of the outer hair cells are embedded in the membrane but this attachment is often broken during histological preparation.

The vestibulocochlear nerve divides deep in the internal acoustic meatus into anterior *cochlear* and posterior *vestibular* components. (Their central connections are described on pp. 1111, 1112.)

The vestibular nerve supplies maculae of the utricle and saccule and the ampullae of the semicircular ducts. The *vestibular ganglion* (of Scarpa), from whose bipolar neurons the nerve fibres arise, lies in the trunk of the nerve in the internal meatus. Distal to the ganglion the nerve divides into superior, inferior and posterior vestibular rami. (It sometimes divides on the proximal side of the ganglion, in which case it is divided into three parts, one in each ramus; when this occurs, the posterior one is situated in the foramen singulare.) Filaments of the *superior ramus* traverse the foramina in the superior vestibular area, ending in the utricular macula and ampullary crests of the anterior and lateral semicircular ducts; those of the *inferior ramus* traverse the foramina in the inferior vestibular area, ending in the saccular macula; the *posterior ramus* traverses the foramen singulare, postero-inferior in the meatal fundus, dividing into filaments for the ampullary crest of the posterior semicircular duct.



The cochlear nerve divides into many filaments at the modiolar base; those for the basal and middle coils traverse the foramina in the tractus spiralis foraminosus and those for the apical coil traverse the central canal, bending out to pass between the lamellae of the osseous spiral lamina. The *spiral ganglion* (7.360), containing the cochlear bipolar neurons, occupies the spiral canal of the modiolus. Reaching the rim of the osseous spiral lamina, the nerve fibres lose their myelin sheaths and pass in bundles through minute foramina in the tympanic labium (*habenulae perforatae*); some fibres end around the bases of the inner hair cells, while others pass between the pillar cells across the inner tunnel to the outer hair cells; they pass between the phalangeal cells, often invaginated in grooves along their sides. The outer hair cells in the basal and middle coils are more richly innervated than those in the apical coil. A vestibular branch of the cochlear nerve supplies the vestibular end of the cochlear duct; filaments of this traverse the foramina in the cochlear recess (p. 1229).

The spiral ganglion neurons are of two types (Spoendlin 1974): type I are large, bipolar cells giving off a large myelinated axon from both poles of the cell, one central and the other peripheral in direction; type II neurons are smaller bipolar cells and have non-myelinated process, the centrally directed axon being particularly narrow. Experimental studies show that type I cells are exclusively afferent to the inner hair cells, 10 ganglion cells being connected to each sensory cell, whereas type II neurons are afferent only to outer hair cells, each supplying more than 10 of these by extensively branched terminals (Spoendlin 1978). There are also efferent nerve fibres within the cochlear nerve, belonging to the olivocochlear system described by Rasmussen (1946), which contains crossed and uncrossed components, the former from retrolateral olivary neurons and the latter from the S-shaped segment of the ipsilateral olivary complex (Whitfield 1967, Iurato 1974). The pathway is apparently purely inhibitory, probably altering the threshold levels of outer hair cells and modifying transmission via the postsynaptic action on the afferents from the inner hair cells. This system has been studied intensively in recent years, in different species, and it has been found that the inner and outer hair cells receive efferents from two distinctive components of the olivocochlear tract. The lateral olivocochlear tract arises mainly from the ipsilateral superior olivary complex and supplies the inner hair cells, while the medial tract, mainly crossed, innervates the outer hair cells. Different neurotransmitters occur in these two tracts.

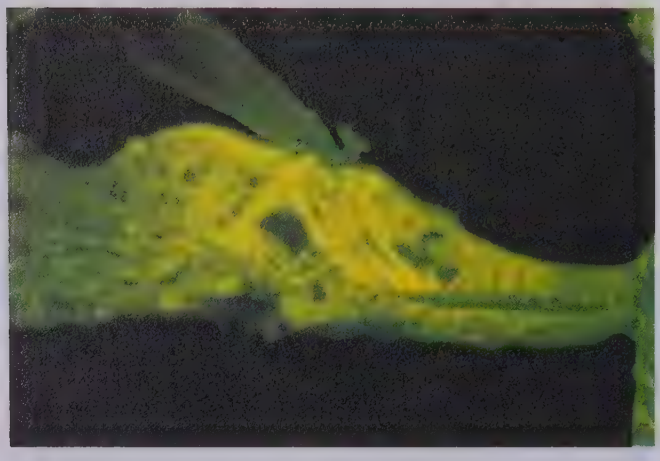
The distribution and courses of the nerve fibres to both groups of hair cells is known in some detail and has proved to be quite complex. Most cochlear fibres are distributed to the internal hair cells, each receiving the terminals of several radially disposed fibres, themselves the sites of synapses from collateral branches of radial inhibitory efferent fibres. Outer hair cells receive a minority of cochlear fibres; their efferent fibres are radial, each synapsing with many hair cells. Afferent fibres curve into a regularly organized spiral system, each fibre innervating numerous hair cells. These fibres form distinct groups with specific cochlear orientations and positions, either radial or spiral, i.e. parallel to the organ of Corti (Spoendlin 1974). Among the various cochlear cells is, firstly, the spiral intraganglionic bundle in the modiolus, consisting of non-myelinated fibres considered to be efferent axons; a similar group of efferent internal *spiral fibres* runs under the row of inner hair cells, traversed by groups of axons emerging from the habenulae. More peripherally, *spiral tunnel fibres* run along the inner canal in bundles or scattered. Individual fibres also run along spaces between the external pillar and the phalangeal cells in three rows, flanked and partially invaded by these supporting cells; these ranks are *external spiral fibres*, consisting of afferent and efferent connections of outer hair cells, as do the spiral tunnel fibres already mentioned. Autonomic endings have been observed but appear to be restricted to regions of the spiral organ on the modiolar side of the inner tunnel. Superimposed on this spiral pattern are the radial fibres afferent to the inner hair cells and, crossing in the tunnel, to outer hair cells. A detailed analysis of cochlear innervation is summarized in illustration 7.364.

The arteries of the labyrinth are: (1) the labyrinthine artery (p. 753), arising from the anterior inferior cerebellar artery or more often the basilar artery; (2) the stylomastoid branch of either the occipital artery or the posterior auricular artery (see p. 739). The labyrinthine artery divides at the bottom of the internal meatus into cochlear and vestibular rami. The cochlear ramus divides into 12–14 twigs, traversing the canals in the modiolus and distributed as a capillary plexus to the lamina spiralis and basilar membrane. Vestibular branches are distributed to the utricle, saccule and semicircular ducts.

The veins of the vestibule and semicircular canals accompany

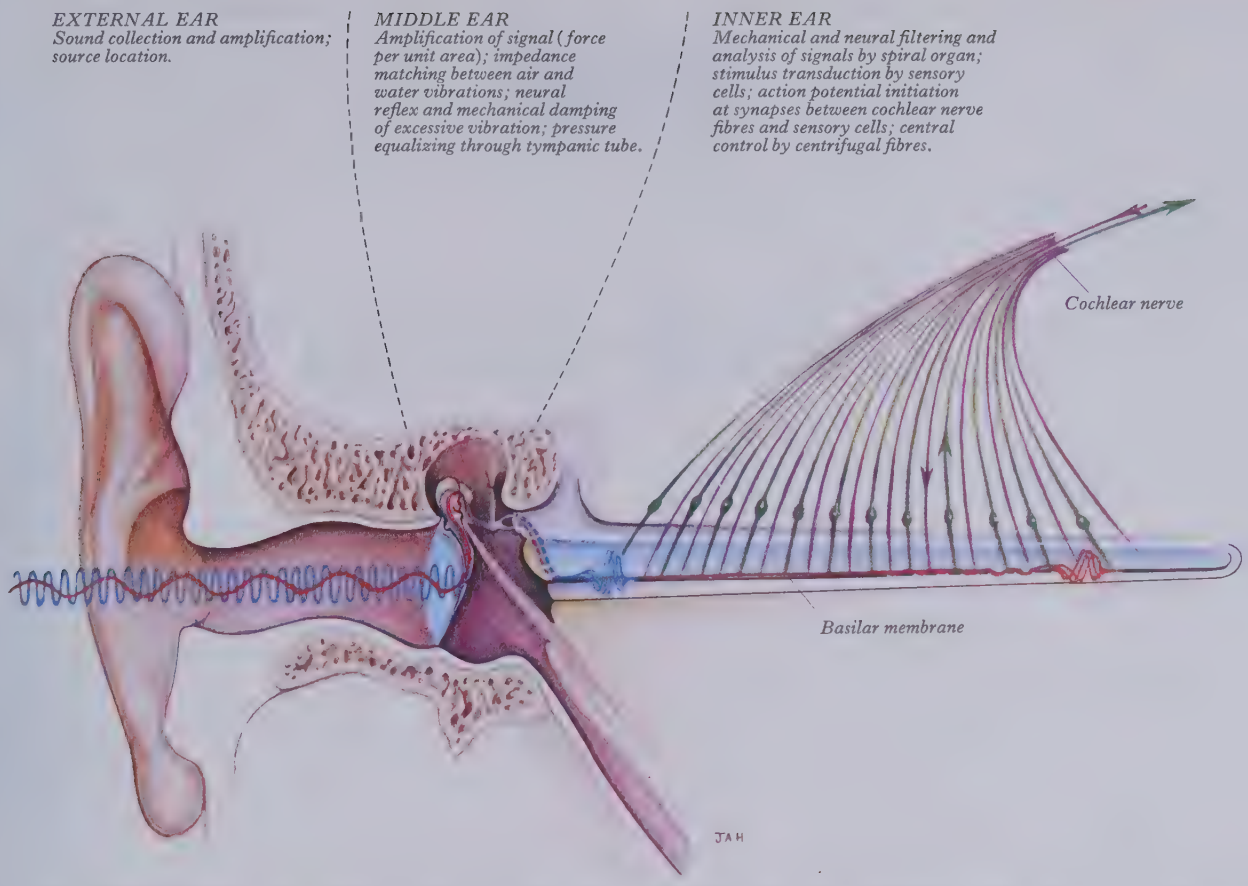
7.369A Electron micrograph of a group of efferent nerve endings at the base of an outer hair cell (guinea pig). Note the numerous mitochondria and vesicles within these endings and the cytoplasmic densities on both the pre- and postsynaptic membranes. Magnification × 10 000.

the arteries; receiving the cochlear veins at the base of the modiolus, they form the labyrinthine vein, ending in the posterior part of the superior petrosal sinus or in the transverse sinus. A small vessel from the basal cochlear turn traverses the cochlear canaliculus to join the internal jugular vein (see p. 795).



THE MECHANISM OF AUDITORY RECEPTION

Much research has been directed to the role of the different auditory components as analysers of sound intensity and frequency patterns and of the sources of the trains of sound waves impinging on them. Sound waves reaching the air column in the external acoustic meatus cause a comparable set of vibrations in the tympanic membrane and auditory ossicles. At the stapedial foot plate the force per unit area of the oscillating surface is increased 20 times. This overcomes the inertia of the perilymph, thus producing in it pressure waves which are conducted almost instantaneously to all parts of the basilar membrane. The latter varies continuously in width, mass and stiffness from the basal to the apical end of the cochlea; but its fibres are *not* under tension, as was once assumed. The behaviour of such a mechanical system as it reacts to periodic pressure waves in the perilymph varies with the frequency of the vibration. At very low frequencies, say 50 Hz, the whole membrane vibrates in phase at a similar frequency. As the frequency of the driving fluid pressure rises, different parts oscillate less rapidly and increasingly out of phase, from the basal to the apical end. *Travelling waves* hence progress along the membrane from the base to the apex. At intermediate frequencies, their *amplitude* rises slowly as they progress from the basal end to a maximum, after which the amplitude falls rapidly. With increasing frequency, the *locus* of *maximum amplitude* moves progressively from the apical to the basal end of the cochlea. Evidence for such a vibratory distribution in the basilar membrane comes from five main sources; (1) observation of the membrane excited in cadavers through drill holes in the cochlear bone, using stroboscopic illumination; (2) indirect biophysical measurements (e.g. by the Mossbauer effect) of vibrations with a probe placed in the (drained) perilymphatic space; (3) electrophysiological recording of *cochlear microphonic potential*, giving the total electrical activity in short sectors of the basilar membrane; (4) the effects of focal lesions at different loci in the membrane; (5) measurements of evoked otoacoustic emissions (see p. 1243) from the cochlea, combined with (3) and (4).



The pattern of vibrations in the basilar membrane thus varies with the intensity and frequency of the acoustic waves reaching the perilymph. Because of the arrangement of the hair cells on the basilar membrane, such oscillations generate a largely transverse shearing force between the outer hair cells which rest (indirectly) on the basilar membrane and the overlying tectorial membrane, in which the apices of stereocilia are embedded (vide infra). The inner hair cell stereocilia, which probably do not touch the tectorial membrane although they come very close to it, are likely to be stimulated by local movements of the endolymph. At most intermediate frequencies an appreciable sector of the basilar membrane oscillates and hence a specific group of auditory nerve fibres are activated. While the mechanical behaviour of the basilar membrane is mainly responsible for a rather broad discrimination between different frequencies, the very fine tuning of which the cochlea is capable appears to be related to differences in physiology between individual hair cells which make them respond best to particular tones, even when experimentally isolated from the spiral organ. Such individual tuning of cells may be caused by differences in shape, stereocilia length or possibly variations in the molecular composition of their sensory membranes. To these factors may be added the activities of the outer hair cells, which are as yet not fully understood but may play an important part in regulating inner hair cell sensitivity at specific frequencies. This is most dramatically seen in the ability of hair cells to change length when stimulated electrically, at frequencies of many thousands per second. The rapidity of such contractions, and various other features, indicate a novel type of contractile mechanism (see Holley & Ashmore 1988). How such motility is used in hearing is not yet understood, but may be related to the need to adjust the mechanics of the spiral organ constantly, under the influence of the efferent pathway (see Brownell 1983, Kim 1985).

At a particular frequency an increase in the *intensity* of stimulus is signalled by an increase in the *number* of activated cochlear nerve fibres (recruitment) *and* in *their rate of discharge*. For discussion of these hypotheses consult Békésy (1960), Spoendlin (1968), Pickles (1985). Pye (1979) has studied the dimensions of the cochlea in many mammalian orders, including primates, equating the dimensions of the basilar membrane with the recorded auditory range. Her results, and others quoted by her, show no simple relation between the degree of cochlear spiralling and basilar membrane width with the frequency range in any mammalian group.

The roles of the two groups of hair cells have been much debated, particularly since differences in their innervation and physiological behaviour have become obvious. Because of their rich afferent supply internal hair cells have been favoured as the major source of auditory sensation, a view supported by much experimental and clinical evidence; e.g. animals treated with

7.370 The principal activities of the peripheral auditory apparatus. For clarity the cochlea is depicted as though it had been uncoiled. The points of maximal stimulation of the basilar membrane by high frequency (blue) and low frequency (red) vibrations, together with their transmission pathways through the external and middle ear, are also indicated.

antibiotics specifically toxic to outer hair cells are still able to hear but discrimination is impaired (Harrison & Evans 1979). The possible role of outer hair cells in the fine tuning of auditory responses to particular frequencies may be related to the recent observation that these cells can, when electrically stimulated, change length very rapidly, at frequencies similar to those of sound stimuli, contracting when depolarized and extending when hyperpolarized (Brownell et al 1985, Holley & Ashmore 1987). The cause of this motile response does not appear to be actin-myosin based, as it is too rapid; it may be associated with a network of fine filaments found beneath the cell membrane (Bannister et al 1988, Holley & Ashmore 1988), but further investigations are needed to elucidate this.

Electrical responses of the cochlea are of considerable interest; extracellular potentials can be readily recorded with relatively crude electrode techniques (Evans 1974, Yost & Nielsen 1977). The most significant is the *endolymphatic potential*, a steady potential recordable between the cochlear duct and the scala tympani and caused by the different ionic compositions of their fluids. Since the resting potential of hair cells is about 70 mV (negative inside) and the endolymphatic potential is positive in the cochlear duct, a total transmembrane potential across the apices of hair cells is 150 mV, a higher resting potential than found anywhere else in the body.

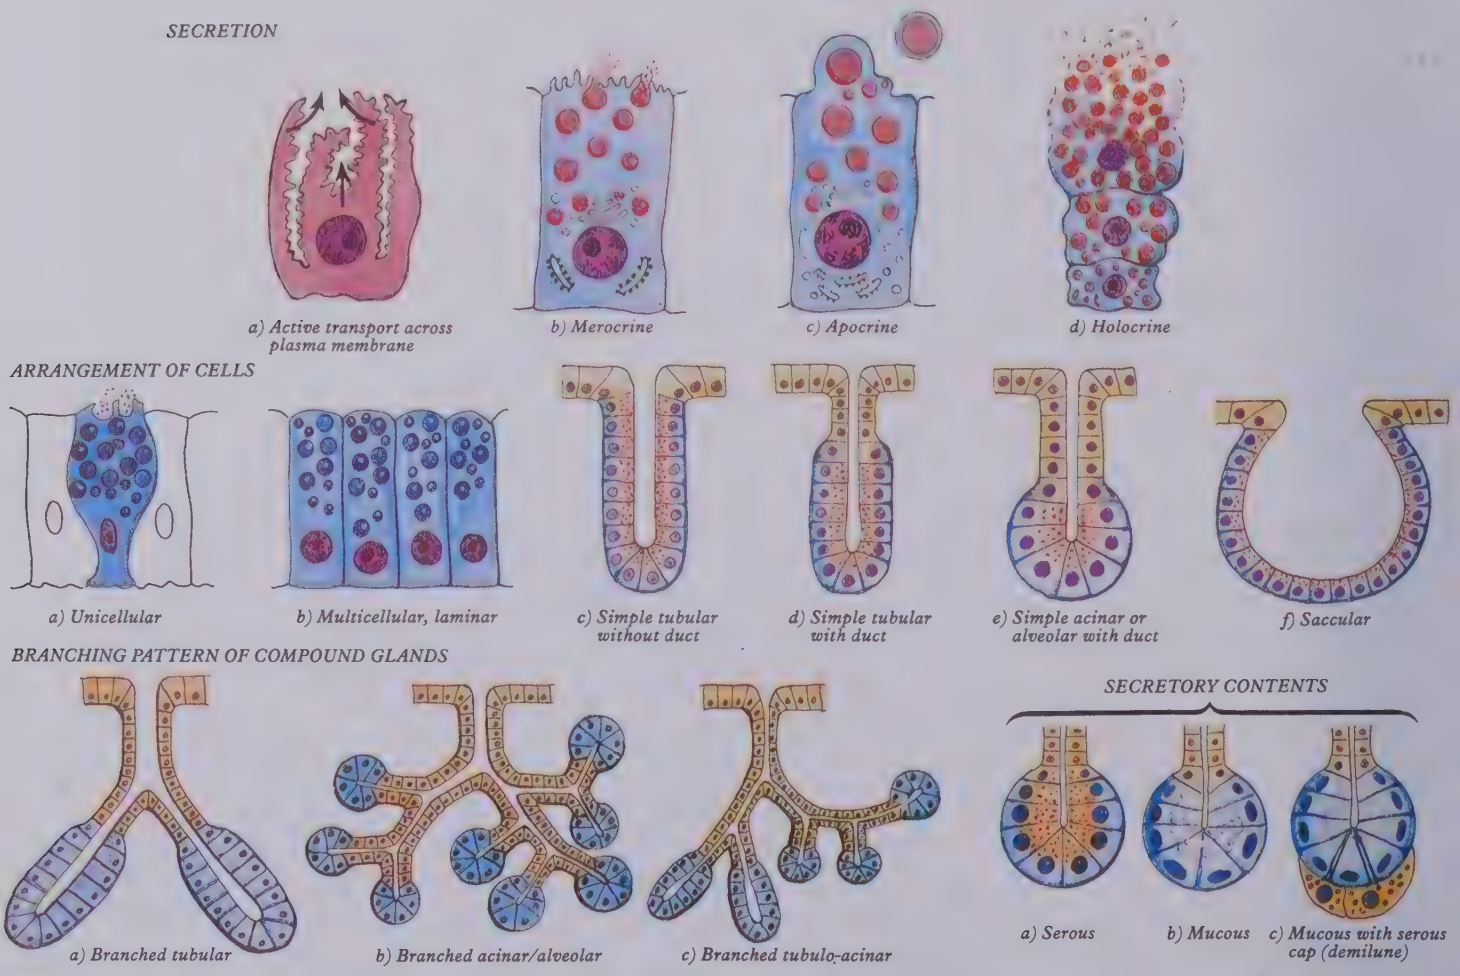
Under stimulation by sound, a rapid oscillatory *cochlear microphonic* potential can be recorded, matching the frequency of the stimulus and movements of the basilar membrane precisely. This appears to depend on fluctuations in the conductance of hair cell membranes, probably that of the outer hair cells. At the same time an extracellular *summating potential* develops, a steady direct current shift related to the (intracellular) receptor potentials of hair cells. Cochlear nerve fibres then begin to respond with *action potentials* also recordable from the cochlea. Intracellular recording of auditory responses from inner hair cells (Russell & Sellick 1977) has shown that these cells resemble other receptors, their steady receptor potentials being related in size to the amplitude of the acoustic stimulus. At the same time, afferent nerve fibres are stimulated by synaptic action at the bases of the inner hair cells, firing more rapidly as vibration of the basilar membrane increases in amplitude.

GRAY'S
ANATOMY

SPLANCHNOLOGY

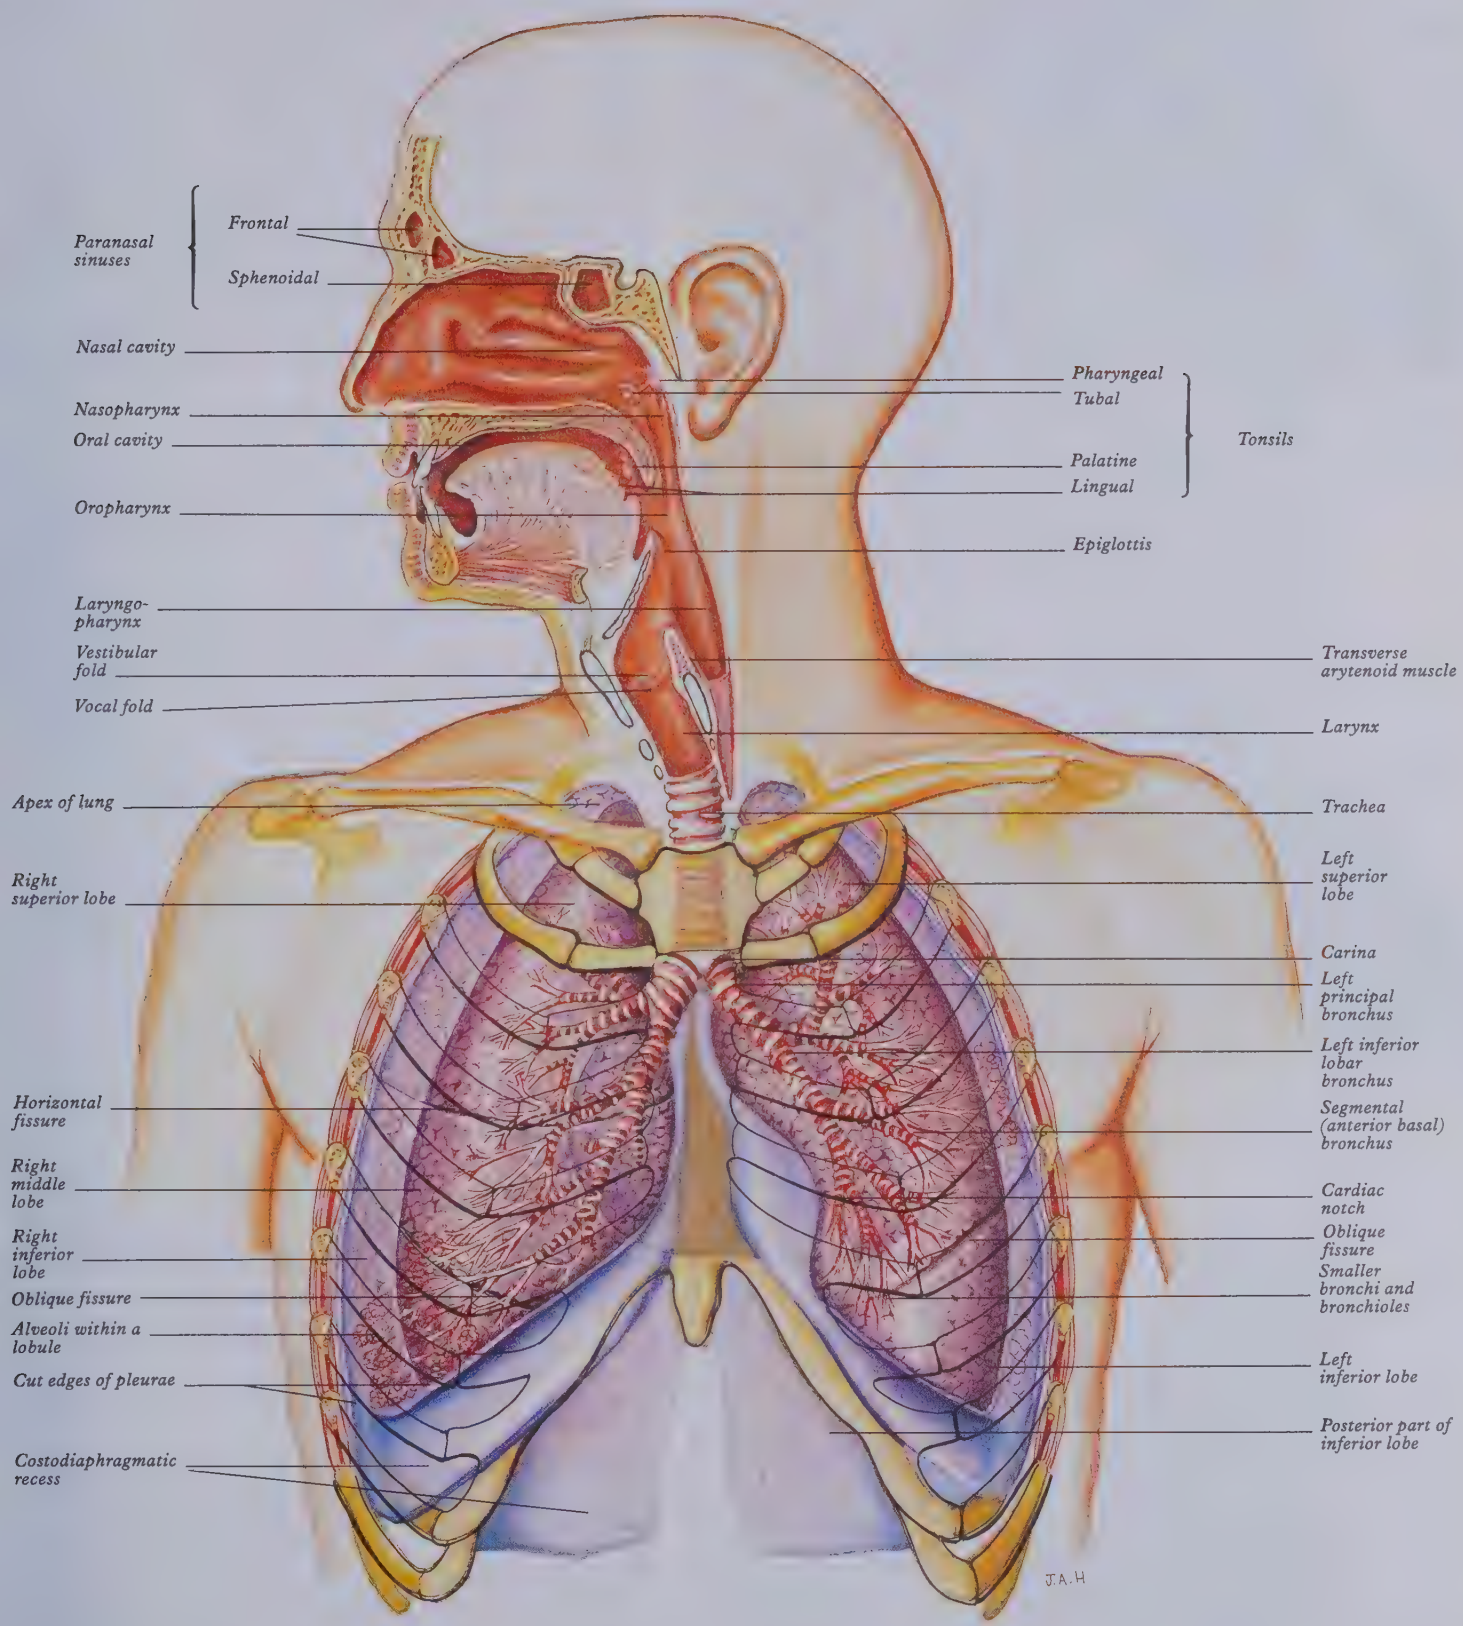
Introduction

The grouping of the organs of respiration, alimentation, urinary excretion, reproduction and the endocrine glands under the umbrella of 'Splanchnology' is more traditional than rational. There is, perhaps, some reason in dividing bodily fabric and function into somatic or locomotor and visceral or metabolic moieties, but osteology, arthrology, myology, angiology and neurology are not customarily incorporated. In any case there is extensive overlap between all the above and the miscellany of viscera or *splanchnoi* gathered under the label of 'splanchnology'. Again, splanchnology is no sooner formed than dismembered into constituent 'systems', as in this volume. Our only reasons for retaining the term are convenience and, admittedly, tradition.



The viscera are, by definition, partly the structures located within, or closely associated with, the pleural and peritoneal cavities and therefore related to the linings of these cavities. Many of these are tubular or saccular in form (hollow viscera), but some are solid; both are suspended within the coelomic cavities by connective tissue sheets covered on either side by a serous membrane or serosa (composed of a single layer of mesothelium and underlying lamina propria), through which vessels, nerves and ducts gain access to the viscera. Other viscera are located on the body wall external to the serous lining and, in the case of the abdomen, are then *retroperitoneal*; or they are more remote from the coelom-derived cavities and are surrounded by the connective tissue of the head, neck and pelvic wall. The serosa is lubricated by tissue fluid, is smooth and allows free movement of adjacent structures within the pleural and peritoneal cavities. The *hollow viscera* (alimentary, respiratory and urogenital tracts) are also lined internally by a mucous membrane (mucosa) consisting of an epithelial layer with its underlying lamina propria and associated glands and, in some parts of the gut, a thin layer of non-striated muscle. The hollow viscera are enclosed in fibromuscular coats in which non-striated muscle, controlled by the autonomic nervous system, predominates.

Extensions of the epithelial and connective tissue linings of the viscera form various types of exocrine glands which pass their secretions to the mucosal surface. Some of these glands are restricted to the walls of the viscera, but others may form very extensive *solid viscera* themselves, e.g. the pancreas and liver. Endocrine glands secreting into the circulation are in some cases derived from the hollow viscera during development (e.g. the thyroid gland), whereas others are formed quite independently from neural (adrenal medulla, neurohypophysis) or mesodermal (adrenal cortex, Leydig cells) sources.



Glandular tissue can be separated into two major categories: the *exocrine* glands secreting through ducts into the hollow viscera (or body surface), and *endocrine glands* (p. 1450), passing their products into the circulation.

Exocrine glands can be classified according to a number of different criteria (p. 57): (1) their mode of secretion (merocrine, apocrine or holocrine); (2) their secretory chemistry (mucous, serous, zymogen, etc.); (3) their morphology (unicellular, multicellular, tubular, acinar/alveolar, tubulo-alveolar). These different categories are illustrated in **8**.1A.

Mode of secretion. Most glands secreting proteinaceous material release their products by the *merocrine* method, vesicles

8.1A Schema which shows the different types of glands classified by currently used methods.

8.1B Diagrammatic representation of the respiratory tract. Those parts of the tract in the head and upper neck are shown in sagittal section, in the lower neck turned anteriorly and, in the remainder of the tract, from the anterior aspect.

containing material synthesized in the granular endoplasmic reticulum and Golgi complex being transported to the cell surface where fusion of the vesicle membrane with the plasma membrane occurs, so releasing the secretory product to the outside. All glands of the alimentary and respiratory tracts are merocrine. In *apocrine* secretion, cells pass their secretory vacuoles to the apical region from which portions of cytoplasm detach periodically, to release the secretion when they disintegrate. This mode of secretion is found in only a few regions, including the mammary glands and apocrine sweat glands. In *holocrine* secretion, the cell progressively fills up with secretory droplets and finally disintegrates; this process appears to be restricted to the epidermal sebaceous glands (p. 92). In addition, some cells release their products without visibly detectable exocytosis, particularly when secreting small molecules or ions (e.g. the parietal cells of the gastric mucosa). In endocrine glands polypeptide or protein-secreting cells are merocrine, but steroid-secreting cells, which typically have many of their synthetic enzymes associated with an extensive agranular endoplasmic reticulum, apparently release their products directly through their plasma membranes, since their products are generally lipid soluble.

Secretory products. These vary greatly according to location, physiological state, degree of development and many other factors. Traditionally the glands of the alimentary, respiratory and urogenital tracts are often classified as either serous or mucous. Serous glands typically have eosinophilic granules and a rounded nucleus in the basal half of the cell, surrounded by a basophilic rim of cytoplasm. Mucous cells, in contrast, have nuclei which lie close to the basal margin of the cell (surrounded also by basophilic cytoplasm) and a wide zone of more apical cytoplasm, often occupying most of the cell, consisting of frothy mildly basophilic secretory material rich in mucinogen and therefore staining strongly for carbohydrate. Mixed glands also occur, mucous lobules sometimes being capped by serous cells (serous demilunes). However, more discerning histochemical methods have shown that this simple picture is far from reflecting the great variety of secretions which these cells contain; cells which are classically serous may secrete many different proteins and carbohydrates and mucus can vary widely in chemistry in different regions of the body. The terms mucous and serous are perhaps most applicable to the major salivary glands, but even there they are really only a convenient shorthand for superficial, if rapid, clinical diagnosis (p. 1293).

Glandular morphology. Exocrine glands are either unicellular (e.g. goblet cells, p.53) or multicellular. The latter may be in the form of simple sheets of glandular cells, as at the surface of the stomach, or may be reflected as diverticula of various shapes and extents. Such glands may be single units (simple glands) or branched, compound structures. Simple unbranched tubular glands exist in the walls of many of the hollow viscera, e.g. the small intestine and uterus, while some glands have expanded, flask-like ends (acini or alveoli). Such glands may consist entirely of secretory cells, or may have a blind-ending secretory portion leading through a non-secretory duct to the lumen of the viscus, in which case the ducts may modify the secretions as they pass along them. Glands with ducts may be branched (compound), sometimes forming elaborate ductular trees. Compound glands generally have acinar or alveolar secretory lobules, but the secretory units may alternatively be tubular or mixed tubulo-acinar. While the significance of these different types of geometry is not yet understood, they all constitute ways of creating a larger area for secretion than would be available at a simple secretory surface.

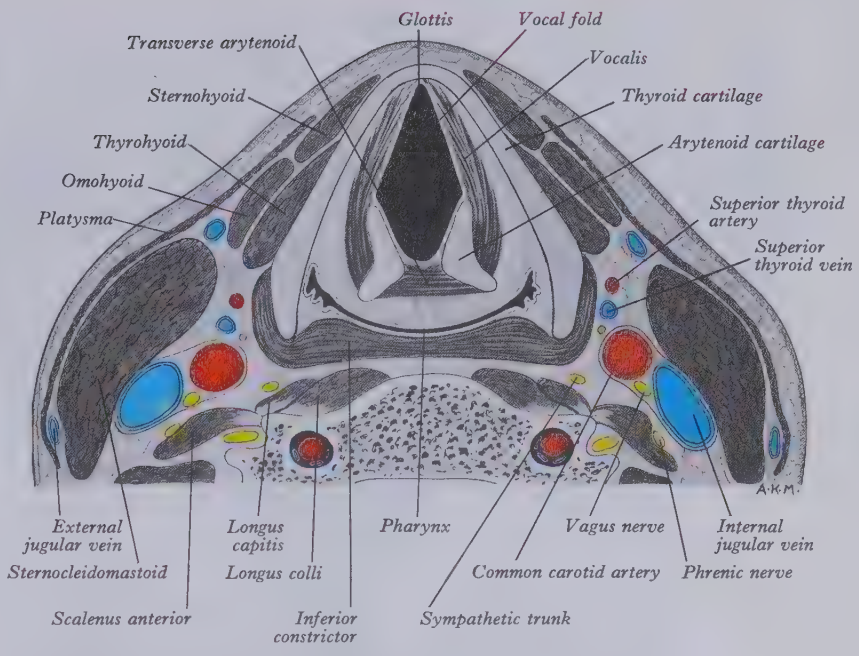
The high metabolic rate of many such glands is reflected in their rich vascular beds which can often be controlled by autonomic vasomotor nerves to modify the activity of the gland. Gland cells are also often under direct secretomotor control by means of synapse-like junctions with efferent nerve endings, which may exert complex actions by a variety of different neuromediator chemicals (see p. 889). Neural control may also be very rapid where contractile myoepithelial cells lie around the secretory units and smaller ducts, since under nervous stimulation the contraction of these can express secretions into the major ducts and so initiate discharge into the visceral lumen, e.g. in salivary glands.

Endocrine glands, secreting directly into the circulation, tend to be grouped around rich beds of capillaries or sinusoids; these are typically lined by fenestrated endothelia (p. 689) which allow the passage of macromolecules through their walls. Endocrine cells may be arranged in clumps around vascular networks or cords between parallel vascular channels or as hollow balls of cells (follicles) surrounding their stored secretions. Single endocrine cells also exist scattered throughout the alimentary and respiratory tracts (the entero-endocrine system, p. 1450).

THE RESPIRATORY SYSTEM

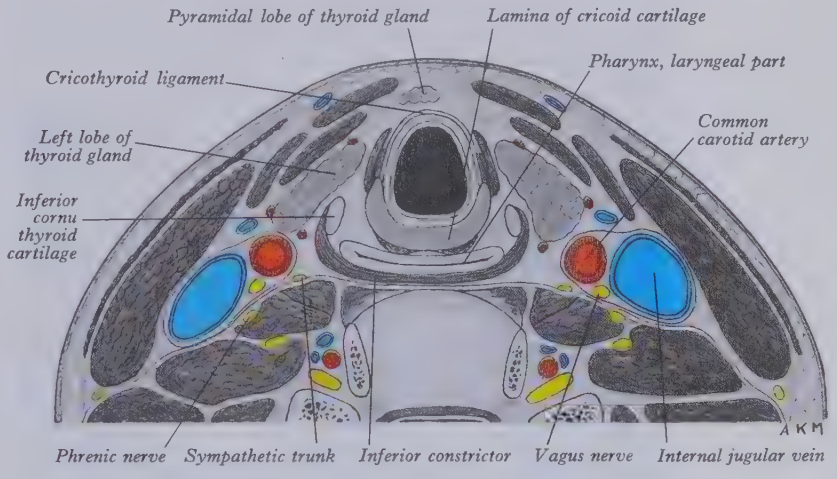
Introduction

Exchange of respiratory gases is essential to life, even in states of suspended animation, hibernation and aestivation, when respiration is greatly diminished. In *Protozoa*, oxygen and carbon dioxide diffuse directly through cell surfaces, establishing concentration gradients effective enough to maintain metabolism. In most *Metazoa* greater mass and hence longer diffusion distances require blood transport systems and specific respiratory areas. Respiratory adaptations assume two roles: the transport of respiratory gases and the development of specialized areas for gaseous exchange. The tracheal system of *Arthropoda* is an example of the former; its chitinous spirals maintain patency in *tracheoles*, and have their equivalents in vertebrates. For *Vertebrata*, and some invertebrate phyla, the two major global environments, *aqueous* and *terrestrial* (or aerial), have posed different problems. In both habitats gaseous exchanges take place between the external environment and circulating blood through the moist epithelium of gills, lungs or skin. Cutaneous respiration is limited to some amphibia, apart from which vertebrate respiratory organs are constantly associated with and largely developed from the branchial arch system and alimentary tract. The first segment of this beyond the mouth is the pharynx, through which, in fish, water passes to the gills for gaseous exchange; diverticula of the pharynx and oesophagus are common, functioning as hydrostatic organs (swim-bladders) but in a few extant species they are also auxiliary respiratory chambers which can be filled directly from the air. From such '*lungfish*' the earliest terrestrial vertebrates, amphibia, probably evolved, acquisition of air-breathing leading to a host of new forms and adaptations (Young 1962, Romer 1970).



Some members of all terrestrial vertebrate classes (amphibia, reptiles, birds and mammals) have returned to an aquatic existence; but only amphibian larvae and a few adult amphibians, e.g. *Salamander atra*, are able to absorb oxygen directly from water. All others must suspend breathing while immersed, surfacing to empty their respiratory organs and take in fresh air. To keep out water and retain inspired air during submersion, a sphincteric mechanism is needed at the junction of the lungs and pharynx. Even in fish which merely swallow air to fill their swim-bladders and in piscine ancestors of land tetrapods able to 'breathe' from water as well as air, this need existed; and perhaps also there was a need for a dilatator mechanism. This led to the evolution of a *larynx*, a structure as basic as the lung itself. In terrestrial

vertebrates the respiratory cavity or *lung* is usually bilateral, though served by a single pharyngeal diverticulum, the *trachea*, and has become highly folded, increasing the epithelial area for gaseous exchange between blood and inspired air. The basic pattern of respiratory organs was thus early established; even in small reptiles, the branching of the trachea, typically dichotomous, into smaller *bronchi* and *bronchioles* and terminal respiratory *alveoli*, is already complex. A tracheobronchial 'tree' of air-transporting tubes and thin-walled alveoli for gaseous exchange is present in all truly terrestrial vertebrates including birds, whose lungs display specializations beyond the scope of this text (Portmann 1950). Though air tubes may be altered in calibre by means of non-striated muscle in their walls, the main respiratory volumetric changes are alveolar. The mechanisms of inflation and deflation of the lungs vary in different vertebrate groups as do the dimensional features of their alveoli and bronchi, bronchial branching and pulmonary lobation. Within groups, however, the structural patterns display considerable constancy; recognition of this in man (p. 1261) has proved important in the diagnosis and treatment of pulmonary disorders.

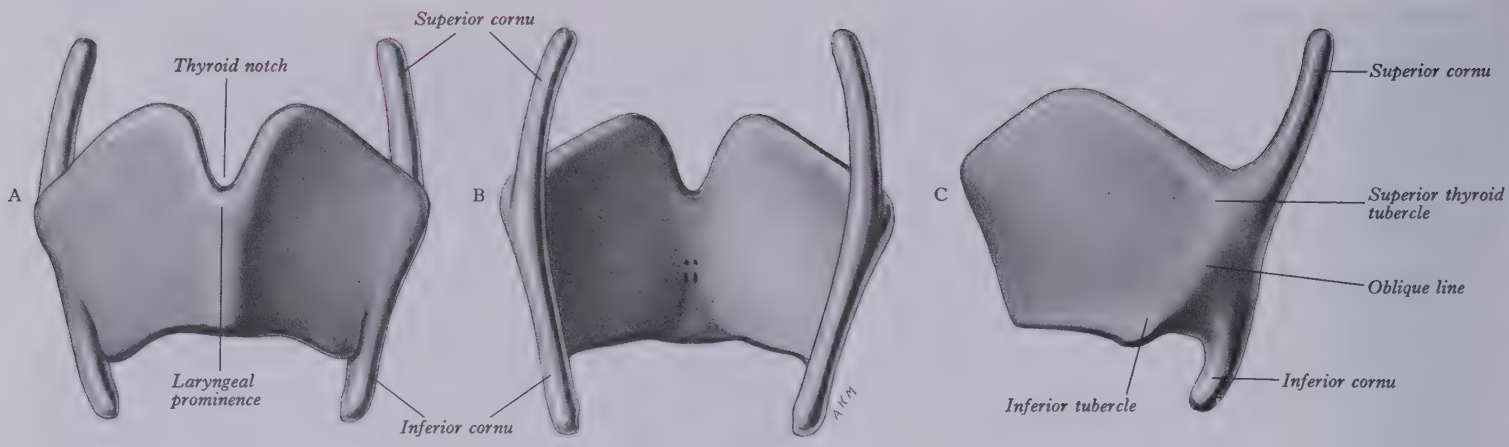


The *larynges* vary considerably in structure in the different vertebrate groups (Negus 1928, 1949). Although they are primarily sphincteric, they also become *phonatory*, even in the most primitive air-breathers, amphibia. The necessary musculature, skeletal elements and neurovascular supplies have evolved from the pharynx and branchial apparatus (pp. 165, 170, 171, 238). Amphibia still 'swallow' air, drawn in through valvular 'nostrils' in the anterior oral roof, there being no separate nasal cavity. The oral floor is lowered to inspire; when it rises and nostrils close, air is pumped into the pharynx, larynx and lungs. The mouth and pharynx therefore serve both for feeding and breathing. The greater activity of some reptiles demands a more efficient respiration, partly achieved by the development of movable ribs and *inspiration* of air by the reduction of pulmonary pressure. This new mode of breathing is finally improved, in mammals, by the evolution of a muscular diaphragm and a complete musculo-osseous thoracic cavity, whose elaborate musculature varies the thoracic and hence the pulmonary volume and also aids venous return. In mammals the oronasal cavity is divided into respiratory and alimentary regions by a *palate*; but the former, evolving in continuity with primitive nares, is consequently *dorsal* to the alimentary cavity, the reverse of the relation of pharynx and larynx. Hence the mammalian airway and alimentary path cross at mid-pharyngeal level. Many adaptations have occurred in the pharynx, palate and especially the larynx to overcome the difficulties of this curious arrangement, both in structure and in breathing and swallowing reflexes.

The mammalian 'airway' (**8**.1B) thus includes the nasal cavity, nasal and oral levels of the pharynx, the larynx, trachea, bronchi and their pulmonary ramifications. Breathing via the mouth is, of course, possible; but this negates the olfactory and 'air-conditioning' functions of the nasal cavity. The separation of respiratory and olfactory functions from the mouth allows predatory mammals to breathe while the mouth is obstructed by prey, whose struggles may be prolonged; and their herbivorous prey may also sense warning odours even when feeding. In aquatic vertebrates, such as crocodiles, dolphins and whales, a spout-like elongation of the larynx can project into the nasopharynx, largely separating the airway, so that respiration can continue at the surface with mouth submerged, open and ready for prey; in marine mammals other specializations also occur (Andersen 1969).

In man speech is the outstanding elaboration associated with the respiratory system. The nasal cavity is still respiratory, olfactory and an organ of exchange for heat and water vapour, though also involved in producing the sounds of speech. But the human larynx, though still an essential sphincter, preventing entry of swallowed material and facilitating respiratory blockade to build up pressure for coughing or in extreme muscular efforts, is so frequently phonatory that this is often considered as its prime function. The elaboration of laryngeal musculature and its neural control, integrating laryngeal sound production with movements of respiratory, pharyngeal, palatal, lingual and labial muscles during the complex articulation of speech, provide mankind with a unique ability. Speech, which must of course be heard and

8.2A Transverse section across the ventral region of the neck at the level of the vocal folds, viewed from the superior aspect.



8.2B Transverse section through the ventral region of the neck, between the fifth and sixth cervical vertebrae, viewed from the superior aspect (semi-diagrammatic).

interpreted but may also be expressed in visible, written form, has led to the increasingly complex symbolism of language (with which mathematical and musical notation may be coupled). In this development, unparalleled in any other animal, very high levels of integration between the nervous system and locomotor structures are attained. The vital function of respiration remains; but its primitive phonational potential, leading finally to speech in all its permutations, is fundamental in the evolution of human intelligence. In the other most 'vocal' vertebrate class, birds, the larynx is commonly a sphincteric mechanism alone, sounds in great variety being produced by the *syrinx* at the tracheal bifurcation. Some birds are notable imitators of human speech; but there is no clear evidence of development of true, symbolic language in any vertebrate other than mankind, in whom high manual dexterity, large cerebral development and emancipated vision have together provided the adequate milieu for linguistic evolution.

The Larynx

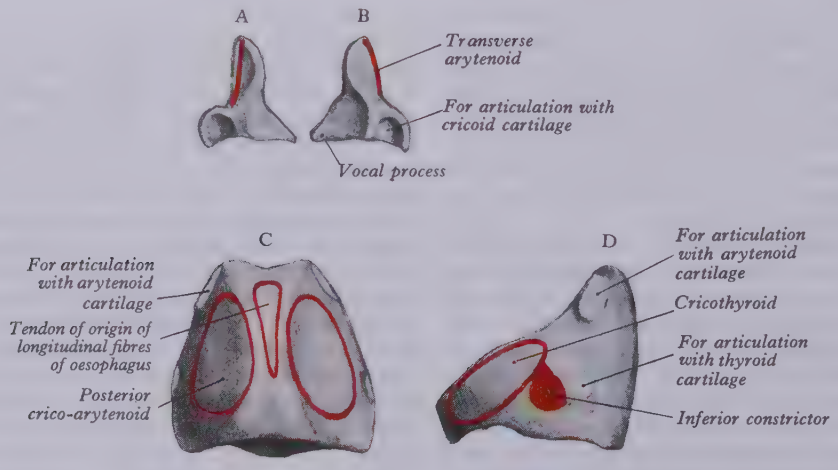
The larynx, an air passage, a sphincteric device and an organ of phonation, extends from the tongue to the trachea (Terracol et al

8.3 The thyroid cartilage. The attachments of the vestibular ligaments (above) and the vocal ligaments (below) are shown in B. A. Anterior aspect. B. Posterior aspect. C. Lateral aspect.

1965, Fink & Demarest 1978.) It projects ventrally between the great vessels of the neck and is covered anteriorly by skin, fasciae and the hyoid depressors (**8**.2A). Above, it opens into the laryngopharynx and forms its anterior wall; below, it continues into the trachea. In adult males it lies level with the third to sixth cervical vertebrae, but is somewhat higher in children and adult females. In infants between six and twelve months, the tip of the epiglottis (highest part of the larynx) is a little above the junction of the axial dens and body. Its average measurements in European adults are:

	In males	In females
Length	44 mm	36 mm
Transverse diameter	43 mm	41 mm
Sagittal diameter	36 mm	26 mm

The larger size of the adult masculine larynx is due to greater growth from puberty onwards; all its cartilages enlarge and the thyroid cartilage projects anteriorly in the midline. Its sagittal diameter is nearly doubled during this process.



Cartilages form the skeletal frame of the larynx, connected by ligaments and membranes and moved by muscles. The lining of the larynx is a mucosa continuous posterosuperiorly with that of the pharynx and inferiorly with that of the trachea.

LARYNGEAL CARTILAGES

These comprise the single thyroid, cricoid and epiglottic cartilages and the paired arytenoid, cuneiform and corniculate cartilages.

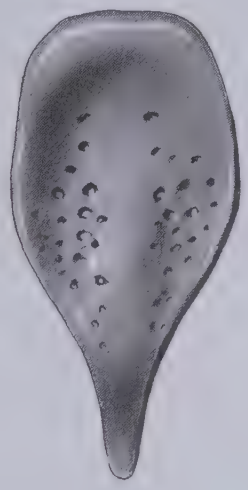
The thyroid cartilage (**8**.1, 2, 3, 13), the largest, consists of two quadrilateral *laminae*, their anterior borders fused inferiorly at a median angle, forming the subcutaneous *laryngeal prominence* ('Adam's apple'). This projection is most distinct at its superior end and is well marked in men but scarcely visible in women. Above, the laminae are separated by a V-shaped superior *thyroid incisure*; posteriorly they diverge, their posterior borders being prolonged as slender horns, the *superior* and *inferior cornua*. On the exterior of each lamina an *oblique line* curves down and forwards, running from a *superior thyroid tubercle* lying anterior to the root of the superior cornu, to an *inferior thyroid tubercle* on the inferior border. To this line, the sternothyroid, thyrohyoid and the thyropharyngeal parts of the inferior pharyngeal constrictor muscles are attached. The smooth *internal surface* is posterosuperiorly slightly concave and covered by mucosa. High in the angle between the laminae the thyro-epiglottic ligament is attached; below this, near the midline, the paired vestibular and vocal ligaments and the thyro-arytenoid, thyro-epiglottic and vocal muscles are attached.

The *superior border* of each lamina is concave behind, convex in front and to it half of the thyrohyoid membrane is attached. The *inferior border* is concave behind, and nearly straight in front, of the inferior thyroid tubercle. At and near the midline it is connected

8.4 The arytenoid and cricoid cartilages. A. The left arytenoid cartilage: medial aspect. B. The right arytenoid cartilage: medial aspect. C. The cricoid cartilage: posterior aspect. D. The cricoid cartilage: left lateral aspect. Muscle attachments are indicated in red.

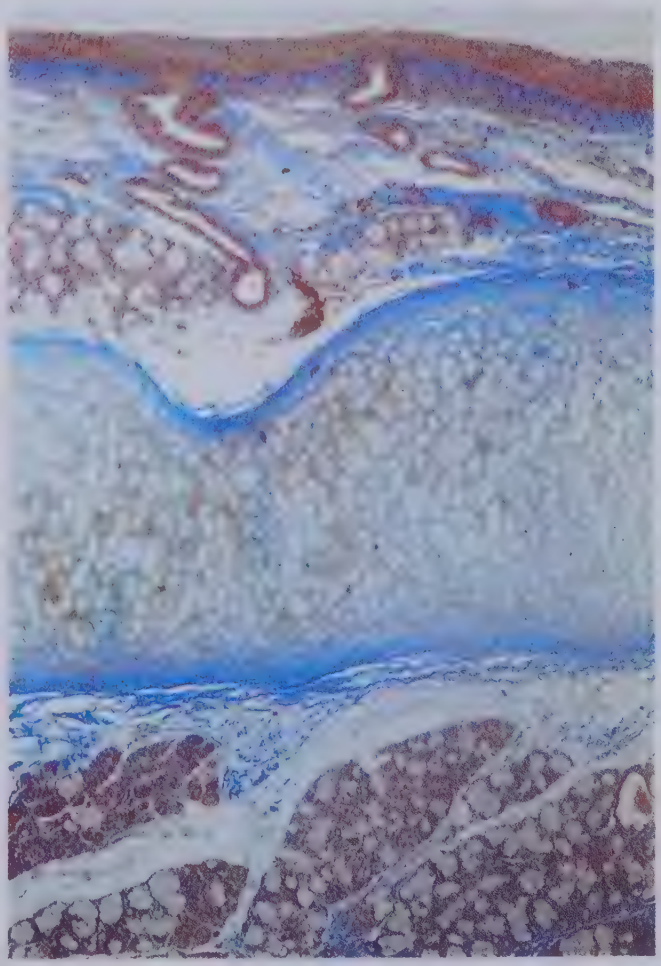
to the cricoid cartilage by the anterior (median) cricothyroid ligament (see p. 1253).

The *anterior* borders fuse at an angle of about 90° in men and about 120° in women. In men the larger laryngeal prominence, the greater length of the vocal folds and the resultant deeper pitch of voice are all associated with a smaller thyroid angle. The thick and rounded *posterior border* receives the fibres of stylopharyngeus and palatopharyngeus. The *superior cornu*, long and narrow, curves up and posteromedially, ending in a conical apex to which the lateral thyrohyoid ligament is attached. The *inferior cornu*, which is short and thick, curves down and slightly anteromedially; on the medial surface of its lower end, a small oval facet articulates with the side of the cricoid cartilage. During infancy a narrow, rhomboidal, flexible strip, the *intrathyroid cartilage*, lies between the two laminae and is joined to them by fibrous tissue.



The cricoid cartilage (8.4, 6, 7, 8), thicker and stronger than the thyroid cartilage and shaped like a signet ring (hence its name), forms the inferior parts of the anterior and lateral walls and most of the posterior wall of the larynx. It has a quadrate posterior *lamina* and a narrow anterior *arch*. Its *lamina* is deep and broad, from 2–3 cm vertically; it has a posterior median vertical ridge, to the upper part of which the two fasciculi of the longitudinal oesophageal fibres are attached by a tendon (p. 1332). Lateral to this are two shallow depressions for the fibres of the posterior crico-arytenoid. The *arch* is narrow in front, from 5–7 mm vertically, but widens towards the lamina. To its front and sides, externally, the cricothyroid is attached and, behind this, part of the inferior pharyngeal constrictor. The arch is palpable below the laryngeal prominence, from which it is separated by a depression containing the resilient conus elasticus. On each side, at the junction of lamina and arch, a prominent circular facet, facing posterolaterally, articulates with the inferior thyroid cornu. The horizontal *inferior border* is joined to the first tracheal cartilage by the cricotracheal ligament, while the *superior border* runs obliquely up and back, giving attachment anteriorly to the thick median part and laterally to the membranous lateral parts of the cricothyroid ligament and the lateral crico-arytenoid muscles. Posteriorly, the lamina has a shallow median notch, on each side of which a smooth, oval, convex facet, directed up and laterally, articulates with the base of an arytenoid cartilage (see, however, Sellars & Keen 1978). The *internal surface* of the cricoid cartilage is smooth and lined by mucosa.

The paired arytenoid cartilages (8.4, 7, 8), sited superolaterally on the cricoid lamina at the back of the larynx, are pyramidal, with three surfaces, two processes, a base and an apex. The *posterior surface*, which is triangular, smooth and concave, is covered by the transverse arytenoid muscle. The *anterolateral surface* is convex and rough; near the apex is an elevation from which a crest curves back, down and then forwards to the vocal process. The lower part of this crest separates two depressions (foveae), the upper triangular, the lower oblong; to the upper is attached the vestibular ligament, to the lower the vocalis and lateral crico-arytenoid muscles. The *medial surface* is narrow, smooth, flat and covered by mucosa; it bounds laterally by its lower edge the intercartilaginous part of the rima glottidis (p. 1254). The *base* is concave, with a smooth surface for articulation with the upper border (lateral part) of the cricoid lamina. Its round, prominent lateral angle, or *muscular process*, projects posterolaterally giving attachment to the posterior crico-arytenoid muscle behind and lateral crico-arytenoid in front. To its pointed anterior angle (the *vocal process*), projecting horizontally forward, is attached the vocal ligament. The *apex* curves posteromedially to articulate with the *corniculate cartilage*.



The corniculate cartilages (8.7, 8, 12) are two conical nodules of elastic fibrocartilage which articulate with the arytenoid apices, prolonging them posteromedially. Lying posteriorly in the aryepiglottic mucosal folds, they sometimes fuse with the arytenoid cartilages.

The cuneiform cartilages (8.8, 12) are two elongated, club-like elastic fibrocartilages, one in each aryepiglottic fold anterosuperior to the corniculate cartilages and visible as whitish elevations through the mucosa.

The epiglottic cartilage (8.5, 7, 8) is a thin foliate lamella of elastic fibrocartilage, projecting obliquely up behind the tongue and hyoid body, in front of the laryngeal inlet. Its free end, which is broad and round, ascends from a long and narrow stalk, connected by the elastic *thyro-epiglottic ligament* to the back of the laryngeal prominence just below the thyroid notch. Its sides are attached to the arytenoid cartilages by aryepiglottic folds (p. 1253). Its free upper *anterior surface* is covered by mucosa (the epithelium is non-keratinized stratified squamous), reflected on

8.5A The epiglottis: posterior aspect. Note its pitted surface.

8.5B A low magnification light micrograph of a transverse section of the epiglottis, showing stratified squamous epithelium covering the anterior surface, mucous glands and fibro-elastic cartilage. to the pharyngeal aspect of the tongue and the lateral pharyngeal walls as a *median glosso-epiglottic* and two *lateral glosso-epiglottic folds*. On each side of the median fold is a depression, the *vallecula*. The lower anterior surface, behind the hyoid bone and thyrohyoid membrane, is connected to the upper border of the former by an elastic *hyo-epiglottic ligament*, and separated from the thyrohyoid membrane by adipose tissue. The smooth *posterior surface* is transversely concave and vertically concavo-convex and covered by respiratory mucosa; its lower projecting part is the *tubercle*. The cartilage is posteriorly pitted by small mucous glands and perforated by branches of the internal laryngeal nerve.

Functions of the Epiglottis

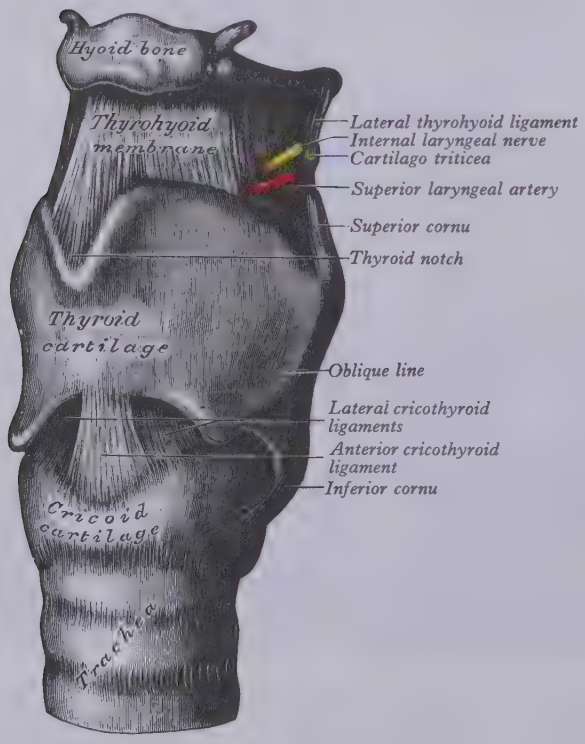
During deglutition (p. 1328) the epiglottis moves upwards and forwards and is squeezed between the base of the tongue and the rest of the larynx; the bolus slips over its anterior surface as it bends back over the laryngeal inlet. In man it is somewhat degenerate in function and is well separated from the soft palate; it is not essential to swallowing, which is normal even if the epiglottis is destroyed by disease; neither is it essential for respiration or phonation. Some mammals, keen-scented even when the mouth is open for feeding, have a large epiglottis which projects into the nasapharynx *above* the soft palate; during feeding, it is drawn down and forward by the hyo-epiglottic muscle (in man a mere *ligament*) against the *upper* surface of the soft palate, keeping the nasal airway clear and the buccal airway closed, thus permitting olfaction even when the mouth is open.

Microstructure of the Laryngeal Cartilages

The corniculate, cuneiform and epiglottic cartilages and the arytenoid apices are composed of *elastic* fibrocartilage with little tendency to ossify or calcify. The thyroid, cricoid and greater part of the arytenoids consist of *hyaline* cartilage and may ossify as age advances, commencing about the twenty-fifth year in the thyroid cartilage and somewhat later in the cricoid and arytenoids; by the sixty-fifth year these cartilages commonly appear, in radiographs, patchily calcified or ossified.

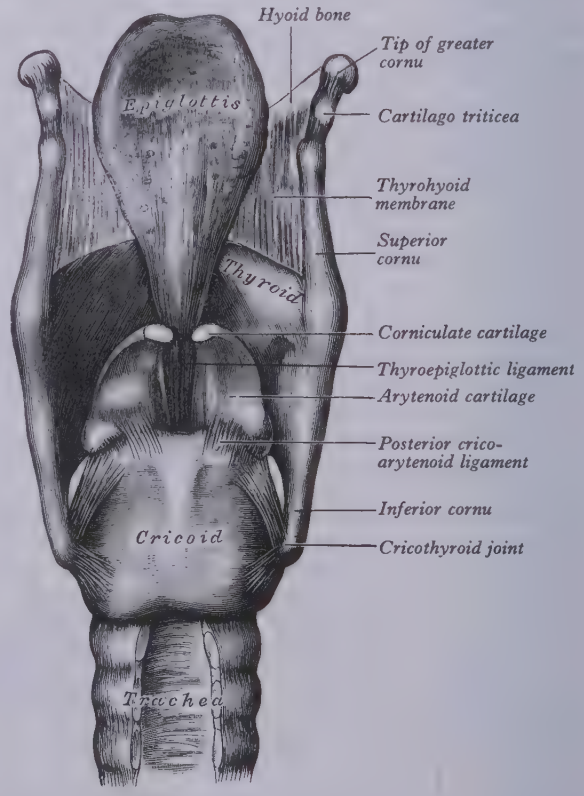
LARYNGEAL ARTICULATIONS

The joints between the inferior thyroid cornua and cricoid cartilage are synovial, each with a capsular ligament strengthened posteriorly by a fibrous band. The cricoid rotates on the inferior cornua around a transverse axis through both joints and, to a limited extent, also glides on them.



A pair of synovial joints exists between the facets on the lateral part of the upper border of the lamina of the cricoid cartilage and the bases of the arytenoids, each joint being enclosed by a capsular ligament; a strong *posterior crico-arytenoid ligament* connects the cricoid to the posteromedial part of the arytenoid base. These joints permit two movements: (1) arytenoid rotation about an oblique axis (dorsomediocranial to ventrolaterocaudal) (Frable 1961), in which each vocal process swings laterally or medially, increasing or decreasing the rima glottidis; (2) a gliding movement, by which the arytenoids approach or recede from one another, the slope of their articular surfaces imposing a forward and downward movement on lateral gliding. The movements of gliding and rotation are associated: medial gliding with medial rotation and lateral gliding with lateral rotation (von Leden & Moore 1961). The posterior crico-arytenoid ligaments limit forward movements of the arytenoid cartilages on the cricoid. (For details consult Sonesson 1959 and Sellars & Keen 1978.) Sometimes the synchondrosis between the arytenoid apex and the corresponding corniculate cartilage is replaced by a synovial joint.

Numerous lamellated (Pacinian) corpuscles, some Ruffini and some free nerve endings occur in the capsules of the laryngeal joints. In cats these respond to mechanical stimuli and are involved in the normal co-ordination of laryngeal muscles during respiration and phonation (Kirchner & Wyke 1965). The human articular supply is chiefly from branches of the recurrent laryngeal nerves, arising independently or from muscular rami (Psenicka 1966).



LARYNGEAL LIGAMENTS AND MEMBRANES

Extrinsic Ligaments

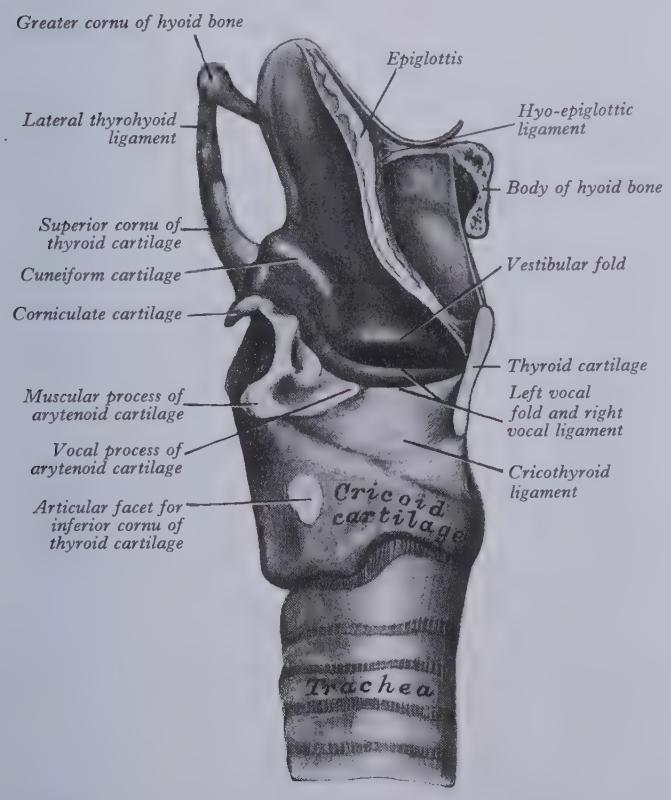
The *thyrohyoid membrane* (8.6, 7) is a broad, fibro-elastic layer, attached below to the cranial border of the thyroid cartilage and the

8.6 The ligaments of the larynx: anterolateral aspect.

8.7 The ligaments of the larynx: posterior aspect.

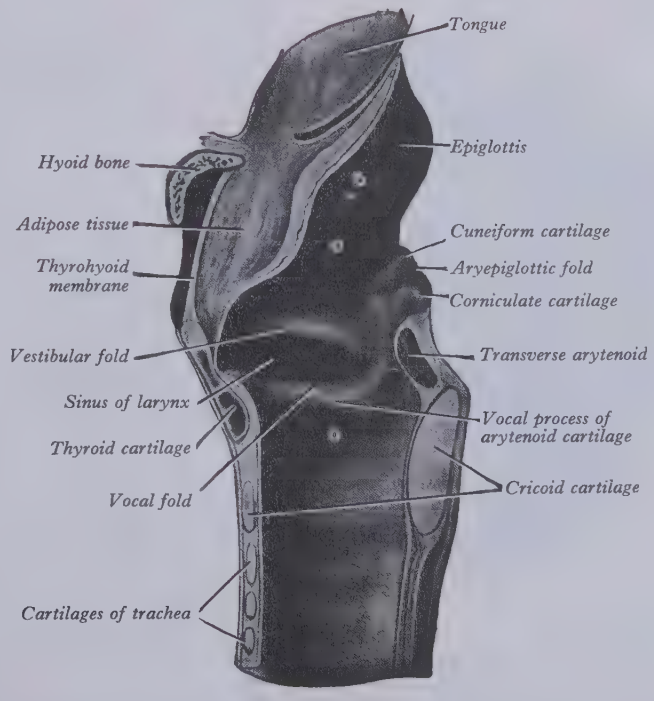
front of its superior cornua and above to the *superior* margin of the posterior surface of the hyoid body and its greater cornua. It thus ascends *behind* the concave posterior hyoid surface, separated from the hyoid body by a bursa facilitating laryngeal ascent during deglutition. Its thicker part is the *median thyrohyoid ligament*; the more lateral, thinner parts are pierced by the superior laryngeal vessels and internal laryngeal nerves. Externally it is in contact with the thyrohyoid, sternohyoid and omohyoid muscles and the hyoid body. Its inner surface is related to the epiglottis and pharyngeal piriform fossae. The round, cord-like elastic, *lateral thyrohyoid ligaments* form the posterior borders of the thyrohyoid membrane, connecting the tips of the superior thyroid cornua to the posterior ends of the greater hyoid cornua. A small *cartilago triticea* occurs frequently in each ligament.

The epiglottis is attached to the hyoid bone and thyroid cartilage by the extrinsic *hyo-epiglottic* and intrinsic *thyro-epiglottic ligaments* (p. 1251). The *cricotracheal ligament* unites the lower cricoid border to the first tracheal cartilage, being thus continuous with the tracheal perichondrium.



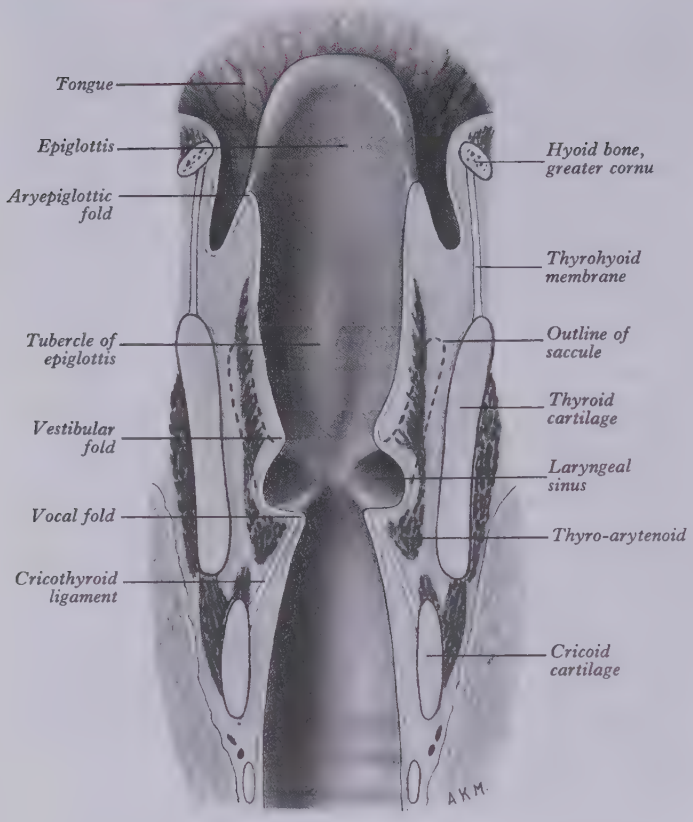
Intrinsic Ligaments

Beneath the laryngeal mucosa is a fibrous sheet containing many elastic fibres, the *fibro-elastic membrane of the larynx*, interrupted on each side by the interval between the vestibular and vocal ligaments; its upper part, the often ill-defined *quadrangular membrane*, extends between the arytenoids and epiglottis, its lower part forming the well-marked *cricothyroid ligament (cricovocal membrane)*, connecting the thyroid, cricoid and arytenoid cartilages. The articular ligaments are described above.

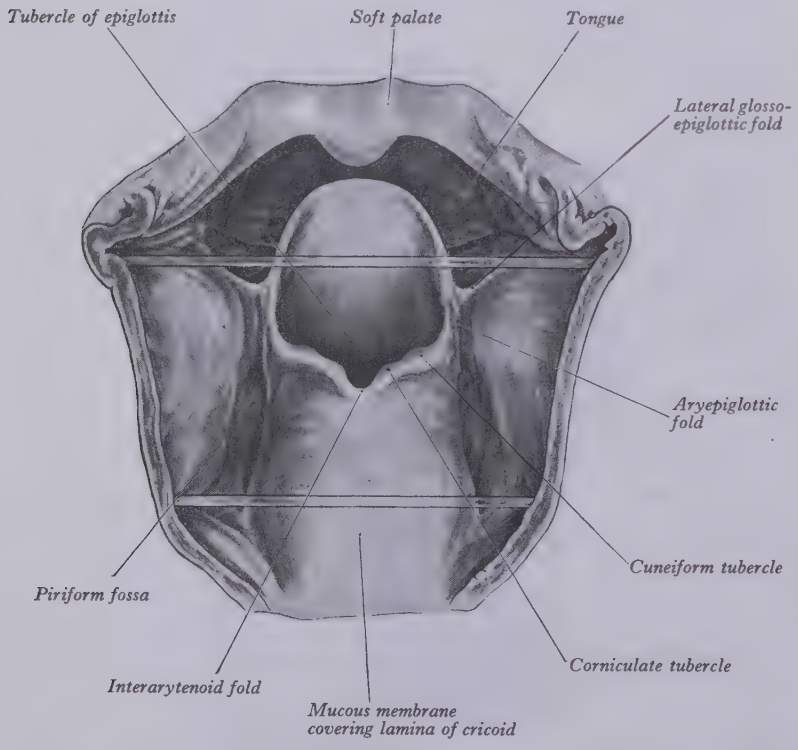


The cricothyroid ligament (**8**.6, 8), comprising the inferior and larger part of the laryngeal membrane, is mainly elastic tissue, with distinct anterior and lateral parts. The thick *anterior (median) cricothyroid ligament*, broad below, narrower above, connects adjacent margins of the cricoid and thyroid cartilages. An anastomosis between the cricothyroid arteries crosses it and supplies perforating rami to the larynx. The smaller, *lateral cricothyroid ligaments* (cricothyroid or cricovocal membranes) are thinner and covered internally by mucosa and externally by the lateral crico-arytenoid and thyro-arytenoid muscles. From the internal rim of the superior cricoid border the ligaments ascend and converge; their superior edges, extending from the dorsal aspect of the thyroid angle (just below its midpoint) to the apices of the arytenoid vocal processes, form the basis of the vocal folds (**8**.10). The thickened edges of the cricothyroid ligamentous complex are the *vocal ligaments* (**8**.8). (The term, *conus elasticus*, is commonly applied to the entire complex but sometimes only its anterior part.)

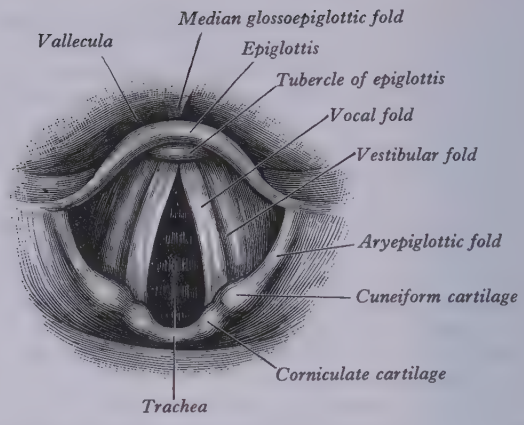
The laryngeal cavity (**8**.9, 10) extends from the laryngeal inlet, its connection with the pharynx, to the cricoid cartilage's lower border, continuing into the trachea. It is partially divided by paired folds of mucosa projecting medially from its sides. The upper pair are the *vestibular folds*, the fissure between them being the *rima vestibuli*; the lower pair, concerned in vocalization, are the *vocal folds*, the fissure between them being the *rima glottidis*, or *glottis*. The laryngeal *inlet* or 'aditus laryngis' (**8**.11), the aperture between the larynx and pharynx, faces back and somewhat up, the anterior laryngeal wall being much longer and sloping down and forwards in its upper part (**8**.9). The inlet is bounded anteriorly by the upper edge of the epiglottis, posteriorly by the mucosa between the arytenoids and on each side by the edge of a mucous fold between the epiglottis and arytenoid apex. This *aryepiglottic fold* contains ligamentous and muscular fibres; in the posterior part of its margin are oval anterosuperior and postero-inferior swellings, due to the cuneiform and corniculate cartilages respectively, separated by a shallow vertical furrow, continuous below with the opening of the laryngeal sinus (vide infra).



The *laryngeal vestibule* (**8**.9, 10), between inlet and vestibular folds, is wide above, narrow below and longer anteriorly than posteriorly. Its anterior wall is the posterior epiglottic surface, its lower part projecting backwards as its *tubercle* (p. 1252). Its lateral walls, deep in front, shallow behind, are the medial aspects of the aryepiglottic folds; its posterior wall is the interarytenoid mucosa, above the vestibular folds.



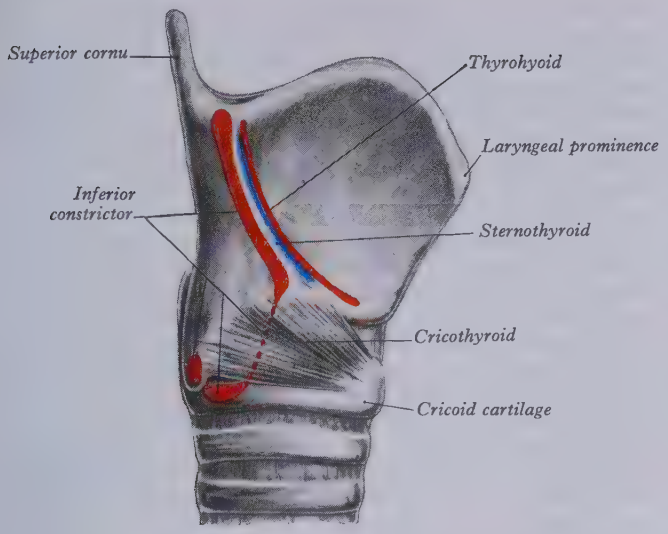
8.8 Dissection to show the right half of the cricothyroid ligament. The right lamina of the thyroid cartilage and the subjacent muscles have been removed.



8.9 Sagittal section showing the medial aspect of the right half of the larynx.

8.10 Coronal section through the larynx and the cranial end of the trachea: posterior aspect.

8.11 The inlet of the larynx, viewed from the posterior aspect. The posterior wall of the pharynx has been divided in the median plane and two glass rods have been inserted to keep the cut portions apart.



8.12 Laryngoscopic view of the interior of the larynx.

The *middle part* of the laryngeal cavity is the smallest, reaching from the rima vestibuli to the rima glottidis. On each side it opens by a slit between vestibular and vocal folds into the *laryngeal sinus* (**8**.9, 10), a fusiform recess between the folds which ascends lateral to the vestibular fold. It is lined by mucosa and covered externally by the thyro-arytenoid muscle. Anteriorly the sinus opens into the *laryngeal saccule* (**8**.10), a pouch ascending forwards from the sinus between the vestibular fold and thyroid cartilage, occasionally reaching the cartilage's upper border; it is conical, curving slightly backwards. On its luminal surface open 60–70 mucous glands, sited in the submucosa. The saccule has a fibrous capsule, continuous below with the vestibular ligament, and is covered medially by a few muscular fasciculi from the apex of the arytenoid cartilage which pass forwards between the saccule and vestibular mucosa into the aryepiglottic fold. Laterally the saccule is separated from the thyroid cartilage by thyro-epiglottic muscles, which compress it, expressing its secretion on to the vocal folds. In most apes the saccules form air sacs, which may extend into superficial cervical and even axillary tissues; they appear to aid resonance. Human saccules occasionally protrude through the thyrohyoid membrane.

The pink mucosa of each *vestibular fold* (**8**.8, 9, 10) covers a narrow *vestibular ligament*, fixed in front to the thyroid angle below the epiglottic cartilage and behind to the anterolateral arytenoid surface above the vocal process. Like the whole interior of the larynx (except the vocal folds) the epithelium is ciliated pseudostratified, respiratory in type. The white mucosal *vocal folds* (**8**.8, 9, 10) stretch from the mid-level of the thyroid angle to the arytenoid vocal processes. They form the anterolateral edges of the rima glottidis and are concerned in producing sound. They are covered by non-keratinized stratified squamous epithelium which is closely bound to the vocal ligaments; since a submucosa and blood vessels are absent, the folds are pearly white. Each *vocal ligament*, continuous below with the lateral part of the cricothyroid ligament (p. 1253), is a band of yellow elastic tissue related laterally to the vocalis (p. 1255).

The *rima glottidis* or *glottis* (**8**.12), the fissure between the vocal folds anteriorly and the arytenoid cartilages posteriorly, is limited behind by the mucosa passing between the arytenoid cartilages, at the level of the vocal folds. Between these folds is the *intermembranous part* of the glottis, comprising about three-fifths of its length, while between the arytenoids is the *intercartilaginous* part. The average sagittal diameter of the glottis in adult males is 23 mm and in adult females 17 mm. It is the narrowest part of the larynx. Its width and shape vary with the movements of vocal folds and arytenoid cartilages during respiration and phonation (see p. 1257).

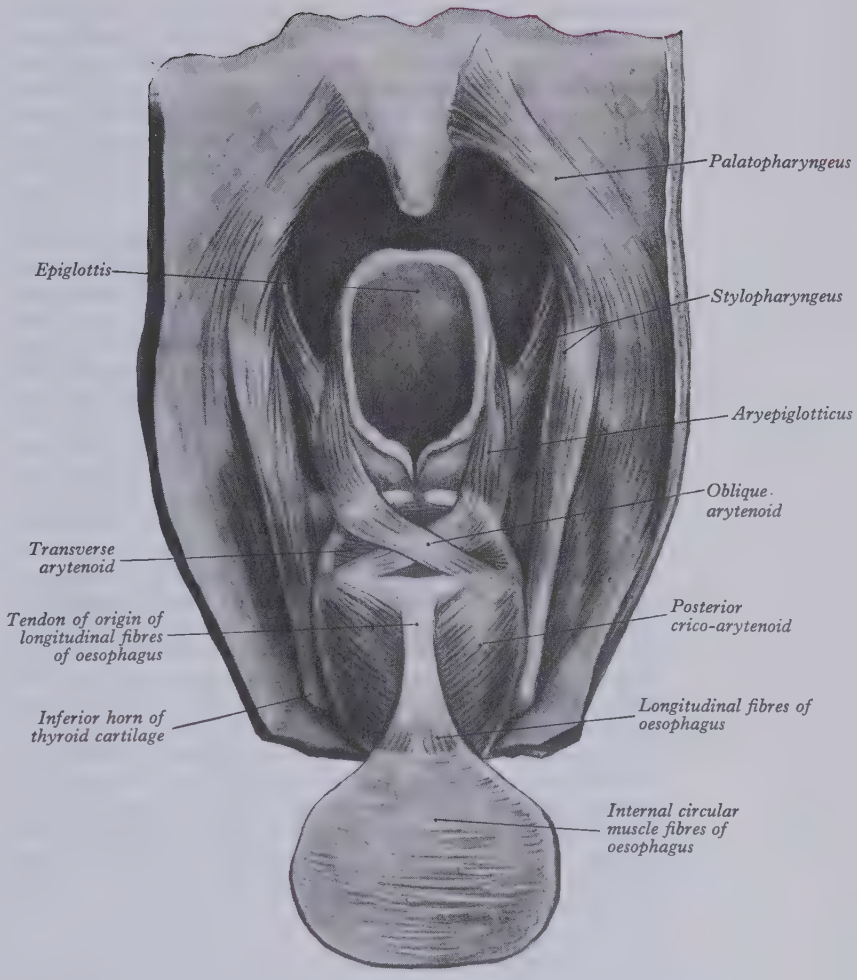
The *lower part* of the laryngeal cavity extends from the vocal folds to the lower border of the cricoid. In transverse section it is elliptical above and wider and circular below; it is continuous with the trachea. Lined by mucosa, its walls are supported by the cricothyroid ligament above and the cricoid cartilage below.

8.13 Lateral view of the larynx, showing the muscular attachments.

LARYNGEAL MUSCULATURE

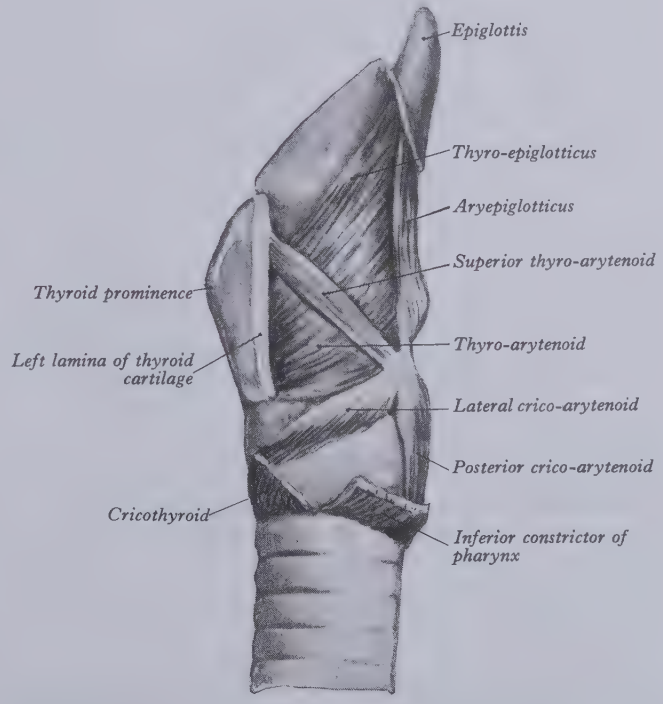
The muscles of the larynx are divisible into *extrinsic and intrinsic* groups. The extrinsic muscles connect the larynx to neighbouring structures (p. 584), while the intrinsic are confined to laryngeal attachments, being the *cricothyroid, posterior* and *lateral cricoarytenoid, transverse* and *oblique arytenoid, aryepiglotticus, thyroarytenoid* and its subsidiary part, *vocalis*, and *thyro-epiglotticus*. All but the transverse arytenoid are paired.

The cricothyroid (8.13) is triangular and extends from the anterolateral external aspect of the cricoid cartilage. Its fibres diverge in two groups, a lower '*oblique*' *part* which slants posterolaterally to the anterior border of the inferior cornu of the thyroid and a superior '*straight*' *part* ascending backwards to the posterior part of the lower border of the thyroid lamina. The medial borders of the two muscles are separated by a triangular interval occupied by the conus elasticus.



The posterior crico-arytenoid (8.14) arises from the posterior surface of the cricoid lamina, on the inferomedial area of the depression present to one side of the midline. Ascending laterally its fibres converge to insert on the back of the arytenoid muscular process of the same side. The highest fibres are nearly horizontal, the middle oblique and the lowest almost vertical, some of the last reaching the anterolateral arytenoid surface.

The lateral crico-arytenoid (8.15), smaller than the preceding muscle, ascends obliquely back from the upper border of the cricoid arch to the front of the arytenoid muscular process of the same side.



The transverse arytenoid (8.14) is a single muscle which bridges the gap between the two arytenoid cartilages and fills their posterior concave surfaces. It is attached to the back of the muscular process and adjacent lateral border of both arytenoids.

The oblique arytenoids (8.14) lying superficial to the transverse, are disposed in two crossed fasciculi, each extending from the back of the muscular process of one arytenoid to the apex of the opposite cartilage. Some fibres continue laterally round the arytenoid apex into the aryepiglottic fold, as the *aryepiglottic* muscle.

The thyro-arytenoid (8.15), a broad, thin muscle, lies lateral to the vocal fold, cricothyroid ligament, laryngeal sinus and saccule. It extends from the lower half of the thyroid angle and cricothyroid ligament, ascending posterolaterally to the anterolateral arytenoid surface. Its lower, deeper fibres appear in coronal section as a triangular bundle attached to the lateral surface of the vocal process and to the inferior impression on the anterolateral surface of the arytenoid cartilage. This bundle, the **vocalis muscle**, is parallel and lateral to the vocal ligament; it is said to be thicker behind than in front, because many deeper fibres start from the vocal ligament and so do not reach the thyroid cartilage. Others consider that all its fibres loop and intertwine

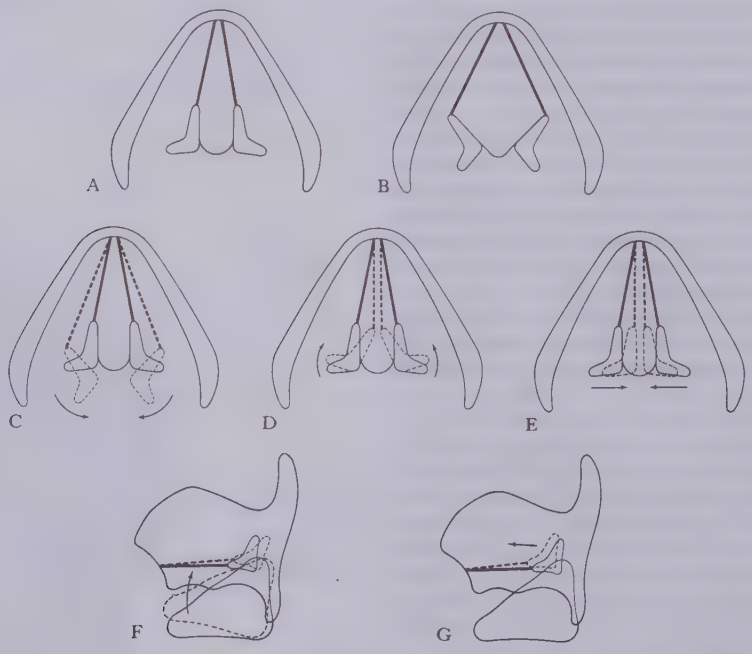
8.14 The muscles of the larynx: posterior aspect.

8.15 The muscles of the larynx (most of the left lamina of the thyroid cartilage has been removed): left lateral aspect.

from the thyroid to the arytenoid (Tautz & Rohen 1967). Many of the thyro-arytenoid fibres are prolonged into the aryepiglottic fold, where some cease, others continuing to the epiglottic margin as the **thyro-epiglotticus**. A few fibres extend along the wall of the sinus from the lateral arytenoid margin to the side of the epiglottis. The **superior thyro-arytenoid** (**8**.15), a small muscle not always present, is on the lateral surface of the thyro-arytenoid, extending obliquely from the thyroid angle to the arytenoid muscular process.

Actions. The laryngeal muscles may be placed in three groups according to their main actions (Negus 1947): (1) those which alter the glottis: *posterior* and *lateral crico-arytenoids* and *oblique* and *transverse arytenoids*; (2) those regulating tension of vocal ligaments: *cricothyroids*, *posterior crico-arytenoids*, *thyro-arytenoids* and *vocales*; (3) those which modify the laryngeal inlet: *oblique arytenoids*, *aryepiglottici* and *thyro-epiglottici* (**8**.16). Bilateral pairs usually act together.

(1) The *posterior crico-arytenoids* are the only laryngeal muscles which open the glottis, rotating the arytenoid cartilages laterally at the crico-arytenoid joints (p. 1252), thus separating the vocal processes and attached vocal folds. They also retract the arytenoids, assisting the cricothyroids to tense the vocal folds. The most lateral fibres draw the arytenoids laterally, so that the rima glottidis becomes triangular when the posterior crico-arytenoid muscles contract. The *lateral crico-arytenoids* close the glottis by rotating the arytenoids medially, to approximate their vocal processes. The *transverse arytenoid* approximates the arytenoid cartilages, closing the glottis in its posterior part.



(2) The *cricothyroids* stretch the vocal ligaments by raising the cricoid arch and tilting back its lamina, thus increasing the distance between the vocal processes and the thyroid angle, to tense the vocal ligaments, an effect which they also produce by pulling the thyroid cartilage forward; this is probably their principal action, for during phonation the cricoid lamina is held immovably against the vertebral column by the cricopharyngeus (p. 1328). During swallowing, however, the cricopharyngeus relaxes, allowing the cricoid to tilt forwards during laryngeal closure. The *posterior crico-arytenoids* tense the vocal ligaments by pulling the arytenoid cartilages backwards. The *thyro-arytenoids* draw the arytenoids towards the thyroid cartilage, shortening and relaxing the vocal ligaments. At the same time, they rotate the arytenoids medially to approximate the vocal folds. Their deeper fibres, the *vocales*, relax the posterior parts of the vocal ligaments, their anterior parts remaining tense and thus raising the vocal pitch. For details of arytenoid movements consult Sellars (1978).

(3) The *oblique arytenoids* and *aryepiglottici* act as a sphincter of the laryngeal inlet by adducting the aryepiglottic folds and approximating the arytenoid cartilages to the epiglottic tubercle. The *thyro-epiglottic* muscles widen the inlet by their action on the aryepiglottic folds.

Neuromuscular spindles exist in all human laryngeal muscles (Keene 1961), the maximum number (23) being in the transverse arytenoid (Voss 1966).

MOVEMENTS OF THE VOCAL FOLDS

In *quiet respiration*, (**8**.16) the anterior, intermembranous part of the rima glottidis is triangular when viewed from above, its apex being in front and its base behind, represented by a line (about 8 mm long) connecting the anterior ends of the arytenoid vocal processes; the intercartilaginous part is rectangular, between the medial surfaces of the arytenoids which lie parallel to each other. In *forced inspiration* the vocal folds are fully abducted; the arytenoid cartilages rotate laterally, their vocal processes moving apart. The glottis is then rhomboid, its intermembranous and intercartilaginous parts being both triangular, with

8.16 Different positions of the vocal folds and arytenoid cartilages.

A. Position of rest in quiet respiration. The intermembranous part of the rima glottidis is triangular and the intercartilaginous part is rectangular in shape.

B. Forced inspiration. Both parts of the rima glottidis are triangular in shape.

C. Abduction of the vocal folds. The arrows indicate the lines of pull of the posterior crico-arytenoid muscles. The abducted vocal folds and the abducted, retracted and laterally rotated arytenoid cartilages are shown in dotted outline. Both parts of the rima glottidis are triangular.

D. Adduction of the vocal folds. The arrows indicate the lines of pull of the lateral crico-arytenoid muscles. The adducted vocal folds and the medially rotated arytenoid cartilages are shown in dotted outlines.

E. Closure of the rima glottidis. The arrows indicate the line of pull of the transverse arytenoid muscle. Both the vocal folds and the arytenoid cartilages are adducted, but there is no rotation of the latter.

F. Tension of the vocal folds, produced by the action of the cricothyroid muscles which tilt the anterior part of the cricoid cartilage cranially and so carry the arytenoid cartilages dorsally.

G. Relaxation of the vocal folds, produced by the action of the thyro-arytenoid muscles, which draw the arytenoid cartilages ventrally.

the greatest width being opposite the attachments of the folds to the vocal processes.

Movements of the vocal folds during phonation have been studied by high-speed cinematography (Pressman 1942). Preparatory to phonation, the intermembranous and intercartilaginous parts of the glottis are reduced to a linear chink by adduction of the vocal folds and by adduction and medial rotation of the arytenoids. The folds then tense, the degree of tension determining sound pitch (frequency). To raise the pitch, tension is increased; the folds may lengthen by 50% in the highest tones. Photographs suggest that this lengthening affects both ends of the folds, indicating that the cricothyroid muscles act not only on the cricoid but also tilt the thyroid cartilage down and forwards. In whispering the intermembranous glottis is closed, but the intercartilaginous part remains widely patent, so that air escapes freely.

Fink (1975, 1978) considered that 'laryngeal biomechanics' depend much on the behaviour of various laryngeal *folds* which project into the laryngeal cavity to highly variable degrees dependent upon respiration, physical effort and phonation. In addition to the vocal, vestibular and aryepiglottic folds mentioned above, he identified *median thyrohyoid* and *interarytenoid folds*. The latter consists of the transverse arytenoid muscle and its covering mucous membrane which *folds* into the larynx when the muscle adducts the arytenoids (thus aiding obliteration of the intercartilaginous part of the rima glottidis). The median thyrohyoid fold is more complex: as shown in Fig. **8**.8, the lower part of the epiglottic cartilage is attached to the hyoid bone and thyroid cartilage by elastic ligaments (hyo-epiglottic and thyro-epiglottic p. 1253), separated from the median thyrohyoid ligament by adipose tissue, anterior to which is the elastic anterior part of the thyrohyoid membrane including the median thyrohyoid ligament. During swallowing (p. 1328) the thyroid cartilage and hyoid bone are approximated (in addition to general elevation of the pharynx, larynx and trachea). This causes the structures defined above to bulge posteriorly into the laryngeal inlet as a transverse fold and narrow it during swallowing. The reverse occurs during inspiration, all folds being reduced to a minimum. Intrusion of *all* the folds is important in phonation, since the vocal cavity (vide infra) is thereby altered, modifying its resonant properties. (The *median thyrohyoid fold* contains the so-called '*pre-epiglottic space*' of laryngeal surgery, an important region in the spread of supraepiglottic tumours (see Maguire & Dayal 1974).

The movements of the larynx during deglutition are described on p. 1329.

THE ANATOMY OF SPEECH

Though the respiratory function of the larynx is basic, its adaptation to speech and derivatives of speech is paramount in the emergence of human society and culture; the mute, deaf and illiterate are at great disadvantage. The intelligence, skill and enterprise of the gregarious primates, especially mankind, depends on intercommunication. Language, in all its permutations, firstly in speech for immediate tribal integrations of effort, then in recorded ideas and experience with all consequent accumulation and transmission of knowledge through time and space, is the foundation of human pre-eminence. Acquisition of language is perhaps the most complex sensorimotor achievement in the individual's life. Large cerebral territories are involved in the sensory, perceptual and motor aspects of speech (p. 1055). In addition to the auditory system and the intricate apparatus producing speech, speech involves not only the larynx and other respiratory organs, but also an extensive array of muscles, from the abdominal wall to the lips. These muscles are largely described elsewhere. Here we are concerned with the larynx and associated respiratory spaces.

The larynx is the primary source of the complicated series of sounds which are the basis of speech. In this context, therefore, its structure must now be considered, including also the pharynx, mouth and nasal cavities, which together constitute a 'vocal tract'. The physics of this phonation, the production of sounds and their articulation into *phonemes*, basic units of speech, has attracted less interest than other aspects of linguistics, which have engendered a vast literature, augmented by interdisciplinary approximation between workers in such diverse fields as 'hemispheric' anatomy, neurophysiology and the 'psychological' aspects of speech. Such investigations are outside the compass of this volume; but the acoustics of speech, in terms of the structure in the vocal tract, must be briefly considered.

As in most musical instruments, the mechanism of speech consists of three essentials: a source of energy, structures capable of periodic and aperiodic oscillations and a resonator. Energy is derived from the velocity of the expired air, oscillation primarily from the vocal folds and resonance from the multiform 'column' of air extending from the folds to the lips and nostrils. Variations in all three are intricate, rapid and require complex neural integration but are, nevertheless, subject to the same physical laws as, e.g., an organ pipe. They can be similarly analysed but not with the same simplicity or precision. The vocal folds vibrate with the same interactions of length, mass and tension as a vibrating string. The available increase in length, almost 50%, does not suffice for the range of frequencies characteristic of speech and certainly not for the octaves used in singing. Ranges vary with age and sex, the total for human speech being 60 to 500 cycles per second, with average central frequencies of about 100 for males, 200 for females and 250 for children. An individual's range is achieved by variation in *tension* and *mass* of the vocal folds, as well as length. Muscles such as the cricothyroid and posterior crico-arytenoid (p. 1255) affect tension *and* length. Changes in mass are probably effected by the thyro-arytenoid muscles, whose *pars vocalis* (p. 1255), partly attached to its vocal ligament, may bring about adjustments of length, tension and mass. Other intrinsic muscles also participate; the geometry of their attachments (p. 1255) indicates their effects. Electromyographic and photographic techniques have not yet contributed much to phonational mechanics. The modes of vibration of the vocal folds are complex (Van den Berg 1968, Wyke 1974, Hinchcliffe & Harrison 1976, Fry 1979). Numerous harmonics accompany any fundamental frequency and the orientation of waves in the vocal folds is complex. High-speed cinematography has revealed transverse and longitudinal waves, whose distribution varies even during a single phoneme. Commonly, at the start of phonation the glottis closes to a linear cleft in both intermembranous and intercartilaginous parts (**8**.16), the latter being narrowed by arytenoid rotation and approximation. The vocal folds come into contact, varying in the precise areas apposed, even during production of a single 'sound'. As air pressure increases below the vocal folds they are suddenly forced apart, recoiling elastically because pressure momentarily drops. This cycle is repeated at a fundamental frequency (and its harmonics) dependent on factors stated above and on the velocity and pressure of the air current. Re-apposition of the folds may be aided by muscular effort and by the 'Bernouilli effect', a kind of suction due to sudden decrease in pressure as the folds open. These events are measured in microseconds and impart pressure waves of like frequencies to the column of air above the vocal folds, which acts as a selective resonator. To term it a 'column' is an over-simplification; not only is it highly variable in shape and dimensions from level to level, and tortuous in its axis, but it is also adjustable within wide limits in respect of these properties *and* in the tension of its walls. The positioning of the tongue, fauces, soft palate and changes in other dimensions, all modify the vocal tract. The sound impressed upon the resonator, in all its dynamic variation of fundamental tone and harmonics, is thus subjected to a second modification, some harmonics being dampened, others enhanced. The analysis of the final 'spectrum' of frequencies in particular sounds may be represented graphically against co-ordinates of frequency and amplitude. Such investigations show that the vocal tract acts as an intricately selective filter and resonator, propagating a remarkably similar and individual pattern or 'envelope' irrespective of the fundamental frequencies produced by the vocal folds. This is essential to maintaining a constant quality or

timbre, despite a continuously varying tone. The term *formant* is also used, as in musical instruments; e.g. a flute sounds like a flute over a wide register, because the formant is characteristic throughout. Each voice similarly has an identifiable formant or quality; if this constantly varied, especially in the tones given to vowel sounds, intelligibility would be lost.

So far we have considered only production of *tones* but, however complex, these do not constitute speech, in which the phonetic permutation of a small repertoire of vowels is vastly enriched by imposition of consonants, i.e. by *articulation*. Consonants are associated with particular anatomical sites, from which they are designated in the terminology of phonetics, e.g. we speak of *labials (p and b)*, *dentals (t and d)*, *nasals (m and n)* and so on. These sites have two similarities: (1) a partial obstruction at some level of the vocal tract, and (2) production of aperiodic vibration, i.e. noise, superimposed upon or interrupting the flow of laryngeal tones. This complex subject can only be touched upon here. It is easy to ascertain subjectively that in pronouncing dental consonants the tip of the tongue is apposed to the back of the teeth. This momentarily obstructs escaping air, modifies resonant parameters and generates local noise. The vocal tract is considered to consist of a long column from vocal folds to lingual tip combined with a short one from teeth to lips. This 'resonator' may be divided by appositional constrictions into less unequal moieties, e.g. by approximation of the tongue to the palate (hard or soft) and at other levels. Each 'setting' of the anatomical resonator, as with the vocal folds, adds a characteristic to the total acoustic product which must be identifiable as a significant event in the stream of speech if this is to be intelligible.

These anatomical changes in the larynx and resonating vocal tract are effected in small fractions of a second, with a speed, adroitness and subtlety impossible to convey in verbal description. The multiplicity of laryngeal, pharyngeal, hyoidean, palatal, lingual and circumoral muscles, linked in rapidly changing combinations for phonation and articulation, reflects the remarkable complexity of speech. It is not surprising that one philosopher (Chomsky 1965) has suggested that the cerebrum, particularly its 'dominant hemisphere', is genetically programmed for language (p. 1065). Apart from these wider implications, phonetics is a larger study than can be considered here, even superficially in its strictly anatomical connections. Enough has been said, perhaps, to demonstrate the usefulness of the anatomy of speech to phoneticians and others and to stimulate anatomists to a deeper appreciation of the phonetic functions of the larynx and vocal tract.

THE LARYNGEAL MUCOUS MEMBRANE

The laryngeal mucosa, continuous with that of the pharynx, mouth and trachea, is loosely attached to the anterior surface of the epiglottis and to the lining of the valleculae. It covers the aryepiglottic folds, which limit the laryngeal inlet and contain some fibro-areolar tissue. It lines the laryngeal cavity, largely forms the vestibular folds and continues into the laryngeal sinus and saccule. It is firmly attached to the posterior epiglottic surface and to the laryngeal surfaces of the cuneiform and arytenoid cartilages. On the vocal ligaments it is thin and adherent. On the anterior epiglottic surface and its posterior upper half, the upper parts of the aryepiglottic folds and the vocal folds, the epithelium is stratified squamous (**8**.5B); other such areas occur above the glottis. Elsewhere in the larynx it is ciliated columnar in type. The ultrastructure of the laryngeal epithelium of the rat has been described in detail by Lewis & Prentice (1980).

The laryngeal mucosa has numerous *mucous glands*, especially over the epiglottis, where they pit the cartilage, and along the margins of the aryepiglottic folds anterior to the arytenoid cartilages, where they are termed the *arytenoid glands*. Many large glands in the saccules secrete periodically over the vocal folds during phonation; the edges of these folds are devoid of glands, their stratified epithelium thus being vulnerable to drying and requiring the secretions of neighbouring glands. Hoarseness due to excessive speaking is due to partial temporary failure of this secretion. Scanning electron microscopy demonstrates microvilli and microplicae on the surface epithelial cells of the vocal folds and elsewhere in the larynx (Andrews 1975, Tillmann et al 1977), features common to other epithelia subjected to drying (e.g. corneal epithelium). Microplicae are regarded as aiding the retention of surface secretions.

Taste buds, like those in the tongue, occur on the posterior epiglottic surface, aryepiglottic folds and less often in other laryngeal regions. Their centripetal pathway is via the vagus nerve.

LARYNGEAL VESSELS AND NERVES

The chief *arteries* of the larynx are rami of the superior and inferior thyroid arteries; their accompanying *veins* join both the superior thyroid vein, opening into the internal jugular, and the inferior thyroid vein, draining into the left brachiocephalic. *Lymph vessels* form groups above and below the vocal folds; the superior accompany the superior laryngeal artery, traverse the thyrohyoid membrane and end in the deep cervical lymph nodes near the bifurcation of the common carotid artery; some of the inferior group of lymphatics pierce the cricothyroid ligament to reach a lymph node in front of the ligament or the upper trachea; others pass below the cricoid cartilage to the deep cervical lymph nodes and to nodes along the inferior thyroid artery. The *nerve supply* is from the internal and external branches of the superior laryngeal and from the recurrent laryngeal and sympathetic nerves. The internal laryngeal ramus is probably entirely sensory and autonomic, although special visceral motor fibres to the transverse arytenoid have been reported (Williams 1951). This nerve enters postero-inferiorly through the thyrohyoid membrane above the superior laryngeal artery; its branches supply both epiglottic surfaces, the aryepiglottic fold and the laryngeal interior as far as the vocal folds. The external laryngeal nerve (p. 1117) supplies the cricothyroid muscle, which it enters via its external surface. Terminally the recurrent laryngeal nerve and the laryngeal branch of the inferior thyroid artery ascend medial to the lower border of the inferior pharyngeal constrictor immediately behind the cricothyroid joint, supplying all the intrinsic laryngeal muscles except the cricothyroid and innervating the mucosa below the vocal folds. Before entering the larynx this nerve usually divides into motor and sensory rami, not 'adductor' and 'abductor' rami as is sometimes asserted (Williams 1954). Motor units in such skilled musculature might be expected to be small: a ratio of 30 muscle fibres to each motor neuron has been estimated (English & Blevins 1969).

Laryngoscopic Examination

The laryngeal inlet, the structures around it and its cavity can be inspected by suitable optics e.g. a laryngoscopic mirror (**8**.12). The epiglottis is seen foreshortened, but its tubercle is visible. From the epiglottic margins the aryepiglottic folds can be traced posteromedially and the cuneiform and corniculate elevations recognized. The pink vestibular folds and white vocal folds are visible and, when the rima glottidis is wide open, the tracheal mucosa and cartilages may be seen. The piriform fossae can also be inspected.

Radiography

In lateral cervical radiographs (**8**.20) the epiglottis, aryepiglottic folds, arytenoid, corniculate and sometimes cuneiform cartilages and laryngeal sinus are all visible, as well as ossification in the cartilages.

Surface and Applied Anatomy

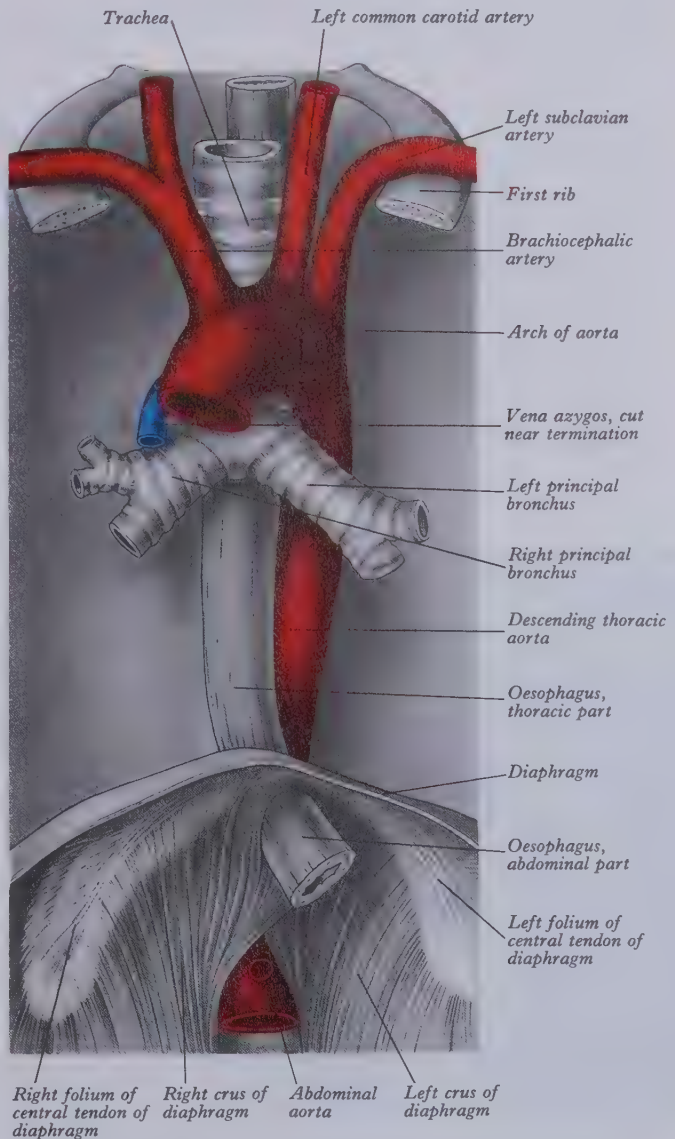
Around the midline of the neck the following structures can be identified (**5**.33). The laryngeal prominence is visible in men, but not always in women. (The vocal folds are nearly level with the midpoint of the prominence.) The superior borders of the thyroid laminae and the thyroid notch are palpable. Above the thyroid, the hyoid bone's body and greater cornua can be felt, the latter most convincingly when the throat at this level is gripped between finger and thumb. The thyrohyoid membrane is in the

depression between the thyroid cartilage and the hyoid bone; below the thyroid cartilage, the cricoid can be felt; it is level with the sixth cervical vertebral body. Between the cricoid and thyroid cartilage is the cricothyroid ligament. Below the cricoid is the first tracheal cartilage. Foreign bodies may obstruct the laryngeal inlet or rima glottidis and suffocation may ensue. Small foreign bodies may enter the trachea or bronchi or lodge in the laryngeal sinus and cause reflex glottic spasm with consequent suffocation. Inflammation of the upper larynx may swell the mucosa by effusion of fluid into an abundant, lax submucous tissue (oedema of the glottis). The effusion does not involve or extend below the vocal folds, since the mucosa adheres directly to the vocal ligaments without the intervention of submucous tissue. Laryngotomy *below* the vocal folds through the cricothyroid ligament or tracheotomy may be necessary to restore a free airway. The mucosa of the upper larynx is highly sensitive; contact with foreign bodies excites immediate coughing. Suicidal wounds are usually through the thyrohyoid membrane, damaging the epiglottis, superior thyroid vessels, external and internal carotid arteries and internal jugular veins; less frequently they are above the hyoid with damage to the lingual muscles and lingual and facial vessels. (For the results of damage to the laryngeal nerves, see p. 1118.)

The Trachea and Bronchi

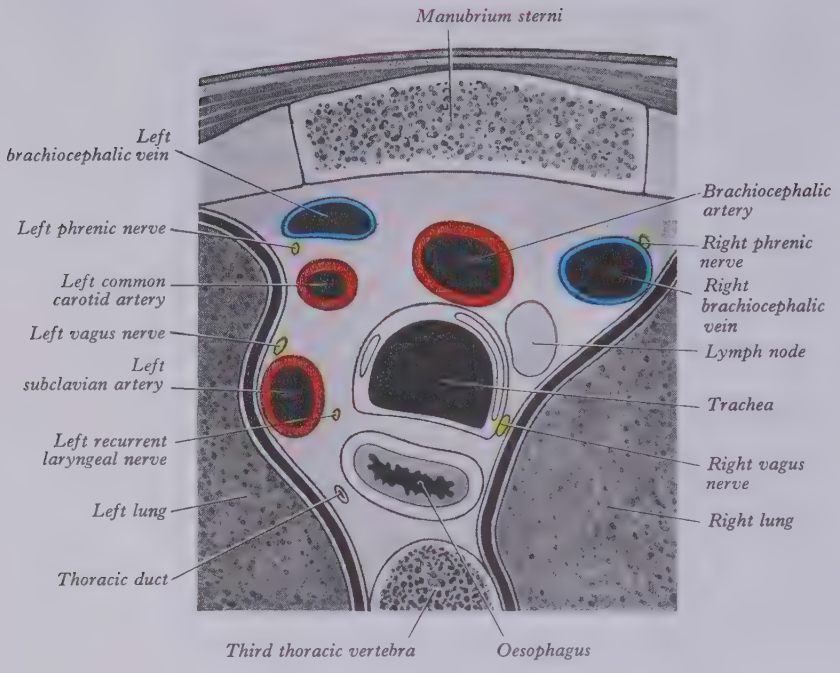
THE TRACHEA

The trachea, a tube of cartilage and fibro-muscular membrane, about 10–11 cm long, descends from the larynx (**8**.21, 22), extending from the level of the sixth cervical to the upper border of the fifth thoracic vertebra, where it divides into right and left principal (pulmonary) bronchi. It lies approximately in the sagittal plane but its point of bifurcation is usually a little to the right. During deep inspiration the bifurcation may descend to the sixth thoracic vertebral level. The trachea is mobile and can rapidly alter in length. It is less than cylindrical, being flattened posteriorly; its external transverse diameter is about 2 cm in adult males, 1.5 cm in adult females. In children it is smaller, more deeply placed and more mobile. In the living the lumen is smaller than in the dead, its diameter in adults being about 12 mm. In the first year, tracheal diameter does not exceed 3 mm while during childhood its diameter in millimetres is about equal to age in years. The transverse shape of the lumen is variable, especially in later decades, being round, lunate or flattened (Campbell & Liddelow 1967). Wang & Tai (1965) have studied tracheobronchial dimensions extensively; in Chinese subjects (presumably cadavers) the tracheal lumen averaged 16.17 mm (range 9.5–22.0 mm).



Relations of the Trachea

The *cervical part* of the trachea (**6**.68) is covered *anteriorly* by skin, superficial and deep fasciae, crossed by the jugular arch and overlapped by the sternohyoid and sternothyroid muscles. The second to fourth tracheal cartilages are crossed by the isthmus of the thyroid gland, above which an anastomotic artery connects the superior thyroid arteries; below this, in front, are the pretracheal fascia, inferior thyroid veins, thymic remnants and the arteria thyroidea ima (when it exists). In children the brachiocephalic artery crosses obliquely in front of the trachea at or a little above the upper manubrial level; the left brachiocephalic vein may also rise a little above the manubrium. *Posterior* is the oesophagus, between the trachea and the vertebral column; the recurrent laryngeal nerves ascend, on each side, in or near the grooves between the sides of the trachea and oesophagus. *Lateral* are the lobes of the thyroid gland, descending to the fifth or sixth tracheal cartilage, and the common carotid and inferior thyroid arteries.

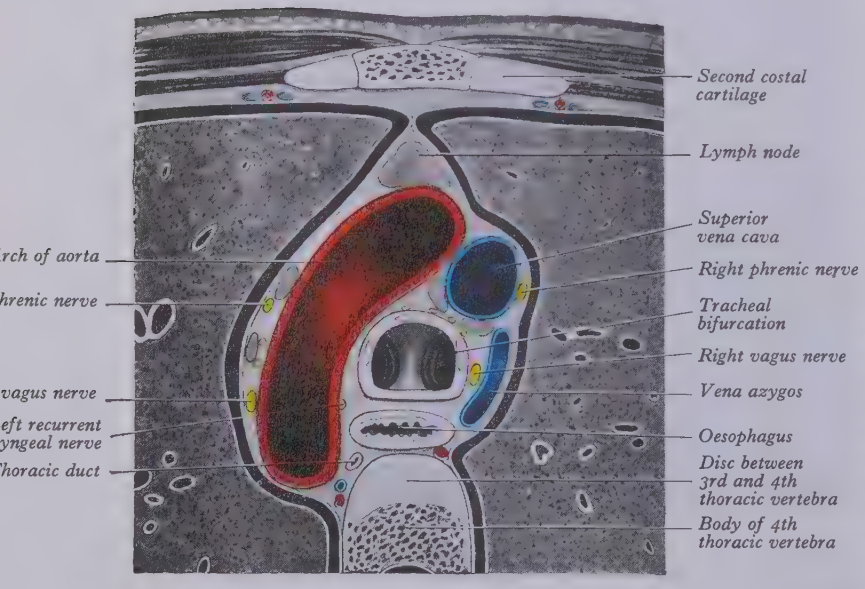


The *thoracic part* of the trachea (**8**.17, 18, 19, 23) descends through the superior mediastinum, related *anteriorly* to: the manubrium sterni, the attachments of the sternohyoid and sternothyroid muscles, the thymic remnants, the inferior thyroid and left brachiocephalic veins, the aortic arch, the brachiocephalic and left common carotid arteries, deep cardiac plexus and some lymph nodes. Diverging as they ascend in the neck the brachiocephalic and left common carotid arteries become respectively right and left of the trachea. *Posterior* is the oesophagus, separating the trachea from the vertebral column. On the *right* are: the right lung and pleura, right brachiocephalic vein, superior vena cava, right vagus nerve and the azygos vein; on the *left*: the arch of the aorta, left common carotid and left subclavian arteries. The left recurrent laryngeal nerve is at first between the trachea and aortic arch, then in or just in front of the groove between the trachea and the oesophagus.

THE RIGHT PRINCIPAL BRONCHUS

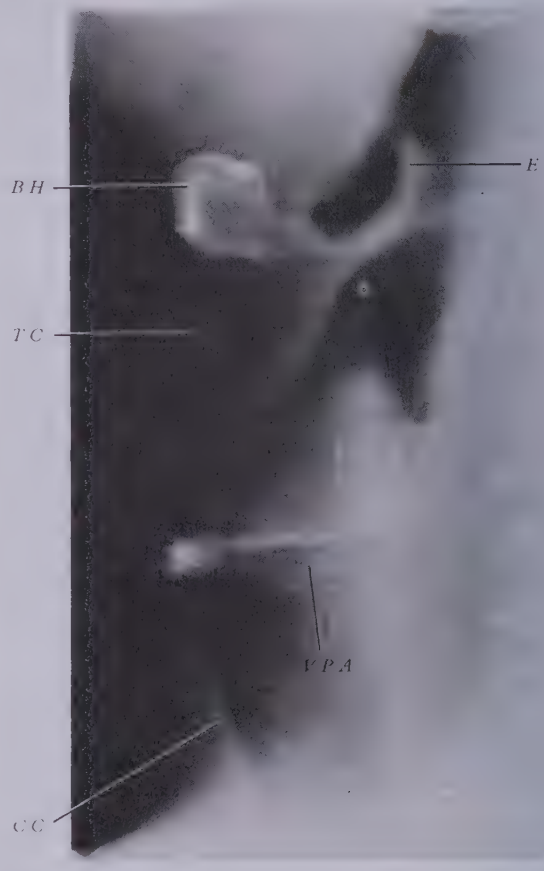
The right principal bronchus (**8**.21, 22, 24) is wider, shorter and more vertical than the left, being about 2.5 cm long. It gives rise to its first branch, the *superior lobar bronchus* and then enters the right lung opposite the fifth thoracic vertebra. Its greater width and more vertical course explain the greater frequency of foreign bodies entering the right principal bronchus than the left. The azygos vein arches over it and the right pulmonary artery lies at first inferior, then anterior to it. Beyond its first branch, the *superior lobar bronchus*, which arises posterosuperior to the

8.17 Dissection to show the bifurcation of the trachea and the principal bronchi.



8.18 Transverse section through the mediastinum at the level of the body of the third thoracic vertebra, viewed from the superior aspect.

right pulmonary artery, it crosses the posterior aspect of this artery to enter the pulmonary hilum postero-inferior to the artery and then divides into a *middle* and an *inferior lobar bronchus*.



The right superior lobar bronchus arises from the lateral aspect of the parent bronchus and runs superolaterally to enter the hilum. About 1 cm from its origin it divides into three segmental bronchi: the *apical segmental bronchus* continues superolaterally towards the apex of the lung, which it supplies dividing near its origin into apical and anterior branches; the *posterior segmental bronchus* serves the postero-inferior part of the superior lobe, passing posterolaterally and slightly superiorly and soon dividing into a lateral and a posterior branch; the *anterior segmental bronchus* runs antero-inferiorly to supply the rest of the superior lobe; it divides near its origin into a lateral and an anterior branch of equal size.

The middle lobar bronchus starts about 2 cm below the superior, from the front of the parent trunk, descends antero-laterally and soon divides into a *lateral* and a *medial segmental bronchus* to the lateral and medial parts of the middle lobe, respectively.

The right inferior lobar bronchus is the continuation of the principal bronchus beyond the origin of the middle lobar. At or a little below this point, it gives off posteriorly a large *superior* (apical) *segmental bronchus* which runs posteriorly to the upper part of the inferior lobe, subsequently dividing into medial, superior and lateral branches, the first two usually arising from a common stem. After giving off this branch, the right inferior lobar bronchus descends posterolaterally. The *medial basal segmental bronchus* branches from it anteromedially, running inferomedially to serve a small region below the hilum; the inferior lobar bronchus continues downwards then divides into an *anterior basal segmental bronchus*, which descends anteriorly, and a trunk which soon divides into a *lateral basal segmental bronchus* descending laterally and a *posterior basal segmental bronchus* descending posteriorly. In more than half of all right lungs a *subsuperior* (subapical) *segmental bronchus* arises posteriorly from the right inferior lobar bronchus 1–3 cm below the superior segmental bronchus. This is distributed to the region of the lobe between the superior and posterior basal segments.

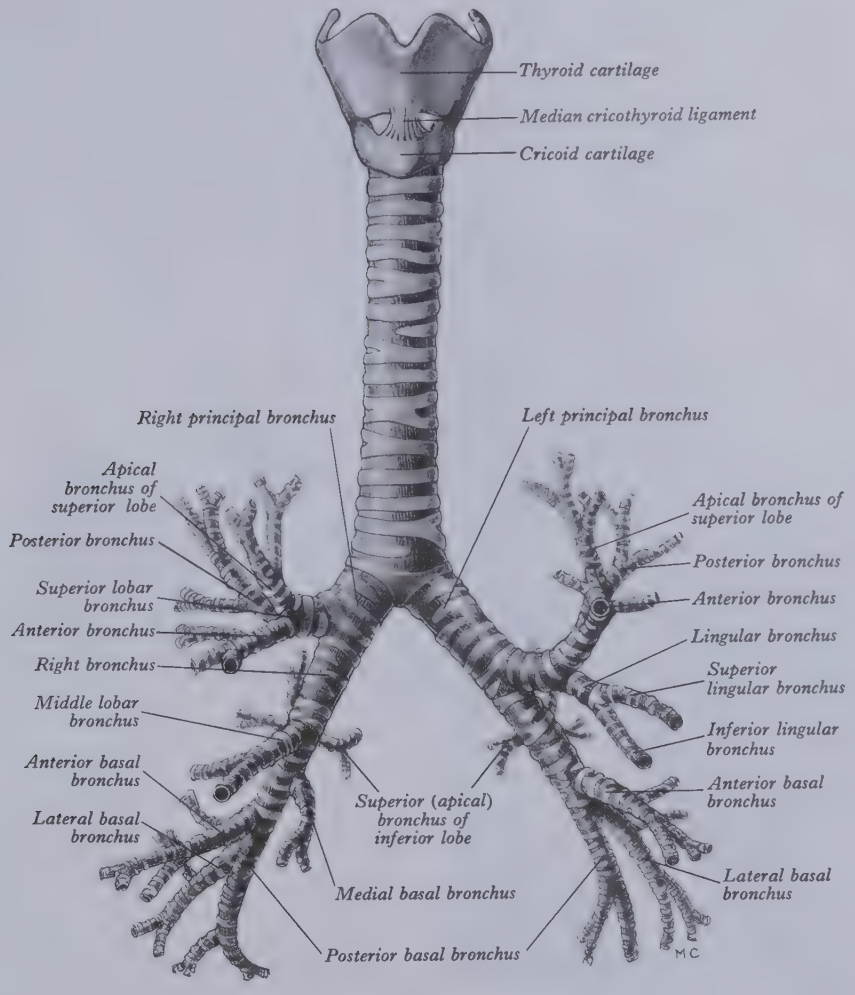
8.20 Lateral soft tissue radiograph of the larynx and adjacent structures in a young adult. BH = body of hyoid bone; CC = cricoid cartilage; E = epiglottis; TC = thyroid cartilage; VPA = vocal process of arytenoid cartilage. Supplied by Shaun Gallagher, Guy's Hospital; photography by Sarah Smith, UMDS, Guy's Campus, London.

THE LEFT PRINCIPAL BRONCHUS

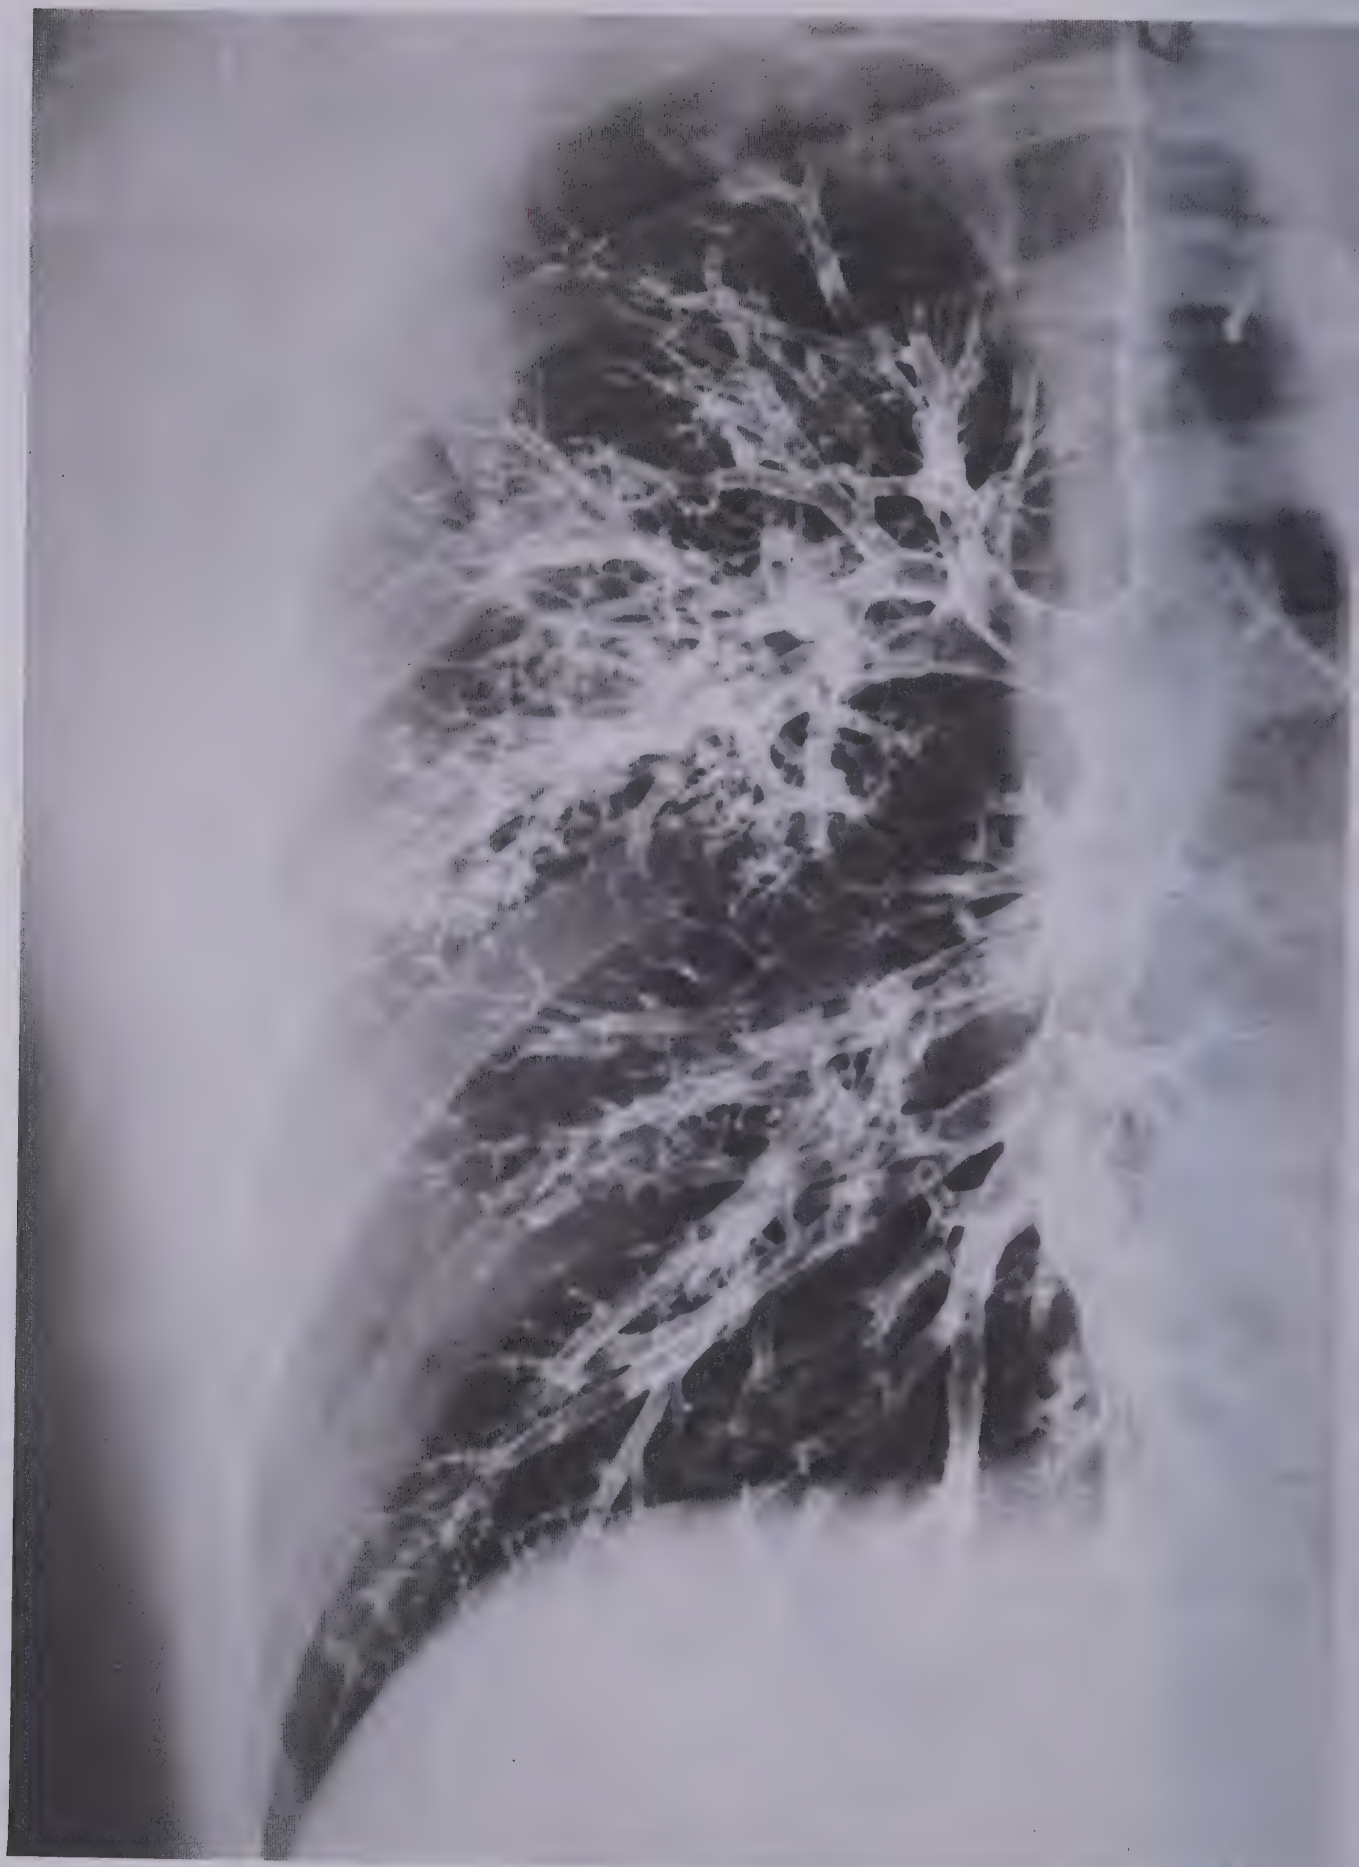
The left principal bronchus (**8**.21, 24), which is narrower and less vertical than the right and nearly 5 cm long, enters the left hilum level with the sixth thoracic vertebra. Passing left inferior to the aortic arch, it crosses anterior to the oesophagus, thoracic duct and descending aorta; the left pulmonary artery is at first anterior and then superior to it. Having entered the hilum it divides into a superior and an inferior lobar bronchus.

The left superior lobar bronchus, arising from the antero-lateral aspect of its parent stem, curves laterally and soon divides into two bronchi. These correspond to the branches of the right principal bronchus supplying the right superior and middle lobes but on the left both are distributed to the left *superior* lobe, there being no separate middle lobe. The *superior division* ascends about 1 cm, gives off an *anterior segmental bronchus*, then continues a further 1 cm as the *apicoposterior segmental bronchus* before dividing into apical and posterior branches. The apical, posterior and anterior segmental bronchi are largely distributed as in the right superior lobe. The *inferior division* descends anterolaterally to the antero-inferior part of the left *superior* lobe, the *lingula*, forming the *lingular bronchus* which divides into *superior* and *inferior lingular segmental bronchi*, unlike the pattern in the right middle lobe.



The left inferior lobar bronchus descends posterolaterally for 1 cm and then the *superior* (apical) *segmental bronchus* arises from it posteriorly and is distributed in essentially the same manner as in the right lung. After a further 1–2 cm it divides into an anteromedial and a posterolateral stem. The former divides into *medial basal* and *anterior basal segmental bronchi*; the latter into *lateral* and *posterior basal segmental bronchi*. The territories supplied resemble those on the right. The medial basal segmental bronchus is an independent branch of the inferior lobar bronchus in about 10% of lungs; this, and the similarity of its territory to that on the right, supports its recognition as a separate segmental bronchus. A *subsuperior* (subapical) *segmental bronchus* arises posteriorly from the left inferior lobar bronchus in 30% of lungs.

BRONCHOPULMONARY SEGMENTATION

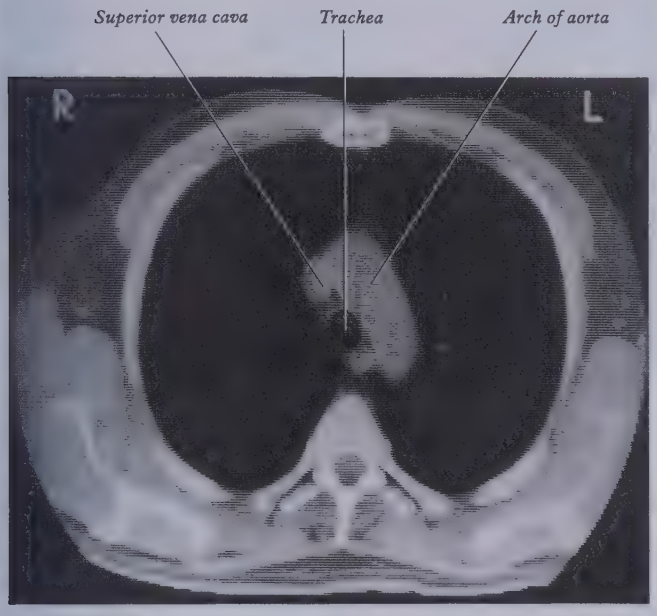


Primary branches of the right and left *lobar bronchi* are termed *segmental bronchi* because each ramifies in a structurally separate, functionally independent unit of lung tissue called a *bronchopulmonary segment* (**8**.24, 25). The main segments are *named* and *numbered* as follows:

Right

Superior lobe:	(1) apical, (2) posterior, (3) anterior.
Middle lobe:	(4) lateral, (5) medial.
Inferior lobe:	(6) superior (apical), (7) medial basal, (8) anterior basal, (9) lateral basal, (10) posterior basal.

8.21 The cartilages of the larynx, trachea and bronchi: anterior aspect. Drawn from a metal cast made by Lord Russell Brock, Guy's Hospital, London.



8.22 A slightly oblique, anteroposterior view of the trachea and right bronchial tree, after insufflation of a radio-opaque contrast medium. For identification of the lobar and segmental bronchi in this bronchogram, compare with illustrations of bronchial tree casts (8.21, 24).

Left Lung

Superior lobe:	(1) apical, (2) posterior, (3) anterior, (4) superior lingular, (5) inferior lingular.
Inferior lobe:	(6) superior (apical), (7) medial basal, (8) anterior basal, (9) lateral basal, (10) posterior basal.

Each segment, surrounded by connective tissue continuous with the visceral pleura, is a separate respiratory unit. The vascular and lymphatic arrangements of the segments are described on pp. 857, 1282. (For further details of segmentation consult Brock 1942, 1943, 1944, 1954, Boyden 1955, Bloomer et al 1960, Volpe et al 1969).

Applied Anatomy. While pathological conditions such as bronchiectasis and some infections may be restricted to one or more bronchopulmonary segments, malignant neoplasms and tuberculosis are not so confined. A knowledge of bronchial branching is essential during bronchoscopy and for the correct interpretation of bronchograms. It is also determinative in the postural drainage of infected pulmonary regions. The superior (apical) segment of the inferior lobe is a common site of abscess following aspiration of material by supine patients. Inhaled foreign bodies may obstruct a main, lobar, segmental or smaller bronchus according to their size. The interpretation of their effects and the design of surgical treatment inevitably involve considerations of bronchial branching patterns. Resection of a single segment is practicable, while more extensive procedures may include the removal of several segments, lobectomy or a complete pneumonectomy.

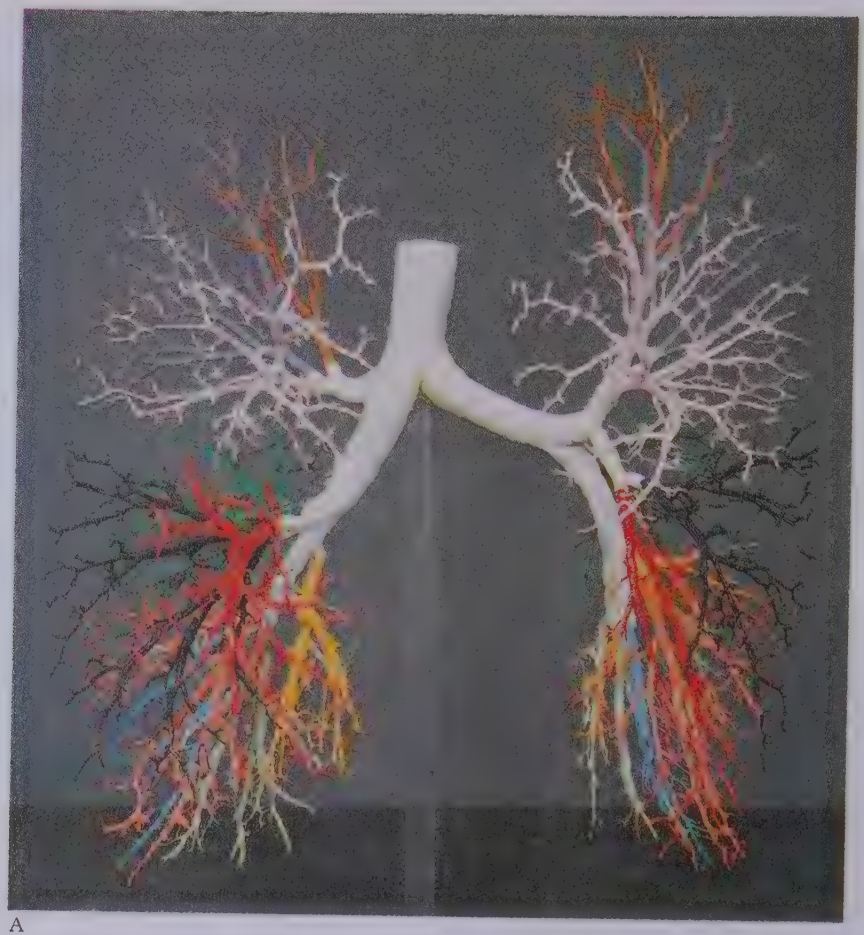
STRUCTURE OF THE TRACHEA AND MAJOR BRONCHI

The trachea and extrapulmonary bronchi have a framework of incomplete rings of hyaline cartilage, united by fibrous tissue and non-striated muscle (8.26) and lined by mucosa (8.27).



8.23A Computed tomogram in the transverse plane of the thorax at the level of the sternoclavicular joint. Provided by Shaun Gallagher, Guy's Hospital; photography by Sarah Smith, UMDS, Guy's Hospital Campus, London.

Tracheal cartilages vary from 16 to 20, each an imperfect 'ring' surrounding approximately the anterior two-thirds of the tracheal circumference; behind, where they are deficient, the tube is flat and is completed by fibro-elastic tissue and non-striated muscle. The cartilages are horizontally stacked, separated by narrow intervals and are about 4 mm vertically and 1 mm in thickness; their external surfaces are vertically flat, their internal convex. Two or more cartilages often unite, partially or completely, and sometimes bifurcate at their ends. They are hyaline but may become calcified in the aged. In extrapulmonary bronchi, cartilages are shorter, narrower and

8.24 (*opposite*) A. A resin corrosion cast of the adult human lower trachea and bronchial tree photographed from the anterior aspect. The segmental bronchi and their main branches have been coloured: apical (brown), posterior (grey/blue), anterior (pink), lateral (middle lobe) and superior lingular (dark blue), medial (middle lobe) and inferior lingular (red), superior (apical) of inferior lobe (dark green), medial basal (yellow), anterior basal (orange), lateral basal (blue), posterior basal (light green).

B. Corrosion cast, left lung: lateral view (colour coding as above).

C. Corrosion cast, right lung: lateral view (colour coding as above). Note that in the final preparation of such specimens large amounts of finer detail have been carefully removed to reveal the major arrangement of the bronchial 'tree'.

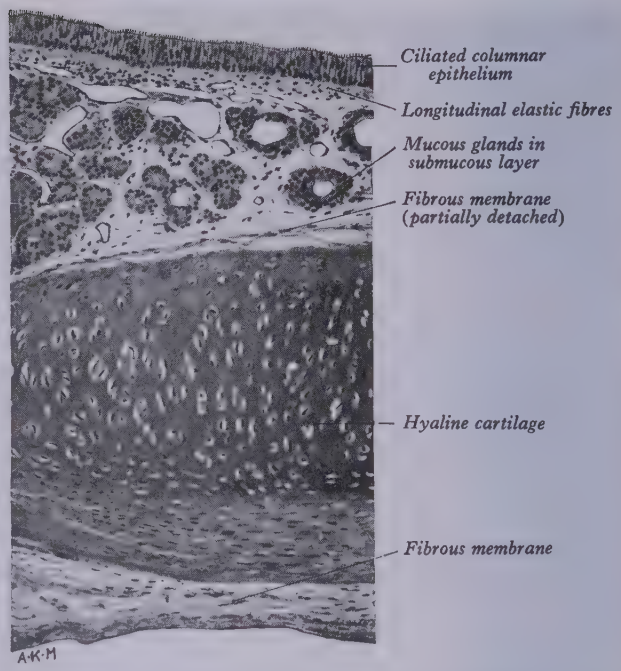
8.25 (*above*) Specimens of human lungs in which the segmental bronchi have been injected with coloured gelatin. Unfixed specimens of the human lungs were obtained at post-mortem. The bronchial trees were washed out with water and individual segmental bronchi, identified by dissection, were cannulated separately and injected with gelatin of contrasting colours. The lungs were subsequently fixed in 10% formaldehyde solution. A. costal surface of left lung; B. costal surface of right lung; C. mediastinal surface of left lung; D. mediastinal surface of right lung. Approximately the same colour convention has been used as for the corrosion cast shown in **8.24**A. In these specimens, however, in the right lung a subsuperior segment is present in the inferior lobe and is coloured white. All specimens were prepared by M C E Hutchinson and photographed by Kevin Fitzpatrick of the Department of Anatomy, Guy's Hospital Medical School, London.

less regular but generally similar in shape and arrangement.

The first and last tracheal cartilages differ (**8**.21); the *first cartilage* is the broadest, often bifurcate at one end, connected by a cricotracheal ligament to the inferior cricoid border and sometimes blended with the cricoid or second cartilage. The *last cartilage* is centrally thick and broad and its lower border, the *carina*, is a triangular unciform process curving down and backwards between the bronchi. On each side it forms an imperfect ring enclosing the start of a principal bronchus. The penultimate cartilage is centrally broader than the others.

The irregularity of the cartilaginous plates in the extrapulmonary bronchi increases distally; as major bronchi approach their lungs and lobes, plates invade their dorsal aspects but never quite encompass their bifurcations. In intrapulmonary bronchi plates of cartilage progressively form less and less of the bronchial wall, disappearing where the bronchioles begin (**8**.19A, 28A, Reid 1976.)

The Fibrous Membrane



Each cartilage is enclosed in perichondrium, continuous with a dense fibrous membrane between the adjacent cartilages which also fills in the back of the trachea. The perichondrium and membrane are mainly composed of collagen with some elastin fibres; fibres cross diagonally, allowing changes in luminal diameter, the elastic component providing some recoil from stretching. Non-striated muscle fibres appear posteriorly in the membrane; most are transverse, being attached to the perichondrium at the ends of the cartilages and forming a transverse sheet between them. Contraction therefore alters the cross-sectional area of the trachea and bronchi. A few external longitudinal fibres also occur. Non-striated muscle in intrapulmonary bronchi is not attached to cartilages and, where these begin to disappear, i.e. in smaller bronchi, contraction may actually obliterate the lumen (Reid 1976).

The Mucous Membrane (Tunica mucosa)

This is continuous with and closely resembles that of the larynx above and the intrapulmonary bronchi below, being a layer of pseudostratified ciliated columnar epithelium interspersed with goblet cells (Dalen 1983), both lying on a basal lamina (**8**.26, 27). Some pseudostratified cells possess unusually large nuclei and may be polytene in chromosomal content. Numerous lymphocytes usually occur deep in the epithelium. The cilia impel mucus towards the laryngeal inlet (aditus). Deep to the basal lamina are a lamina propria with abundant longitudinal elastic fibres and a submucosa of loose connective tissue containing larger blood vessels, nerves and most of the tubular (tracheal) seromucous glands and lymphoid nodules; external to the submucosa are the perichondrium and the fibrous membrane. Most external of all is the deep fascia, merging with the fascial planes of the surrounding muscles, oesophagus and associated structures.

Vessels and Nerves

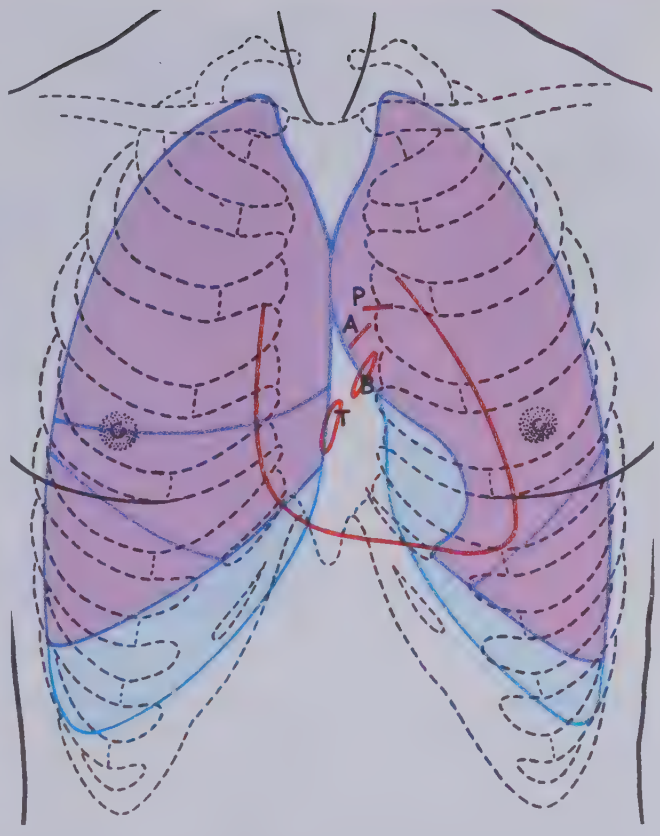
The trachea is supplied with blood mainly by the inferior thyroid *arteries*, while its thoracic end is also supplied by the bronchial arteries, whose branches ascend to anastomose with the former; all the vessels also supply the oesophagus. The *veins* draining the trachea end in the inferior thyroid venous plexus. The *lymph vessels* pass to the pretracheal and paratracheal lymph nodes. The *nerve supply* is from the tracheal branches of the vagi, recurrent laryngeal nerves and the sympathetic trunks and is distributed to the tracheal muscle and mucosa. Sympathetic nerve endings evoke bronchodilatation by releasing catecholamines; they may also exert a direct aminergic effect on glandular acini in the bronchi (Pack & Richardson 1984). Parasympathetic activity which is cholinergic causes bronchoconstriction. Many small postsynaptic ganglia occur in the autonomic plexuses of the tracheal and bronchial walls (Feyler 1965). In cats, paraganglia composed of chromaffin cells and arteriovenous anastomoses appear in the bronchial wall

8.26 Transverse section through a part of the wall of a human trachea.

(Muratori 1965). For a quantitative technique of assessing amounts and distribution of the tissues in the bronchial walls, normal or pathological, see Hale et al (1968).

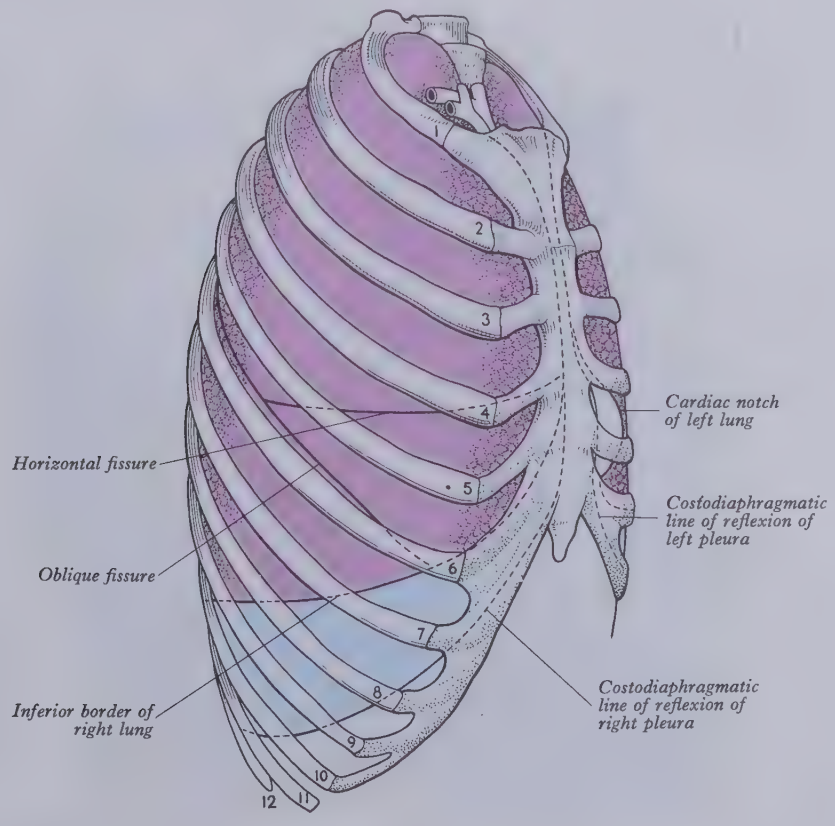
Surface and Applied Anatomy. The *trachea* is about 2 cm wide and extends almost vertically in the midline from the cricoid cartilage to the sternal angle, inclining slightly to the right. The *right principal bronchus* runs from the trachea down to the right for 2.5 cm to the right hilum behind the sternal end of the right third costal cartilage. The *left principal bronchus* runs for 5 cm more obliquely to its left and down to the hilum behind the left third costal cartilage, 3.5 cm from midline. The trachea may be opened by median vertical incision above the thyroid isthmus

8.27 Surface view of the ciliated epithelium of the trachea (rat). Mucus-secreting goblet cells occur between the ciliated cells. Prepared by Michael Crowder, Department of Anatomy, Guy's Hospital Medical School, London. Magnification × 5100.



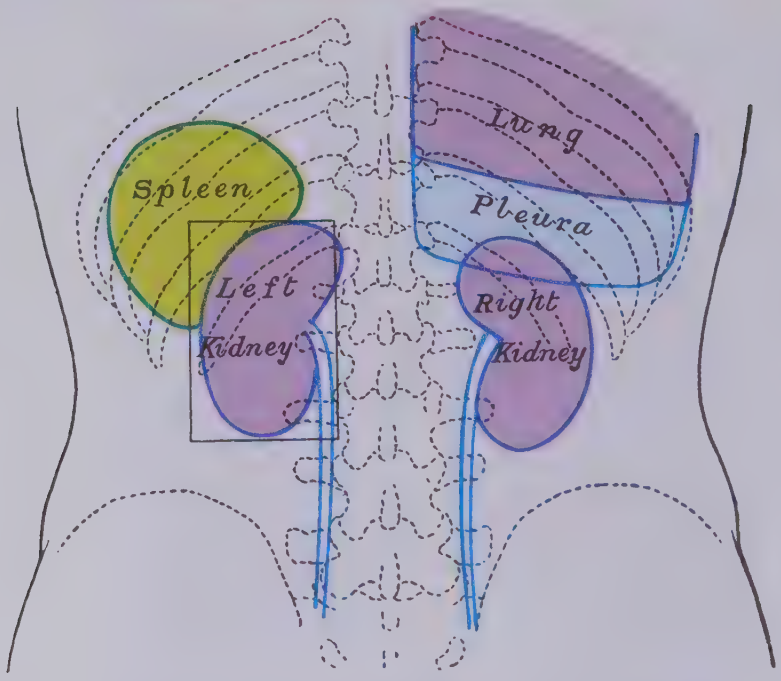
(high tracheotomy) or below it (low tracheotomy), the latter being more difficult because the trachea recedes as it descends and has hazardous anterior relations (p. 1259). The trachea may be compressed by pathological enlargements of the thyroid gland, thymus and aortic arch. The radiological appearances of the trachea, bronchi and lungs are dealt with on p. 1286.

Bronchoscopy. By means of a bronchoscope passed through the mouth and larynx under local anaesthesia, the interior of the larynx, trachea and bronchi, with the openings of the main segmental branches (pp. 1259–1263), may all be examined and biopsies taken; foreign bodies or accumulations of fluid may also be removed.



The Pleurae

Each lung is covered by *pleura*, a serous membrane arranged as a closed invaginated sac. Part of the pleura adheres to the pulmonary surface and its interlobar fissures as *visceral* or *pulmonary pleura*. Its continuation lines the corresponding half of the thoracic wall, covers much of the diaphragm and structures occupying the middle region of the thorax; this is *parietal pleura*. The pulmonary and parietal pleurae are continuous around the hilar structures. They remain in close though sliding contact at all phases of respiration, the potential space between them being the *pleural cavity*. When air or fluid collects between the two layers, the pleural cavity expands. The right and left pleural sacs are distinct from each other and touch only behind the upper half of the sternal body (**8**.28A), although they are also close to each other behind the oesophagus at the mid-thoracic level. The region between them is the *mediastinum* (interpleural space). The left pleural cavity is the smaller of the two because the heart extends further left. Upper and lower pleural limits are about the same on the two sides, but the left sometimes descends lower in the mid-axillary line.



The pulmonary pleura is adherent to the lung over all its surfaces including those in the fissures, but absent from the hilar

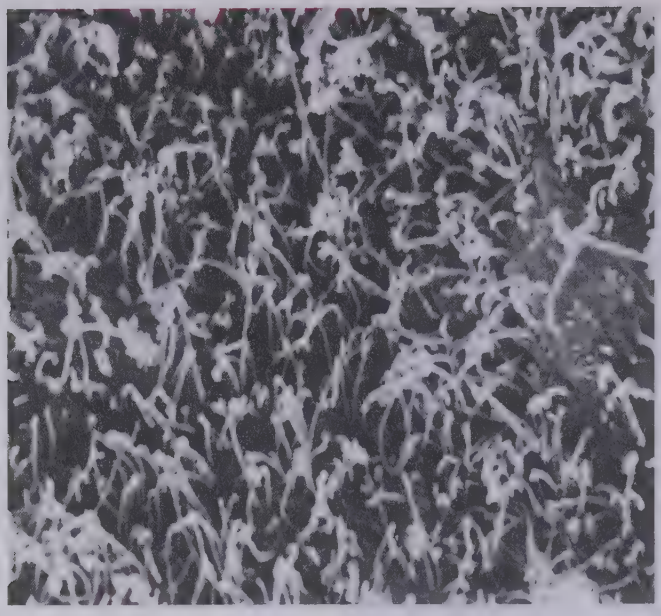
area and along a line descending from this, marking the attachment of the pulmonary ligament (8.34A,B).

The parietal pleura. Different regions of parietal pleura are customarily distinguished: the part internal to the thoracic wall (p. 591) and the vertebral bodies is the *costovertebral pleura*, that on the thoracic surface of the diaphragm is the *diaphragmatic pleura*, the part over the pulmonary apices (in the neck) is the *cervical pleura (domes of the pleura)* and that applied to the structures between the lungs is the *mediastinal pleura*.

The *costovertebral (costal) pleura* (8.28A–C) lines the sternum, ribs, transversus thoracis and intercostal muscles and the sides of the vertebral bodies; it is easily separated from them. Outside it a thin areolar layer of *endothoracic fascia* corresponds to the transversalis fascia of the abdominal wall. The costal pleura begins behind the sternum where it is continuous with the mediastinal pleura, at a junction extending from behind the sternoclavicular joint down and medially to the midline behind the sternal angle, where right and left junctions descend in contact to the level of the fourth costal cartilages, below which the lines of junction differ. On the right it descends to the back of the xiphisternal joint. On the left it diverges laterally and descends 2–25 mm from the sternal margin (Woodburne 1947) to the sixth costal cartilage. On each side the costal pleura sweeps laterally, lining the internal surfaces of the costal cartilages, ribs, transversus thoracis and intercostal muscles; posteriorly it passes over the sympathetic trunk and branches and to the sides of the vertebral bodies, where it is again continuous with the mediastinal pleura. The costal pleura is continuous with the cervical at the inner margin of the first rib and below it becomes continuous with the diaphragmatic along a line differing slightly on the two sides. On the right this *line of costodiaphragmatic reflexion* begins behind the xiphoid process, passes behind the seventh costal cartilage to reach the eighth rib in the mid-clavicular line, the tenth rib in the mid-axillary line and, ascending slightly, crosses the twelfth level with the upper border of the twelfth thoracic spine (8.28C). On the left the line follows at first the *sixth* costal cartilage but is otherwise as on the right, although it may be slightly lower.

The thin *diaphragmatic pleura* covers most of the upper surface of its own half of the diaphragm. Its circumference is largely the line described above, along which it is continuous with the costal pleura; it is continuous with the mediastinal pleura along the line of attachment of the pericardium to the diaphragm.

 8.29 Structures in relation to the cervical pleura of the left side: inferior aspect.

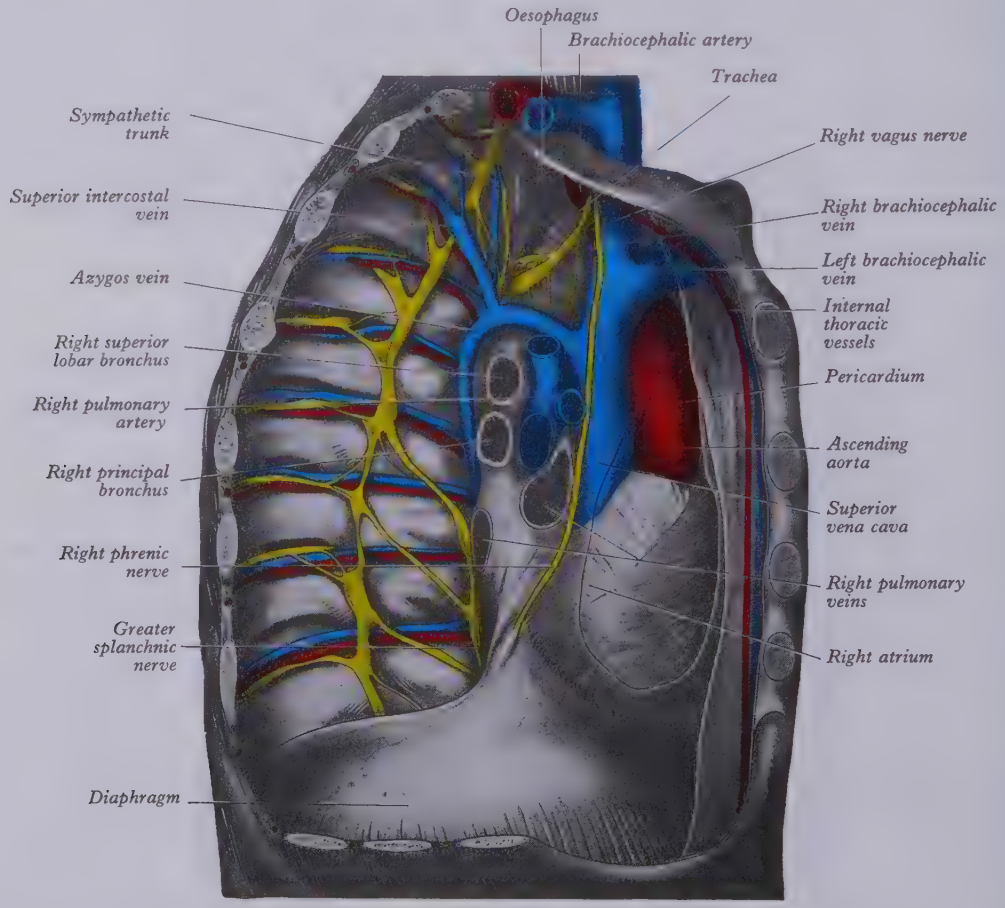


8.30A Transverse section of the mediastinum at the level of the lower part of the body of the fifth thoracic vertebra, viewed from the superior aspect.

The *cervical pleura* is the continuation of the costal pleura over the pulmonary apex (**8.28B**). It ascends medially from the first rib's internal border to the apex of the lung, as high as the lower edge of the neck of the first rib, descending lateral to the trachea to become the mediastinal pleura. Due to the rib's obliquity, the cervical pleura extends 3–4 cm above the first costal cartilage but not above the neck of the first rib. The cervical pleura is strengthened by a fascial *suprapleural membrane*, attached in front to the first rib's internal border, behind to the anterior border of the seventh cervical transverse process. It contains a few muscular fibres spreading from the scaleni (p. 586). A *scalenus minimus* muscle often extends from the anterior border of the seventh cervical transverse process to the inner border of the first rib behind its subclavian groove, spreading also into the pleural dome, which it therefore tenses. Some regard the suprapleural membrane as the tendon of this muscle. The cervical pleura (like the pulmonary apex) reaches the level of the seventh cervical spine 2.5 cm from the midline. Its projection is a curved line from the sternoclavicular joint to the junction of the medial and middle thirds of the clavicle, its summit being 2.5 cm above it. The subclavian artery ascends laterally in a furrow below the summit of the cervical pleura, the relations of which are like those of the apex of the lung (p. 1272, and **8.29**).

The *mediastinal pleura* is the lateral mediastinal boundary (p. 1271). Above the hilum of the lung it is continuous from sternum to vertebral column. On the right it covers: the right brachiocephalic vein, the upper part of the superior vena cava, the terminal part of the azygos vein, the right phrenic and vagus nerves, the trachea and oesophagus; and on the left the aortic arch, left phrenic and vagus nerves, left brachiocephalic and superior intercostal veins, left common carotid and subclavian arteries,

8.30B Transverse section of the mediastinum at the level of the body of the sixth thoracic vertebra, viewed from the superior aspect.



8.31 The surface of the pleura viewed by scanning electron microscopy, showing the numerous processes of the mesothelial cells lining this structure (murine). Magnification × 7000.

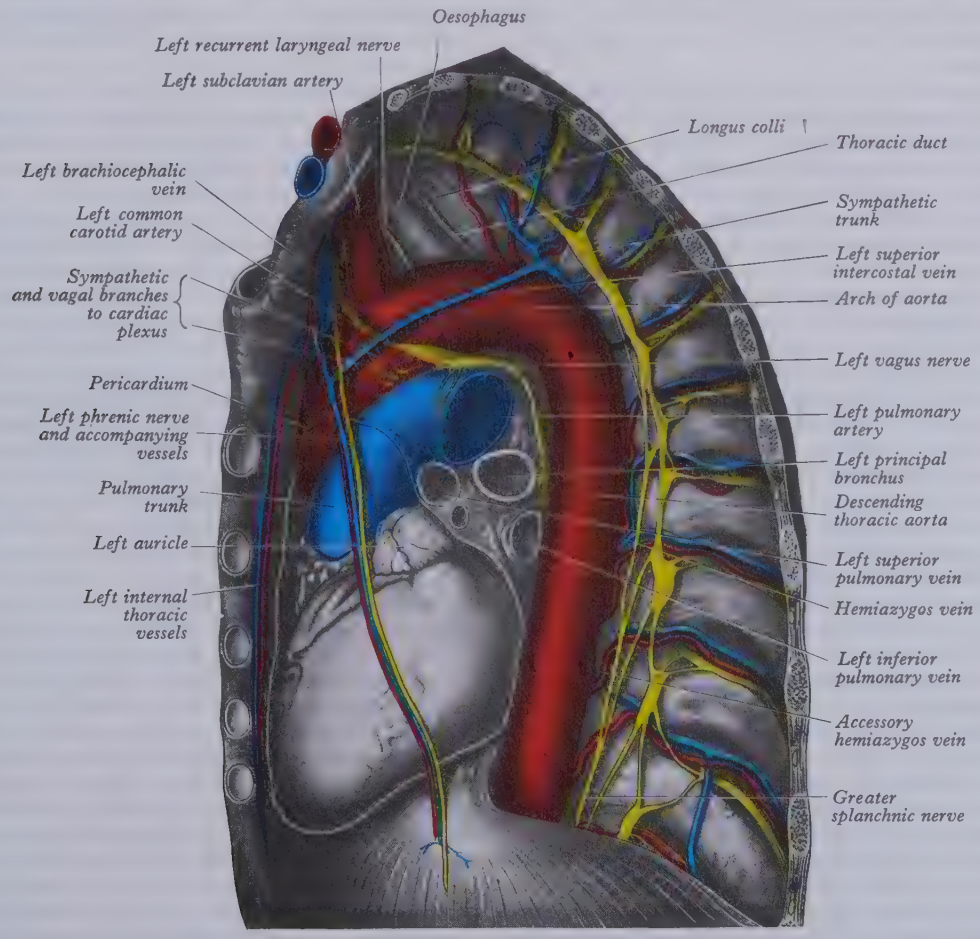
thoracic duct and oesophagus. At the hilum it turns laterally as a tube enclosing the hilar structures and continuous with the pulmonary pleura. Below the hilum the mediastinal pleura extends as a double layer from the lateral surface of the oesophagus to the mediastinal pulmonary surface, where it is continuous with the pulmonary pleura; this double layer is the *pulmonary ligament* (8.34A,B), continuous above with the pleura around the hilar structures; below it ends in a free falciform border.

The pleura extends beyond the inferior pulmonary border (8.23A–C) but not to the diaphragm's attachments. Hence below the line of pleural reflexion from the thoracic wall to the diaphragm the latter is in contact with the costal cartilages and intercostal muscles. In quiet inspiration the lung's inferior margin does not reach this reflexion, the costal and diaphragmatic pleurae being separated merely by a potential *costodiaphragmatic recess*. In quiet inspiration the lung is about 5 cm above the lower pleural limit. A similar *costomediastinal recess* exists behind the sternum and the costal cartilages, where the thin anterior pulmonary margin falls short of the line of pleural reflexion. The extent of this recess, the anterior costomediastinal line of pleural reflexion and the position of the anterior pulmonary margin all vary individually.

Microscopic structure. The pleural surface is smooth, moistened by serous fluid and consists of a single layer of flat mesothelial cells on a basal lamina beneath which are networks of elastic and collagen fibres embedded in ground substance, containing fibroblasts, macrophages and other cells typical of areolar tissue (p. 58). The deeper layers of fibrous tissue are continuous with tissue around the pulmonary lobules. Blood and lymph vessels and nerves are distributed in the pleura. In ultrastructural details pleural mesothelial cells are like those of the peritoneum (p. 1346). Material from human biopsies (de Gasperis & Miani 1969) shows that their basal lamina has a lamina densa 30–40 nm thick, but their highly folded basal plasma membranes are separated from it by a lamina lucida 20–30 nm. Adjacent cell surfaces interdigitate and are joined by desmosomes. Their luminal surfaces bear microvilli and numerous cilia (see 8.31). Micropinocytotic vesicles are common in their cytoplasm. Structural squamous variants are recognized, one probably being a stem cell.

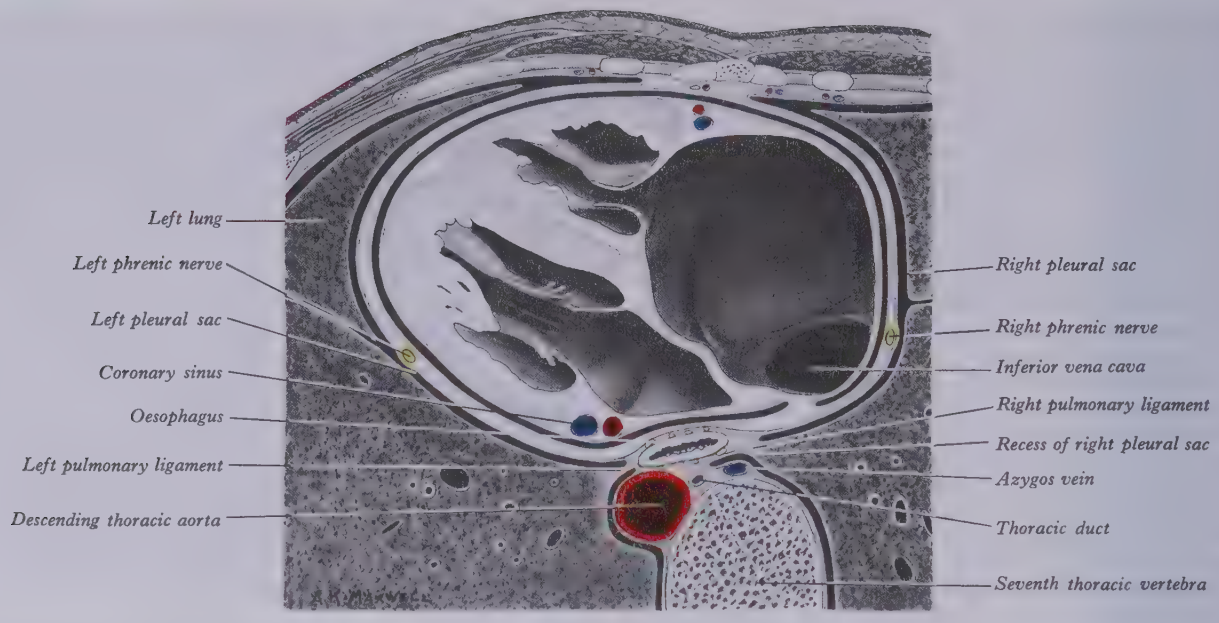
8.32A The mediastinum: right lateral aspect. A part of the pericardial sac has been removed to expose the lateral surface of the right atrium.

Vessels and Nerves



Parietal and visceral pleurae are developed respectively from somatopleural and splanchnopleural layers of the lateral plate mesoderm (pp. 132, 238). The parietal pleura therefore derives its blood from somatic arteries (intercostal, internal thoracic and musculophrenic); its veins join systemic veins in the thoracic wall; its lymphatics also join those in the wall, draining into intercostal, parasternal, posterior mediastinal and diaphragmatic nodes; and its nerve supply is from spinal sources (intercostal and phrenic nerves). The visceral pleura, which is integral with the lung, has a vascular supply from bronchial vessels; its lymphatics join those of the lung and its nerve supply is autonomic, reaching it along bronchial vessels. (For details of the lymphatics of visceral pleura consult Pennell 1966.) Whereas tactile or thermal stimuli to the parietal pleura elicit pain, these stimuli are inadequate when applied to the visceral pleura (cf. peritoneum, p. 1346). Costal and peripheral diaphragmatic pleurae are supplied by intercostal nerves; mediastinal and central diaphragmatic pleurae by the phrenic. Irritation of the former results in pain referred along intercostal nerves to the thoracic or abdominal wall; irritation of the latter causes pain referred to the lower neck and shoulder tip, i.e. to the area of skin supplied by the same spinal segments as the phrenic nerve (C.3,4,5).

Applied Anatomy. Normally visceral pleura glides on parietal during respiration without sound or pain; but when the pleura is inflamed friction sounds can auscultated. If fluid then distends the pleural cavity, the sounds disappear and the lung gradually collapses, the heart and mediastinum being displaced towards the opposite side. Air in the cavity (pneumothorax), whether admitted by a penetrating wound, rupture of the lung or as a therapeutic measure (e.g. to rest the lung in tuberculosis), also entails pulmonary collapse, as the elastic tissue of the lung recoils. Normally such recoil is prevented by a negative intrapleural pressure and the cohesion between the opposed parietal and visceral pleura. In renal incision the relation of the costal pleura to the twelfth rib is a hazard; usually the pleura crosses the rib at the lateral border of the erector spinae, so that the kidney's medial region is above the reflexion (**8**.28C). If this rib does not project beyond this muscle, the eleventh may be mistaken for the twelfth in palpation; an incision prolonged to this level will damage the pleura. Whether the lowest palpable rib is the eleventh or twelfth can be ascertained by counting from the second (identified at its junction with the sternal angle).



The Mediastinum

The mediastinum is the *partition* between the lungs and includes the mediastinal pleura; but it is commonly applied to the *interval* between the two pleural sacs. It is situated between the sternum and the thoracic vertebral column (**8**.23A,B,C, 30A,B), extending from the thoracic inlet to the diaphragm. For description it is divided into *superior* and *inferior* mediastina, the latter being subdivided into *anterior, middle* and *posterior* parts. The plane of division into upper and lower mediastina traverses the manubriosternal joint and the lower surface of the fourth thoracic vertebra.

The superior mediastinum (**8**.18, 19), lying between the manubrium sterni and the upper four thoracic vertebrae, is bounded below by the sternal plane already noted, above by the plane of the thoracic inlet and laterally by the mediastinal pleurae. It contains: the lower ends of the sternohyoid, sternothyroid and longus colli muscles, the aortic arch, the brachiocephalic artery, left common carotid and subclavian arteries, the brachiocephalic veins and upper half of the superior vena cava, the left superior intercostal vein, the vagus, cardiac, phrenic and left recurrent laryngeal nerves, the superficial part of the cardiac plexus, the

8.32B The mediastinum: left lateral aspect.

8.33 Transverse section through the mediastinum at the level of the body of the seventh thoracic vertebra, viewed from the superior aspect.

trachea, oesophagus, thoracic duct, thymic remnants and the paratracheal, brachiocephalic and tracheobronchial lymph nodes.

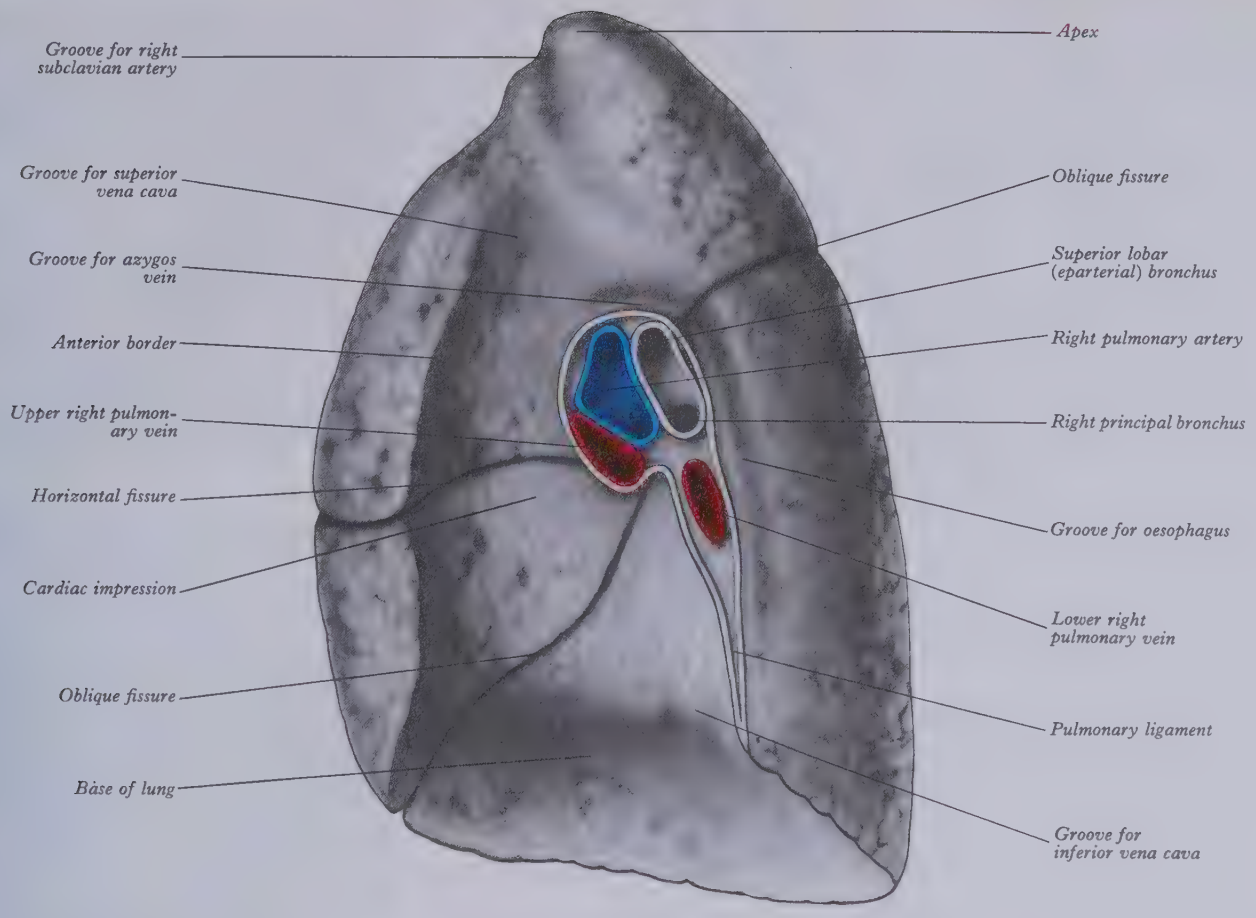
The anterior mediastinum, lying between the sternal body and pericardium (**8**.30A), is narrow above the fourth costal cartilages, where the pleural sacs are close. It contains loose areolar tissue, the sternopericardial ligaments, a few lymph nodes and the mediastinal branches of the internal thoracic artery and sometimes part of the thymus gland or its degenerated remains.

The middle mediastinum (**8**.30B, 33), the broadest part of the inferior mediastinum, contains: the heart, pericardium, ascending aorta, the lower half of the superior vena cava, the terminal azygos vein, tracheal bifurcation and both main bronchi, the pulmonary trunk dividing into right and left pulmonary arteries, both pulmonary veins, the phrenic nerves, the deep part of the cardiac plexus and the tracheobronchial lymph nodes.

The posterior mediastinum (**8**.30A,B, 32A,B, 33) is bounded: *in front* by the tracheal bifurcation, pulmonary vessels, pericardium and the posterior part of the upper surface of the diaphragm; *behind* by the vertebral column from the fourth (lower border) to the twelfth thoracic vertebrae and *on each side* by the mediastinal pleura. It contains: the descending thoracic aorta, the azygos and hemiazygos veins, the vagus and splanchnic nerves, the oesophagus, thoracic duct and the posterior mediastinal lymph nodes.

Mediastinal radiology (**6**.43, 44, 45). Viewed in anteroposterior radiograms (**6**.43) the heart and large blood vessels appear as the 'mediastinal shadow'. Forming its left border, from above down, are the left subclavian artery, arch of aorta ('aortic knuckle'), left auricle and ventricle. Below the arch the right ventricle's infundibulum or pulmonary trunk may be recognizable. On the right border are the right brachiocephalic vein, superior vena cava, right atrium and thoracic inferior vena cava. Enlargements or displacements of these structures accentuate the normal bulges on the shadow's borders. On both sides opacities due to pulmonary vessels form *hilar shadows*. In the upper thorax the less dense tracheal shadow is median. In lateral or oblique views the cardiac shadow is above the anterior part of the diaphragm. In front of it is the retrosternal space (anterior mediastinum); behind is the retrocardiac space (posterior mediastinum) containing the oesophagus, visualized by a barium swallow (**8**.105), and the descending thoracic aorta. Above, the less dense trachea and bronchi are recognizable; the aortic arch and large vessels produce faint shadows in the superior mediastinum.

The Lungs



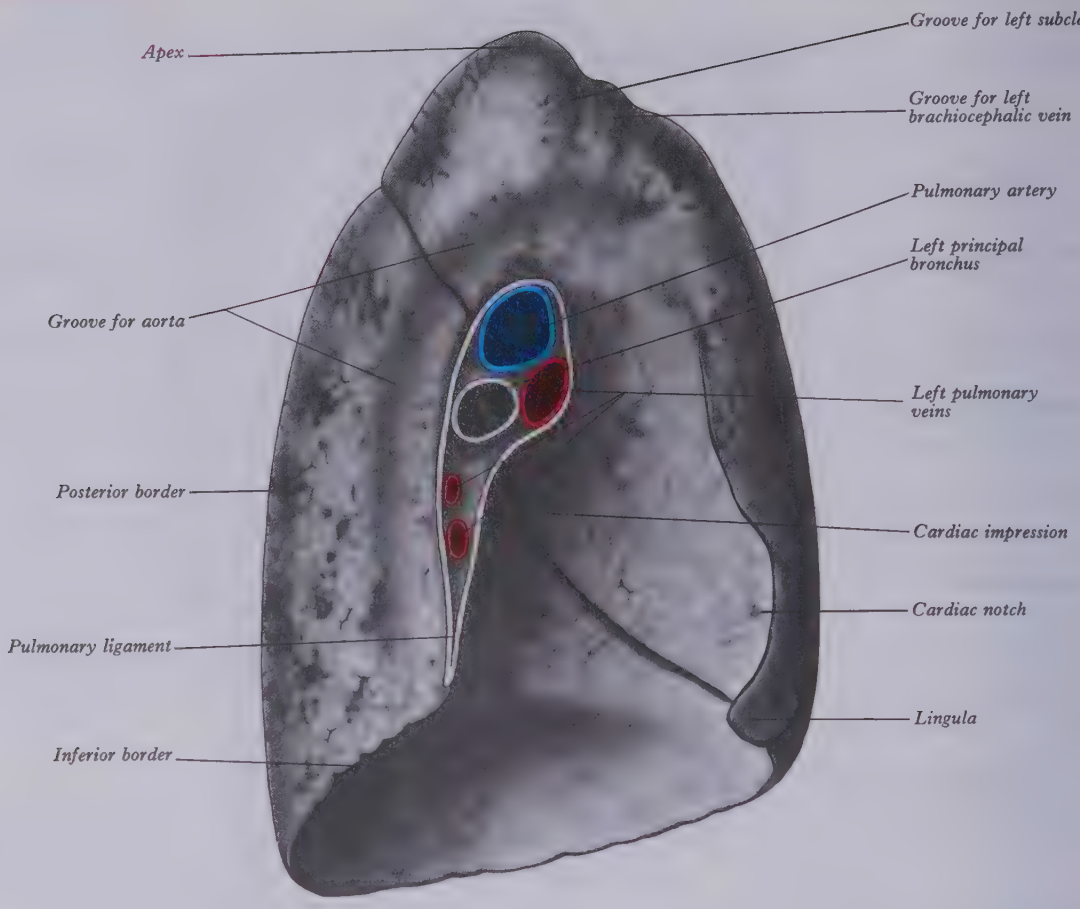
The lungs are separated by the heart and other mediastinal contents (**6**.29, **8**.33). Except for attachment to the heart and trachea by hilar structures (and the pulmonary ligament) each lung is free in its pleural cavity. A lung, being spongy, floats in water and crepitates when handled, due to air in its alveoli; it is also highly elastic and hence retracts when removed from the thorax. Its surface is smooth, shiny and marked by fine, dark lines into numerous polyhedral areas, indicating its lobules, each crossed by numerous finer lines.

At birth the lungs are pink, in adults a dark grey and patchily mottled; as age advances this maculation becomes black, due to granules of inhaled carbonaceous material deposited in loose connective tissue near the surface; it increases as age advances, often more abundantly in men and is greater in those who have dwelt in industrial areas and in smokers. The posterior pulmonary border is usually darker than the anterior. In the upper, less movable parts, surface pigmentation tends to be opposite the intercostal spaces. Lungs from fetuses or stillborn infants who have not respired differ from those of infants who have, being firm, non-crepitant and unable to float in water.

The adult right lung weighs about 625 g, the left 565 g, but they vary greatly. Weight also depends on the content of blood or serous fluid. Lungs are heavier in males, absolutely and relative to stature.

Each lung has an apex, base, three borders and two surfaces. In shape they each approximate to half a cone.

The apex is rounded, protruding above the thoracic inlet, in contact with the cervical pleura. Owing to the inlet's obliquity (p. 336), the apex is 3–4 cm above the level of the first costal cartilage but level with the neck of the rib. Its summit is about 2.5 cm above the medial third of the clavicle; the apex is therefore in the root of the neck (**8**.28B). It has been asserted that the apex is intrathoracic, close to the neck of the first rib, and that it is the anterior surface which ascends highest in inspiration (Andreassi 1967); this requires confirmation. The cervical pleura lies between the apex and suprapleural membrane (p. 1269), on which the subclavian artery arches up and laterally, grooving the anterior surface near its summit and separating it from scalenus anterior. Posterior to the apex are the cervicothoracic sympathetic ganglion, the



8.34A The medial surface of the right lung.

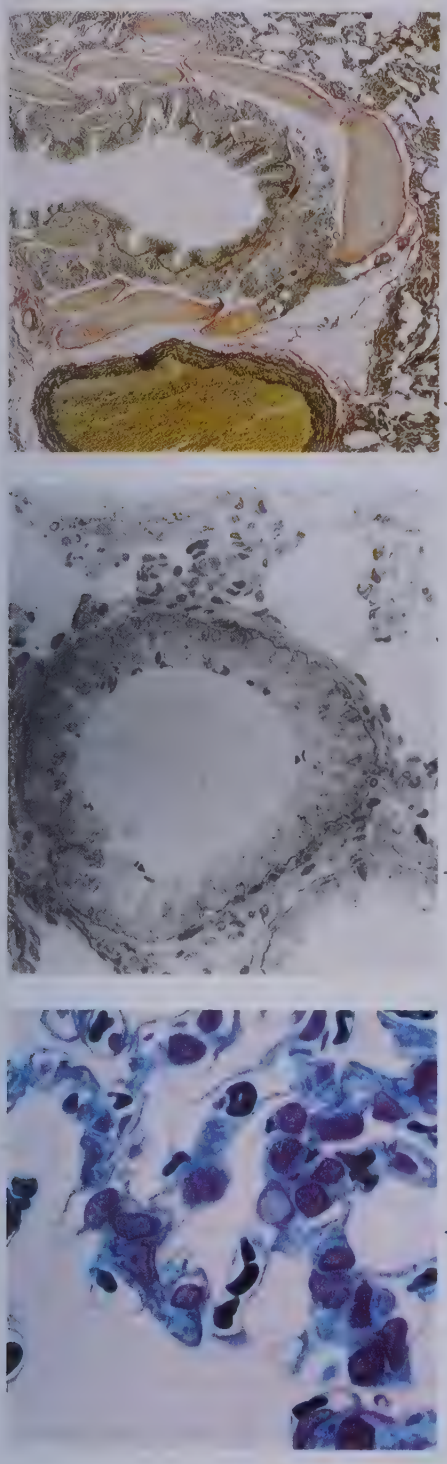
ventral ramus of the first thoracic spinal nerve and the superior intercostal artery (**8**.29). Scalenus medius is lateral and the brachiocephalic artery, right brachiocephalic vein and trachea are on the right, while the left subclavian artery and left brachiocephalic vein are on the left.

The base is semilunar and concave, resting upon the superior surface of the diaphragm, which separates the right lung from the right lobe of the liver and the left lung from the left hepatic lobe, gastric fundus, and spleen. Since the diaphragm extends higher on the right than on the left, the concavity is deeper on the right lung's base. Posterolaterally the base has a sharp margin adapted to the costodiaphragmatic recess (p. 1270). **The costal surface** is convex, adapted to the thoracic wall which is deeper behind. It is in contact with the costal pleura and exhibits, in specimens preserved in situ, grooves corresponding with the overlying ribs. **The medial surface** has posterior, *vertebral* and anterior, *mediastinal* parts. The former is in contact with the sides of the thoracic vertebrae and intervertebral discs, the posterior intercostal vessels and the splanchnic nerves. The mediastinal area, deeply concave, is adapted to the heart as the *cardiac impression*, which is much larger and deeper on the left lung, the heart being more to the left of the median plane. Posterosuperior to this is the somewhat triangular *hilum*, where structures (p. 1275) enter and leave the viscus, collectively surrounded by pleura, which also extends below the hilum and behind the cardiac impression as the pulmonary ligament. In other features markings on the mediastinal surfaces differ when seen in preserved specimens (**8**.32A,B, 34A,B). On the *right lung* the cardiac impression is related to the anterior surface of the right auricle, the anterolateral surface of the right atrium and partially to the anterior surface of the right ventricle. The impression ascends anterior to the hilum as a wide groove for the superior vena cava and the end of the right brachiocephalic vein (**8**.34A). Posteriorly this groove is joined by a deep sulcus arching forwards above the hilum and occupied by the azygos vein. The right side of the oesophagus makes a shallow vertical groove behind the hilum and the pulmonary ligament; nearing the diaphragm it inclines left and leaves the right lung; the groove, therefore, does not reach the lower limit of this surface. Postero-inferiorly the cardiac impression is confluent with a short wide groove adapted to the inferior vena cava. Between the apex and azygos groove the trachea and right vagus are close to the lung, but do not mark it. On the *left lung* (**8**.34B) the cardiac impression is related to the anterior and left surfaces of the left ventricle and auricle and the anterior infundibular surface and adjoining part of right ventricle; it ascends in front of the hilum to accommodate the pulmonary trunk. A large groove arches over the hilum, descending and behind it and the pulmonary ligament, adapted to the aortic arch and descending aorta; from its summit a narrower groove ascends to the apex for the left subclavian artery. Behind this, above the aortic groove, the lung contacts the thoracic duct and oesophagus. In front of the subclavian groove is a faint linear depression for the left brachiocephalic vein. Inferiorly, the oesophagus may mould the surface in front of the lower end of the pulmonary ligament.

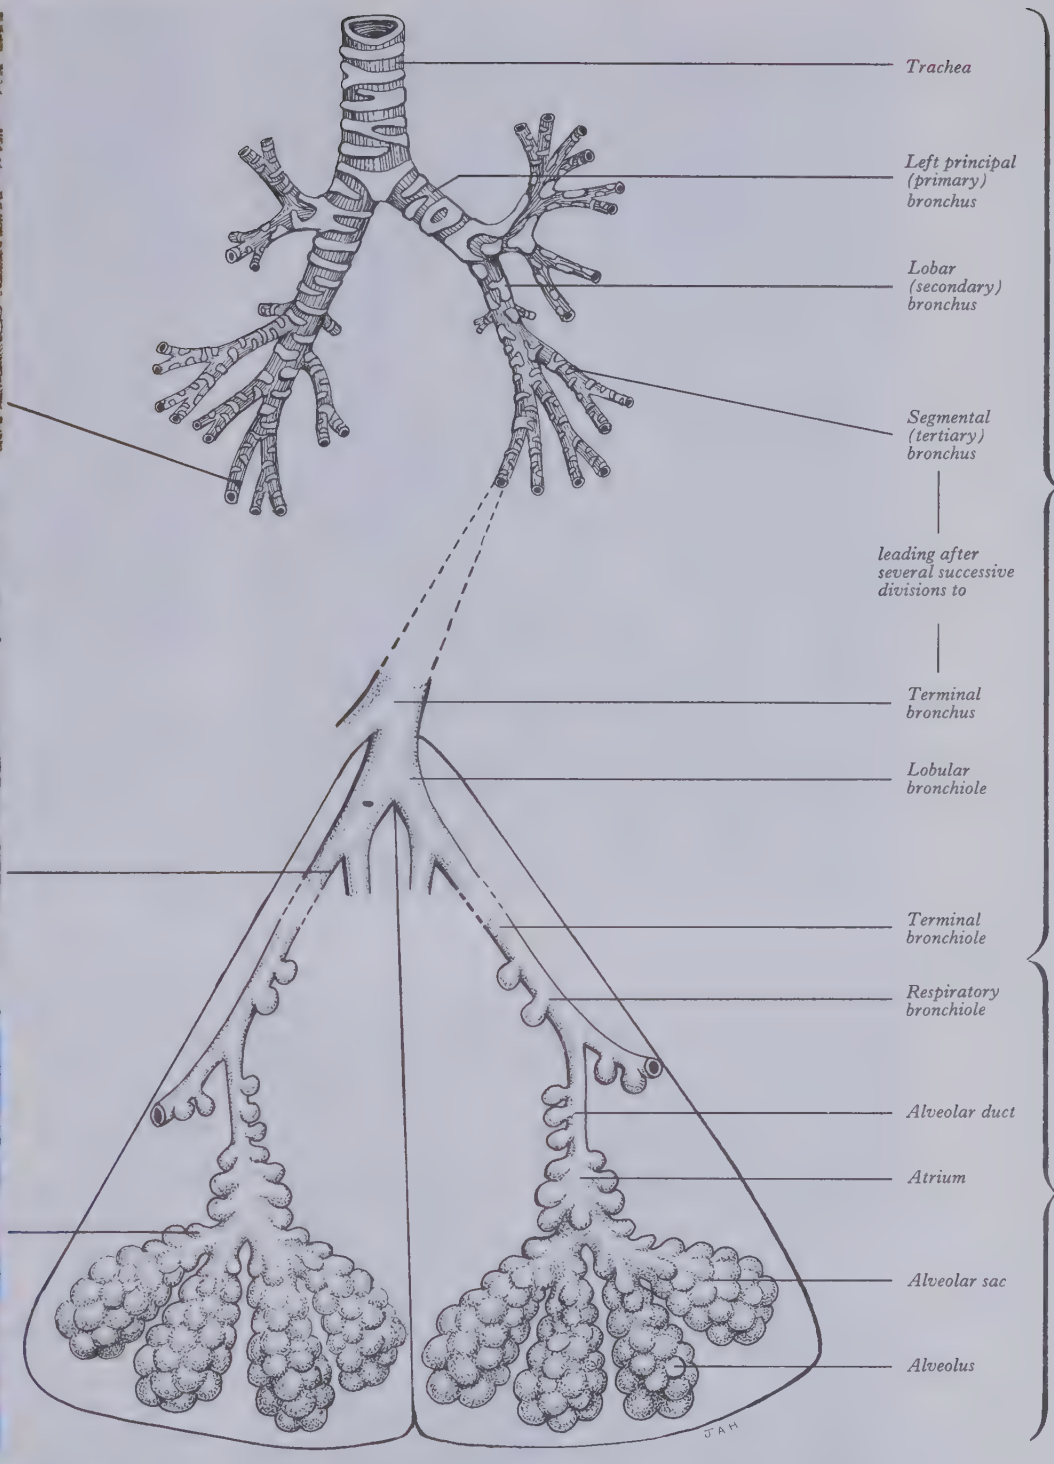
The *inferior border* is thin where it separates the base from the costal surface and extends into the costodiaphragmatic recess; medially, where it divides the base from the mediastinal surface, it is rounded. It corresponds, in quiet respiration, to a line from the anterior border (vide infra) to the eighth rib in mid-axillary line (nearly 10 cm above the costal margin) continued medially and slightly up to a point 2 cm lateral to the tenth thoracic *spine* (**8**.28C). The *posterior border* separates the costal surface from the mediastinal, corresponding to the heads of the ribs. It has no recognizable markings and is really a rounded junction of costal and vertebral (medial) surfaces. The thin, sharp, *anterior border* overlaps the pericardium; on the *right* it corresponds closely to the

8.34B The medial surface of the left lung.

costomediastinal line of pleural reflexion, being almost vertical; on the *left* it approaches the same line above, but below the fourth costal cartilage it shows a variable *cardiac notch*, the edge of which passes laterally for about 3.5 cm before curving down and medially to the sixth costal cartilage about 4 cm from midline. It thus does not reach the line of pleural reflexion here (**8**.28A), leaving the pericardium covered by a double layer of pleura (area of superficial cardiac dullness, p. 713). However, surgical experience suggests that the line of pleural reflexion, the anterior pulmonary margin and the costomediastinal pleural recess are all most variable.



PULMONARY FISSURES AND LOBES



The left lung is divided into a superior and an inferior lobe by an *oblique fissure* (**8**.34B) extending from the costal to the medial surfaces of the lung both above and below the hilum. Superficially this fissure begins on the medial surface at the posterosuperior part of the hilum and ascends obliquely back to cross the posterior border of the lung about 6 cm below the apex. It then descends forwards across the costal surface (**8**.28A), reaching the lower border almost at its anterior end. It finally ascends on the medial surface to the lower part of the hilum. At the posterior border the fissure is indicated by a surface point 2 cm to the side of the midline between the spines of the third and fourth thoracic vertebrae, but may be above or below this level. Traced around the chest, the fissure reaches the fifth intercostal space (at or near the mid-axillary line) and follows this to intersect the inferior border close to or just below the sixth costochondral junction (7.5 cm from the midline). The left oblique fissure is usually more vertical than the right, and is indicated approximately by the medial scapular border when the arm is fully abducted above the shoulder. The *superior lobe*, anterosuperior to this fissure, includes the apex, anterior border, much of the costal and most of the medial surfaces of the lung. At the lower end of the cardiac notch is usually a small process, the *lingula*. The larger, *inferior lobe*, postero-inferior to the fissure, comprises almost the whole of the *base*, much of the costal surface and most of the posterior border. (See pp. 1261–1265 for details of bronchopulmonary segmentation.)

The right lung is divided into superior, middle and inferior lobes by two fissures (**8**.34A). The upper, separating the inferior from the middle and superior lobes, corresponds closely to the left *oblique fissure* but is less vertical, crossing the inferior border of the lung about 7.5 cm behind its anterior end. On the posterior border it is level with the fourth thoracic vertebral spine or slightly lower. It descends across the fifth intercostal space and follows the sixth rib to the sixth costochondral junction. A short *horizontal fissure* separates the superior and middle lobes, passing from the oblique fissure, near the mid-axillary line, horizontally forwards to the anterior border level with the sternal end of the fourth costal cartilage; on the mediastinal surface it reaches the hilum. The small *middle lobe* is thus cuneiform and includes some of the costal surface, the lower part of the anterior border and the anterior part of the base of the lung. Sometimes the medial part of the upper lobe is partially separated by a fissure of variable depth containing the terminal part of the azygos vein enclosed in the free margin of a mesentery derived from the mediastinal pleura, forming the '*lobe of the azygos vein*'. This varies in size and sometimes includes the apex; it is always supplied by one or more branches of the apical bronchus. Radiographically, pleural effusion may be limited to the azygos fissure.

Attempts to equate the lobation in the two lungs, particularly the right middle lobe and lingula, are not supported by developmental data (p. 239). For discussion and bibliography consult Yokoh (1977).

Since the diaphragm rises higher on the right to accommodate the liver, the right lung is vertically shorter (by 2.5 cm) but due to

8.35 Bronchopulmonary structure. The diagram on the right shows the gross architecture of the conducting and respiratory parts of the trachea and lungs at segmental levels. On the left are three sections at the levels indicated. Top: A small bronchus lined by highly convoluted epithelium, surrounded by plates of hyaline cartilage. A pulmonary arteriole is visible below. Middle: A bronchiole. Note absence of cartilage and conspicuous non-striated muscle external to the epithelium. Note capillaries containing erythrocytes (dark blue) separated from air spaces by thin alveolar epithelial cells. Epoxy resin section stained by toluidine blue.

cardiac asymmetry it is broader, and in capacity and weight greater, than the left.

PULMONARY HILA AND ROOTS

The pulmonary root (8.32A,B), connecting the medial surface to the heart and trachea, is formed by a group of structures entering or leaving the hilum. These are: the principal bronchus, pulmonary artery, two pulmonary veins, bronchial arteries and veins, a pulmonary autonomic plexus, lymph vessels, bronchopulmonary lymph nodes and loose connective tissue, all enveloped by pleura. The pulmonary roots, or pedicles, are level with the fifth to seventh thoracic vertebrae. The right is behind the superior vena cava and right atrium and below the terminal part of the azygos vein. The left root is

below the aortic arch and in front of the descending thoracic aorta. Common to both are: *anterior*, the phrenic nerve, pericardiacophrenic artery and vein, and anterior pulmonary plexus; *posterior*, the vagus nerve and posterior pulmonary plexus; *inferior*, the pulmonary ligament.

The major structures in both roots are similarly arranged, as follows: the upper pulmonary vein in front and the pulmonary artery and principal bronchus behind, the bronchial vessels most posterior. Their vertical arrangement differs slightly on the two sides. On the right, from above down, the sequence is: superior lobar bronchus, pulmonary artery, principal bronchus, lower pulmonary vein; on the left: pulmonary artery, principal bronchus, lower pulmonary vein. The lower left pulmonary vein is inferior to the principal bronchus which is the lowest hilar structure (**8**.34A,B).

Pulmonary regions do not all move equally in respiration. In quiet respiration the juxtahilar part of the lung scarcely moves and the central region only slightly. The superficial parts of the lung expand most, while the mediastinal surface, posterior border and apex move less, being related to less movable structures. The diaphragmatic and costomediastinal regions expand most of all (see Movements of Respiration, p. 594). Most of the lung's volumetric change during respiration occurs in the alveoli, which number more than 20 million in a neonatal lung, increasing to 300 million or more during childhood. An alveolus varies from 200–300 μm in diameter and numerous capillary segments (1800 is suggested) may contact each alveolus. The air-epithelium-blood interface is enormous even in childhood. Figures of 70–100 m^2 have been estimated (Peters 1969, Fisherman & Pietra 1974) and even higher values are suggested (Gehr et al 1978).

Microscopic Structure of the Lung

Lungs are epithelial outgrowths of the anterior foregut (pp. 231, 238), forming tubes which branch as they grow, and surrounded by very vascular mesenchymal tissue. This developing mass, protruding into the anterior coelomic cavity (later pleural cavities), is covered by coelomic mesothelium which eventually becomes the epithelium of the pulmonary pleurae. Within each lung the larger proximal tubes become *conducting* airways and the more distal form cavities for *respiratory exchange* between the atmosphere and adjacent capillaries. The individual components of this complex will now be considered in detail.

THE SEROUS TUNIC AND ASSOCIATED CONNECTIVE TISSUE

The *tunica serosa* forms the visceral pleura, a thin, transparent layer composed of a single-layered mesothelium and its subjacent lamina propria, inseparably connected to the underlying lung tissue which it invests except at the hilum. Subserous areolar tissue covers the entire pulmonary surface and extends along the conducting tubes and blood vessels from the hilum to finally delineate numerous small *lung lobules*. Each lobule is a small polyhedral mass receiving a lobular bronchiole and the terminal rami of arterioles, venules, lymphatics and nerves. Lobules vary in size, the superficial being large and pyramidal, their bases visible as polygonal areas about 5–15 mm across separated by thin layers of connective tissue. Internal lobules are smaller and vary in shape. In structure the lung resembles a lobulated gland, consisting of terminal lobules for respiratory exchange and extralobular ducts for ventilation (Miller 1947, von Hayek 1960, Engel 1962, Krahl 1964). The terminal lobules are also called *secondary lobules*, delineated on the surface by substantial septa enclosing areas of 1–2 cm^2, subdivided by delicate septa into areas of about 1 mm^2, the surfaces of the *primary lobules*.

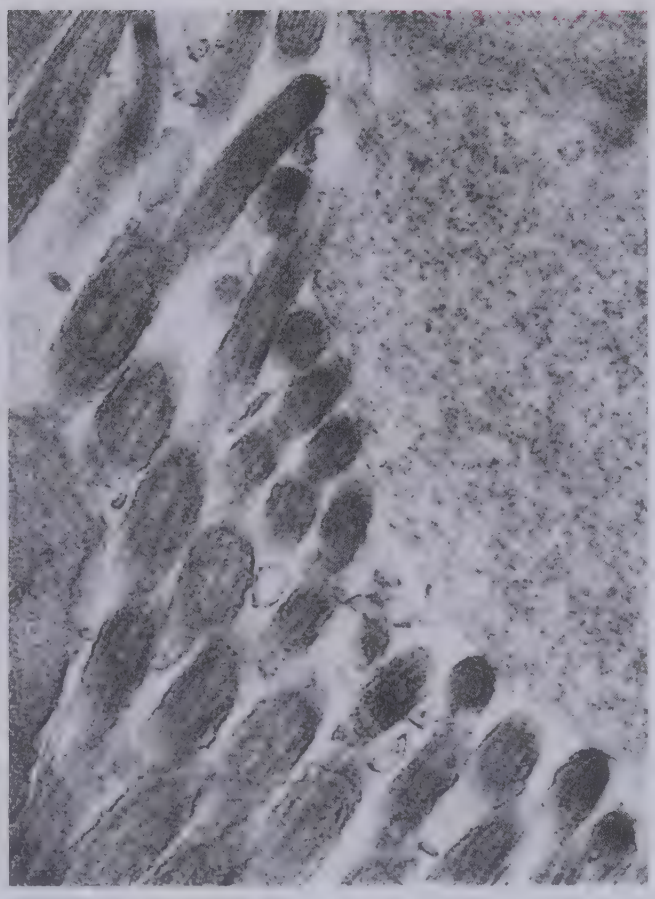
RESPIRATORY PASSAGES AND SPACES

The 'lower' respiratory tract includes the larynx, trachea, extrapulmonary bronchi (vide supra) and various orders of intrapulmonary tubes which repeatedly dichotomize. *Secondary (lobar) bronchi* supply whole lobes; *tertiary* (or quaternary), *segmental bronchi* supply bronchopulmonary segments; further subdivisions branch repeatedly within segments, becoming increasingly narrower. All intrapulmonary bronchi are kept patent by cartilaginous plates which decline in size and number and disappear from tubes less than 1 mm in diameter, termed *bronchioles*. After repeated branching, one *lobular bronchiole* enters each lobule, dividing at once into about six *terminal bronchioles*; these subdivide into one to three generations of *respiratory bronchioles* (Spencer 1977). Terminal bronchioles are the most distal air passages to be lined solely by simple columnar epithelium. Respiratory bronchioles in contrast have a few small alveoli arising directly from their walls and finally end in two or three *alveolar ducts*, thin walled tubes expanding terminally into *atria*, which lead into *alveolar sacs*. The thin walls of the alveolar ducts, atria and sacs are studded with *alveoli* or *acini*, separated from adjacent alveoli by thin *interalveolar septa* of connective tissue and capillary plexuses. The above arrangement, shown diagrammatically in **8**.35 and **8**.37, 38, is normal in adults; variations occur during active growth in childhood (Engel 1947).

N.B. The terminology used here for the orders of branches is not universally agreed and confusion persists in the naming of conducting passages smaller than bronchi. For example, some authors define a terminal bronchiole as serving a lobule (often of unspecified type) and others adopt a simpler view of the passages leading to the alveoli.

MICROSCOPIC STRUCTURE OF THE BRONCHIAL TREE

Air Passage Epithelium



The epithelium of the intrapulmonary bronchi and bronchioles resembles that of the trachea and the extrapulmonary bronchi (Collet et al 1967). In larger intrapulmonary passages it is pseudostratified and largely ciliated; in terminal and respiratory bronchioles it is a single layer of lower columnar to cuboidal cells, many non-ciliated.

There has been a systematic survey of the ultrastructure of the epithelial cell types present at different air passage levels in the rat (Jeffrey & Reid 1975) and in the mouse (Pack et al 1981). The following description is of that found in the rat. Ten types, eight epithelial and two mesenchymal (probably migratory), have been identified. All the epithelial cells rest on a basal lamina but in the larger bronchi some do not reach the lumen. Epithelial cells proper were classed as: *ciliated, serous, Clara, goblet, intermediate, brush, basal* and *Kulchitsky*. Of these the serous had not been described before in air passage epithelium. Mesenchymal cells are either '*globule*' *leucocytes* or *lymphocytes*. The ultrastructural features of these cells are tabulated below. In rats goblet cells occur in the epithelium of all air passages but as less than 1% of the cells; in some species they are absent from smaller bronchioles. Basal cells decrease distally and are almost absent from smaller bronchioles, where the epithelium is simple. Clara cells occur throughout the system. Even in the most proximal regions over 40% of cells are non-ciliated (Jeffery & Reid 1975).

Ciliated cells, essential to the ciliary rejection current in the bronchial tree, have electronlucent cytoplasm containing numerous mitochondria, a euchromatic nucleus and cilia with apical, claw-like projections (**8**.36B,C) described by Jeffery & Reid (1975). The cilia extend into a low-viscosity liquid partly produced by the serous cells (vide infra); above this are flakes and droplets of more viscous mucus (Van As & Webster 1972) from goblet cells and the exocrine cells of bronchial mucous glands. According to Sleigh (1974) only the ciliary tips contact this mucus, which they 'claw' along towards the larynx. The mucus-secreting *goblet cells* are

distended by supranuclear electron-lucent granules often with electron-dense cores.

Serous cells have an irregular nucleus, copious granular endoplasmic reticulum and homogeneously electron-dense supranuclear granules. Most numerous in the trachea and extrapulmonary bronchi, they also occur in intrapulmonary passages. Similar cells exist in human bronchial submucosal glands (Meyrick & Reid 1970), probably contributing to the low-viscosity circum-ciliary fluid.

Clara cells, originally considered typical of terminal bronchioles (Clara 1937), also occur at more proximal levels and even in nasal mucosa (Matulionis & Parks 1973). They are non-ciliated, with blunt luminal projections, irregular homogeneously electron-dense secretory granules, many lysosomes, osmiophilic lamellar bodies and much agranular endoplasmic reticulum, often apically concentrated, which may be connected to the rest by a narrow 'waist' (Spencer 1977). Niden & Yamada (1966) first suggested Clara cells as a source of surfactant material, a view supported by Etherton & Conning (1971), whose localization of radioactively labelled dipalmitoyl lecithin (a constituent of alveolar surfactant) to secretory granules of Clara cells, within five minutes of intraperitoneal injection, weakened the case for type II alveolar cells (p. 1280) as the sole source of surfactant.

'Intermediate' epitheliocytes have been observed in the bronchial epithelium of rats (Rhodin & Dalhamn 1956, Jeffery & Reid 1975) and in human tracheal epithelium (Rhodin 1966). They have long, luminal filopodia, electron-dense cytoplasm with no secretory granules, but sometimes contain fibrogranular accumulations, suggesting ciliogenesis (Sorokin 1968). They may be undifferentiated forms of ciliated or secretory cells (Rhodin 1966).

Brush cells are non-ciliated, with a distinct luminal border of microvilli. Numerous pinocytotic vesicles near the bases of the microvilli suggest a specialization for absorption. Most numerous in the tracheal epithelium, where they amount in rats to about 1%

C

of the epithelial cells; they are also dispersed throughout the other air passages (Jeffery & Reid 1975).

Bronchial Kulchitsky (argentaffin) cells (Bensch et al 1965) are the rarest type, with electron-lucent cytoplasm containing dense-cored secretory granules which accumulate between the nucleus

DISTINGUISHING ULTRASTRUCTURAL FEATURES OF CELLS WITHIN THE EPITHELIUM LINING THE AIR PASSAGES

(Modified from Jeffery & Reid 1975)

and cell base, discharging their contents in response to hypoxia (Moosavi et al 1973, Lauweryns & Cokelaere 1973). Termed *Feyrter* cells by Moosavi et al (1973) and P_a *cells* by Capella et al (1978) in the human lung, they resemble the D_1 cells (p. 1376) of the gastro-entero-pancreatic system in storing and secreting amines (Ericson et al 1972), and should thus be included in the diffuse endocrine system of APUD cells (Pearse & Polack 1971, Hage 1973). Innervated groups of similar cells form neuro-epithelial bodies in human bronchial and bronchiolar mucosa (Lauweryns & Peuskens 1972). Suggested functions include involvement in the regulation of lobular growth (Rosan & Lauweryns 1971) and chemoreception (Lauweryns et al 1972).

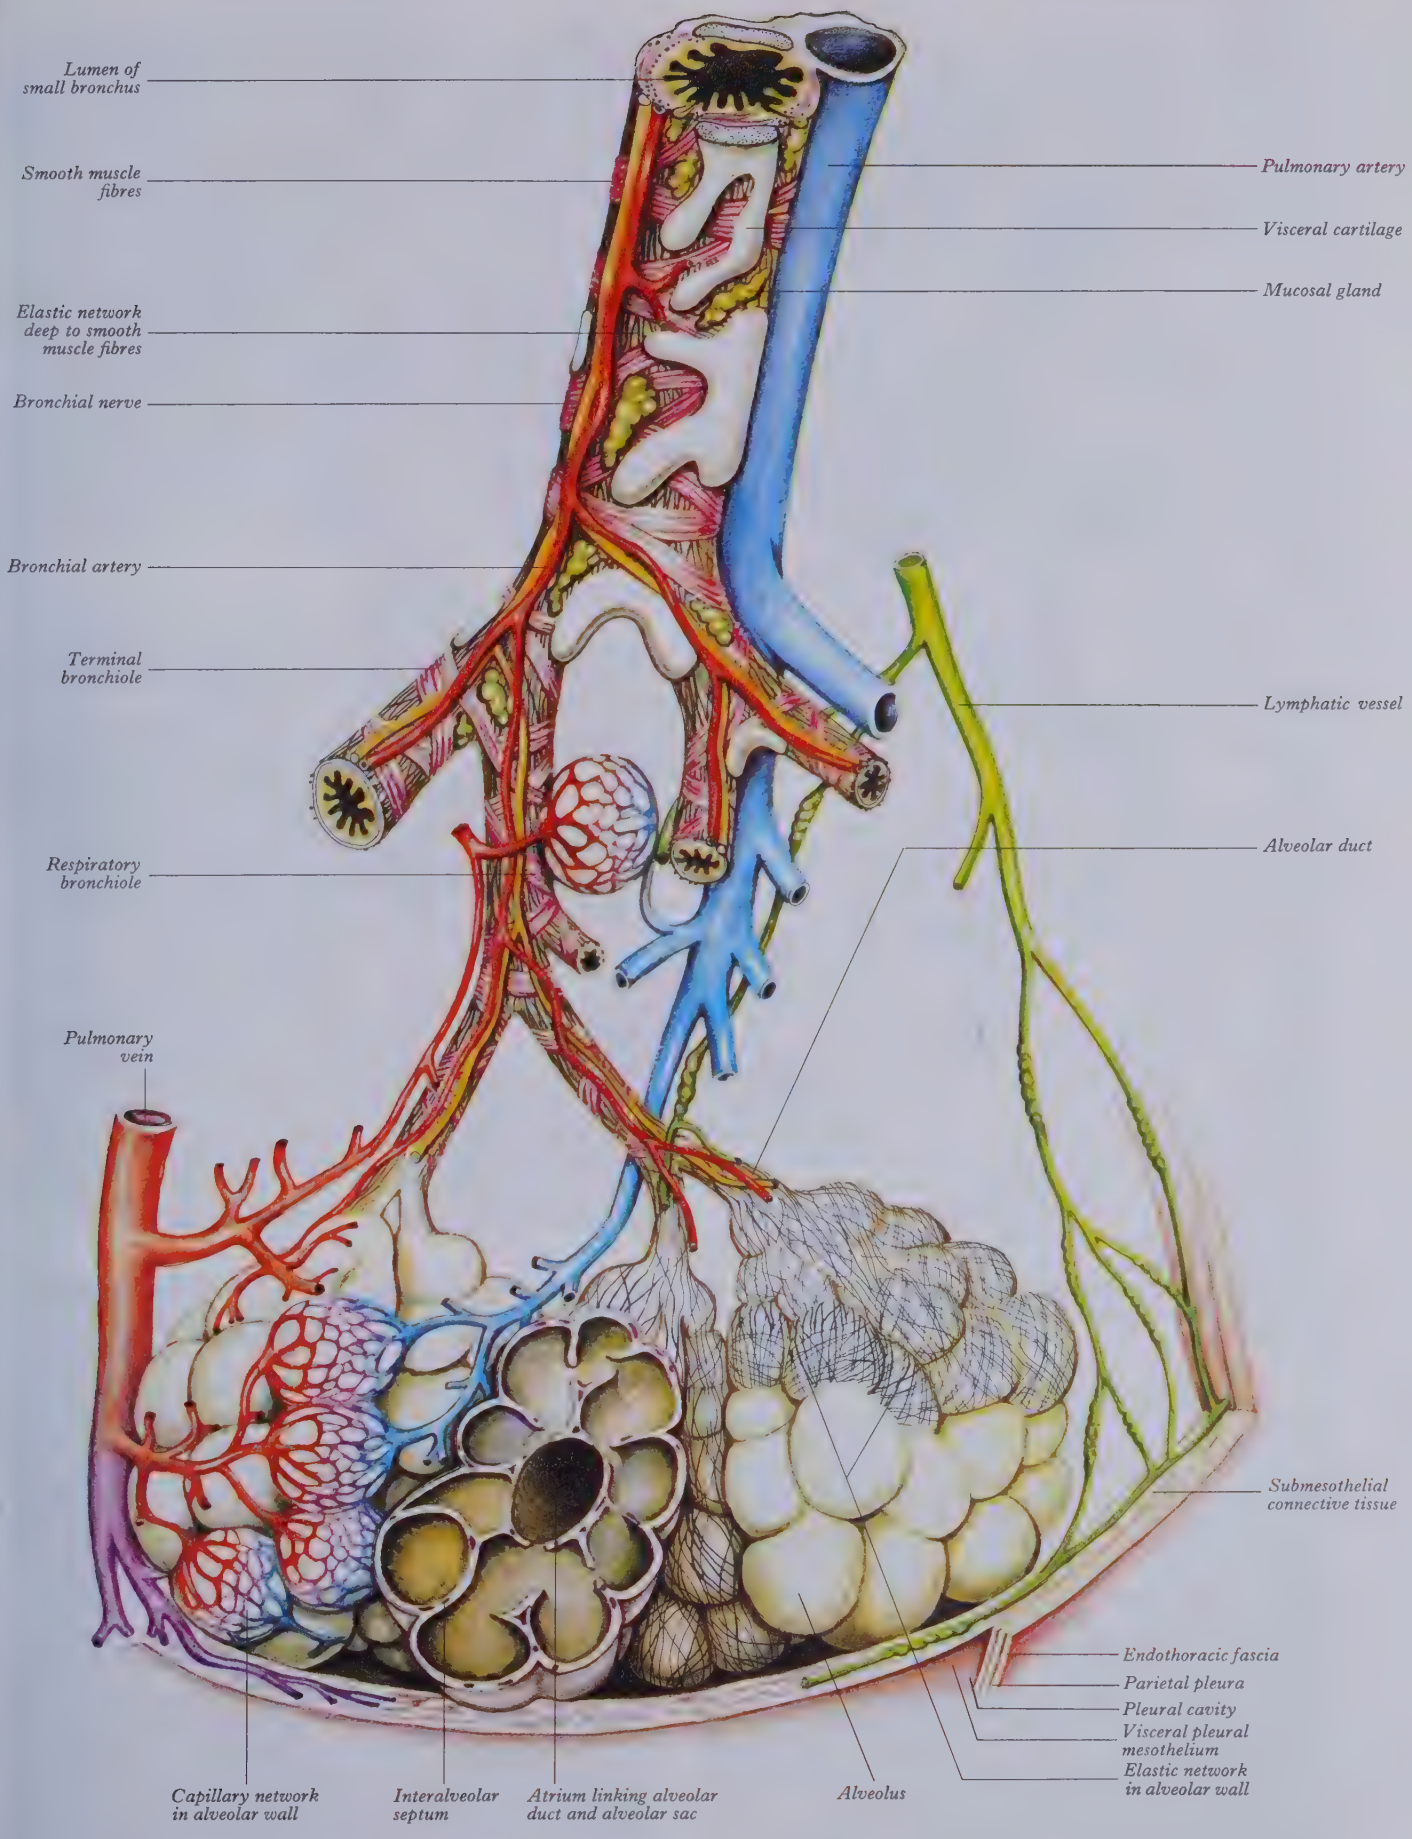
Undifferentiated *basal cells*, in parts of the airway lined by pseudostratified epithelium, divide to replace other epithelial types (Blenkinsopp 1967). In smaller bronchi, undifferentiated cells amongst the mature epitheliocytes perform this function.

The remaining cells are either 'globule' leucocytes or lymphocytes, both being migratory cells and not epithelial cells proper. *'Globule' leucocytes* have very electron-dense granules, numerous filopodia and resemble mast cells, from which they may be derived (Murray et al 1968). The *lymphocytes*, with sparse electron-lucent cytoplasm, are most numerous in extrapulmonary bronchi. Their ultrastructural appearance in human bronchi has been described by Meyrick & Reid (1970). They are typically T cells derived from the circulation and stemming from mucosal lymphoid tissue and are probably concerned with immune surveillance of the epithelium and the destruction of virus-infected cells, etc. (see p. 1281).

The epithelium of smaller bronchi and bronchioles is folded into conspicuous longitudinal ridges which allow for changes in luminal diameter (**8**.37). In the respiratory bronchioles it progressively thins towards the alveolar termination, eventually being composed of cuboidal, non-ciliated cells; the lateral pouches are lined with squamous cells, providing an accessory respiratory surface.

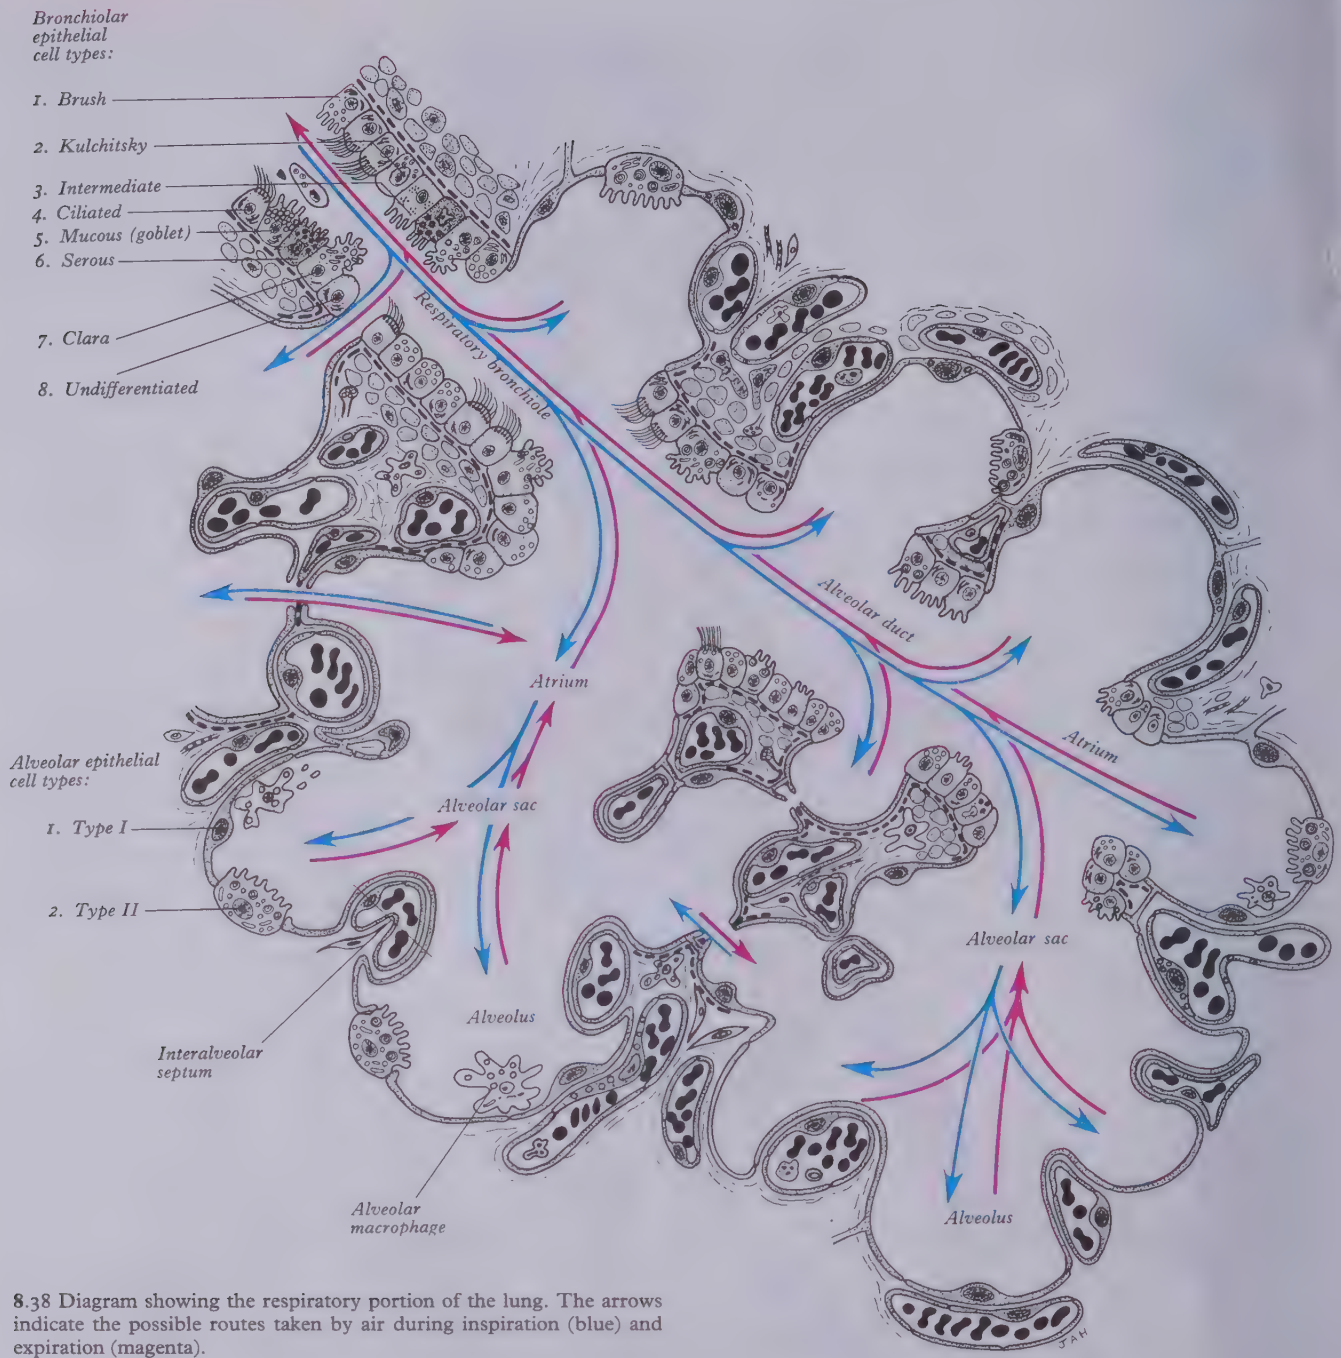
Connective Tissue and Muscle of the Bronchial Tree (**8**.37,38,39)

The epithelium of the bronchi and bronchioles rests on a basal lamina attached to a lamina propria in which broad, longitudinal bands of elastin follow the course of the bronchial tree, branching at bifurcations and finally joining the elastin networks of the respiratory spaces. This elastic framework is a vital mechanical element, responsible for much elastic recoil during expiration, although in respiratory regions surface tension may be more important (vide infra and Peters 1969). Non-striated myocytes in the submucosa (within the confines of the visceral cartilages where present) form two opposed helical tracts along the entire intrapulmonary bronchial tree, becoming thinner and finally absent at the alveolar bases (Stephens & Kroeger 1980). They are under nervous and hormonal control and narrow the airway, their relaxation permitting bronchodilatation. Normally there is some tone in the muscular bands, which relax slightly during inspiration and contract during expiration, assisting the tidal flow of air. Abnormal contraction may be caused by circulating stimulants of non-striated muscle or by local release of excitants such as serotonin, histamine and leukotrienes, producing bronchospasm and impaired respiration.



Diverticula and Glands

Diverticula of the mucosa extend outside the muscle layers in some bronchi and bronchioles, forming deep mucosal crypts which may develop into canals providing additional connections between peribronchiolar alveoli and the more proximal air spaces (Lambert 1955). Tubular glands also occur in the submucosa of bronchi and bronchioles, both *mucous* and *serous* in type, as in the extrapulmonary passages.



ALVEOLAR STRUCTURE

The alveoli are thin-walled pouches which provide collectively a large respiratory area that is a minimal barrier to gaseous exchange between the atmosphere and the blood of the capillaries lying close to their surface lining (Karrer 1956, Collet et al 1967, Klika & Petřík 1965).

The alveolar walls consist of a thin luminal epithelium resting on a basal lamina adjacent to a layer of connective tissue (**8**.38, 40A–D). Since the walls are thin and in contact with those of adjacent alveoli, the connective tissue and its blood vessels frequently form a thin irregular sandwich between two layers of epithelium, an *interalveolar septum*. Apertures occur in such septa, passing air between adjacent alveoli and between the alveoli and respiratory bronchioles (Macklin 1936, Lambert 1955, Suarez 1979). The alveolar epithelium is generally a single layer of attenuated squamous cells, *type I alveolar epithelial cells* or *type I pneumonocytes*, forming a continuous layer as thin as 0.05 μm. Since the basal laminae of this epithelium and of the subjacent capillaries may be fused and measure only about 0.1 μm and capillary endothelium about 0.05 μm, the total barrier to diffusion between air and blood may be as little as 0.2 μm (Collet et al 1967). However, the

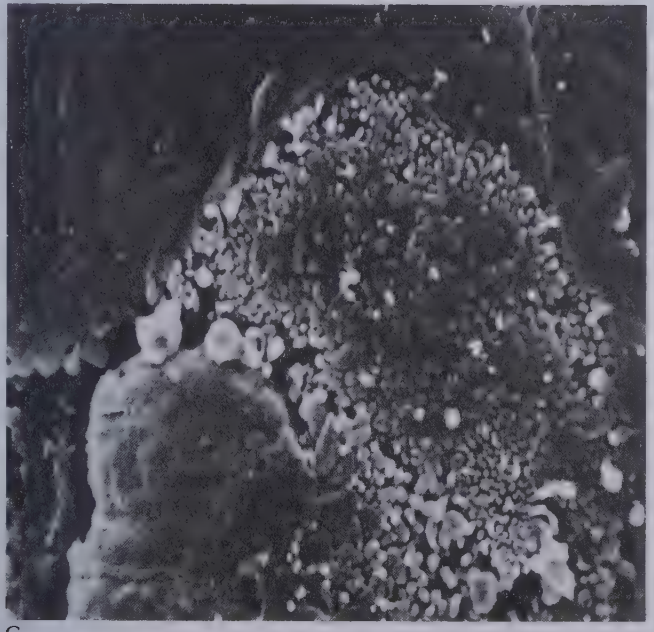
mean barrier thickness is 2.2 μm in the normal human lung (Gehr et al 1978), much exceeding the range of 0.6–1.5 μm in other mammals (Meban 1980), due mainly to a broader interstitial space rich in connective tissue fibres found in the interalveolar septa. Over about half the total barrier area, the separation between the alveolar epithelium and capillary endothelium is reduced to two fused basal laminae, but in large areas there are also much wider separating spaces, containing free fluid, fixed and free cells and collagen and elastic fibres (8.38). The greater thickness, over much of its area, of the human air–blood barrier, compared with other mammals, is unexplained, but Wang & Ying (1977) have suggested that the large human lung needs more fibrous tissue to support the weight of the contained blood. This cannot be the full explanation, for the barrier is much thinner in the still larger lungs of cattle and horses (Gehr et al 1978). Perhaps bipedalism is a factor in this phenomenon.

The stereological evaluation of electron micrographs of random samples of normal human lungs has led to revised estimates of the total alveolar area (Gehr et al 1978); the mean in eight pairs of lungs was $143 \pm 12 m^2$, a value 75% higher than light microscopic estimates, due mainly to the higher resolution of the electron microscope resulting in more precise definition of the alveolar surface. Capillary surface area and volume were estimated at 126 ± 12 m² and 231 ± 31 ml respectively.



The alveolar surface is normally covered by a film of *pulmonary surfactant*, composed mainly of a phospholipid (tubular 'myelin') secreted mainly by type II alveolar epithelial cells (vide infra), although Clara cells of bronchioles may also be involved (Etherton et al 1973). It is a recognized reducer of surface tension (Goerke 1974, King 1974, Tierney 1974, Kikkawa & Smith 1983). Likened to emulsifying agents which stabilize bubbles in an aqueous phase, it is essential for normal alveolar expansion (Macklin 1954), preventing alveolar collapse during expiration (Pattle 1965). The introduction of polar solvents and aqueous embedding media, cryosectioning, or the use of tannic acid-containing fixatives in electron microscopy has improved the retention of lipids and carbohydrates in ultrathin sections, leading to re-assessment of the ultrastructure of the pulmonary surfactant

(Kalina & Pease 1974, Stratton 1977, Stratton 1978, Shimura et al 1986) and that of its precursors, the multilamellar bodies of type II alveolar epithelial cells (Douglas et al 1975, Stratton 1976). The pulmonary surfactant appears to be five-layered, each layer representing a stage in transformation of the multilamellar bodies. The layers typical of human surfactant are: (1) recently secreted multilamellar bodies nearest to the alveolar epithelium, (2) paired lamellae expanded and re-arranged as tubules, (3) mature tubular 'myelin' surfactant, (4) a surfactant-air interface, usually a single lipid bilayer, and (5) degraded surfactant, consisting of lipid bilaminar spheres formed at the air interface (Stratton 1978). Alveolar macrophages remove degraded surfactant, leaving some areas denuded of this covering until it is replaced by further secretion of multilamellar bodies. Localized lack of surfactant is part of the normal cycle of secretion and degradation.

The cells of the interalveolar septa can be grouped into those of three principal components: alveolar epithelium, capillary endothelium and interstitial space.

Alveolar epithelium is a mosaic of at least two cell types. Forming over 90% of the alveolar area are simple squamous *type I alveolar epithelial cells*, which resemble endothelial cells, having a highly attenuated cytoplasm about 0.05–0.2 μm wide extending from a thicker perinuclear region. The thinness of the cytoplasm facilitates gaseous diffusion between the lumen of the alveolus and its capillaries. Deep cytoplasmic extensions occasionally traverse the interstitial space between the capillaries to reach and expand on the opposite side of the septum (Weibel 1971). Since one cell extends on two surfaces, while its nucleus is only on one, cell division is impeded and type I cells do not proliferate. If damaged they are replaced by the multiplication of primitive type II cells which may later differentiate into type I pneumonocytes (Spencer 1977). The attenuated cytoplasm of type I cells contains pinocytotic vesicles, while the perinuclear cytoplasm contains a few mitochondria, a little agranular endoplasmic reticulum and occasional lysosomes. Edges of adjacent cells overlap, bound by non-leaky tight junctions. The lack of diffusion between the intercellular junctions is a vital feature which, with a similar endothelial barrier, limits the movement of fluid from blood and intercellular spaces into the alveolar lumen (the *blood–air barrier*) (see Simionescu 1985).

Type II alveolar epithelial cells, first reported by Reinhardt in 1847, are rounded secretory cells mainly engaged in the production and secretion of surfactant (Gil & Weibel 1969, King & Clements 1972, Gil & Reiss 1973). They are more numerous than type I cells, but are much less extensive and form only about 3% of the total alveolar surface. They project into the alveolar lumen and their free surfaces are covered by numerous short microvilli. In the human lung they are often associated with alveolar septal gaps (Takaro et al 1987). Their cytoplasm contains abundant mitochondria, granular endoplasmic reticulum, lysosomes and multilamellar bodies or secretory granules, composed of dipalmitoylphosphatidylcholine (50%), cholesterol (10%) and some protein, a precursor of pulmonary surfactant (Gil & Reiss 1973, Golde 1985, Bourbon & Rieutort 1987), stacked in regular lamellae, each a phospholipid bilayer. The ultrastructure of the multilamellar bodies has been described in detail by Stratton (1976), who found a lamellar width (and hence periodicity, there being no interlamellar interval) of 5.5 n or 6.6 n (depending on processing) and a tendency for the lamellae to fracture at bends, to divide and to join. Freeze-fracture preparations have shown that the lamellae are arranged in cup-shaped layers around a core (Weibel et al 1976). In mice, radioactive palmitate, a component

of surfactant injected intraperitoneally, is rapidly incorporated into the multilamellar bodies of both type I and Clara cells; hence both may be involved in surfactant production (Niden 1967). Although primarily secretory, type II cells may be phagocytic (Corrin 1970, Suzuki et al 1972). Type II cells respond to injury by rapid proliferation and may replace damaged type I cells (Weibel 1974A).

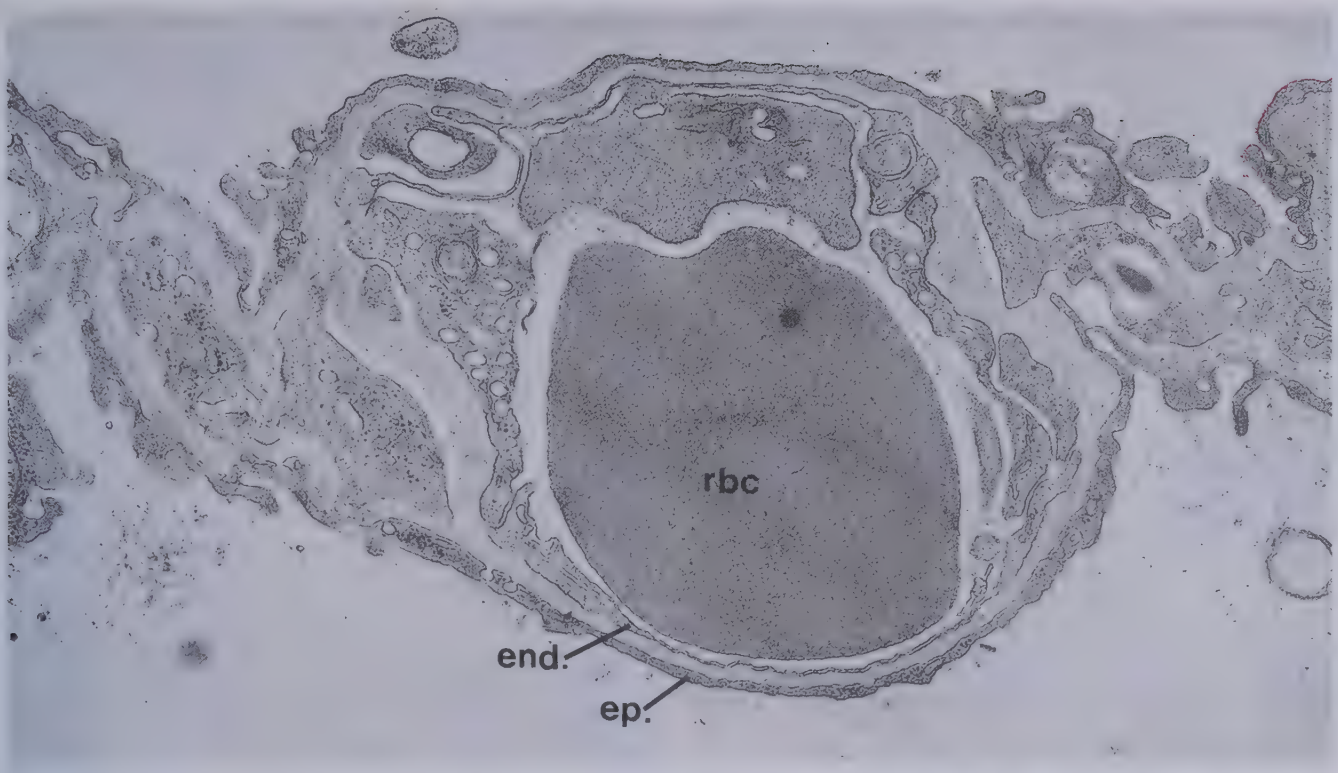
A third type, the *brush cell* (Meyrick & Reid 1968), is a rare alveolar epitheliocyte occurring in some species; also called the *type III cell*, it was not observed by Gehr et al (1978) in an exhaustive study of human pulmonary ultrastructure but its occurrence was not excluded.

In addition to a respiratory role, *pulmonary endothelial cells* have other activities: they can clear up emboli and thrombi (Heinemann & Fishman 1969), assist in the metabolism of chylomicrons (Schoefl & French 1968), convert angiotensin I to angiotensin II, produce thromboplastin (Zeldis et al 1972), process hormones and prohormones arriving via the circulation (Vane 1969), synthesize prostaglandins and related substances (Ryan & Ryan 1977), inactivate serotinin and carry out a wide range of other metabolic activities. Their microanatomy and ultrastructure accord with these functions. The capillary endothelium is a simple continuous layer of squamous cells (Smith & Ryan 1973), whose particular features are abundant transcytotic vesicles (Smith & Ryan 1970, Simionescu 1985), extreme thinness (less than 0.1 μm in some areas) and an extensive array of luminal projections, thus presenting a huge surface area to blood, an area which in man must be many times greater (Ryan & Ryan 1977) than the commonly quoted 70 m^2 (Fishman & Pietra 1974). According to Ryan & Ryan (1977) the adult human lung may have 3×10^8 alveoli, each with a thousand or more capillary segments in its walls; the pulmonary capillary bed may measure 1500 miles or more, 1.0 ml of blood occupying 10 miles of capillaries. The capillaries are enclosed in alveolar walls or interalveolar septa and course through the interstitial space, interlacing with connective tissue fibres and bulging alternately into one or other of the alveoli on either side of each interalveolar septum. Thus, while on one side the capillary endothelium is separated by connective tissue fibres from the alveolar epithelium, on the opposite aspect their fused basal laminae are a minimal barrier, on about half the capillary surface, to gas and other solutes in blood. Where the endothelium is closely apposed to an epithelial cell, the endothelial wall is particularly thin (as little as 35 nm) and devoid of vesicles (Simionescu 1985).

The *interstitial spaces* of the interalveolar septa contain, in addition to fluid, some collagen and elastic fibres and various cells, both fixed and free (migratory). Fixed interstitial cells, fibroblasts and pericytes are the most numerous, the last demonstrated in the human lung by Weibel (1974a). All of these are capable of contraction (Kapanci et al 1974) and are structurally quite similar (p. 60), but are distinguished by their position, fibroblasts being associated with the connective tissue fibres whose components they manufacture, while pericytes lie close to the capillary basal lamina. Interstitial cells located around the openings into alveolar sacs resemble non-striated myocytes. They are stellate in form and are anchored to the basal lamina of epithelial cells; they are rich in actin and myosin and are contractile. It is thought that these cells may be able to alter the extensibility of alveoli and so modify lung compliance (see Kapanci et al 1974). Macrophages, mast cells and lymphocytes are the most numerous free cells in the septa; plasma cells also occasionally are present.

Within the alveoli, *alveolar phagocytes* (dust cells) are frequent; they are similar to connective tissue macrophages found beneath the epithelia and to circulatory monocytes and form part of the mononuclear phagocyte system (p. 669). They migrate from capillaries through the epithelium to wander about on the alveolar surfaces (Collet & Normand-Reuet 1967). Such phagocytes can clear the respiratory spaces of inhaled particles small enough to reach them, migrating back into the lymphatic channels or moving to the base of the bronchial tree to be swept up by the ciliary rejection current (vide infra) for elimination via the larynx. Whenever erythrocytes escape from pulmonary capillaries, the phagocytes become brick-red, due to engulfed cells, and are detectable in 'rusty' sputum; such cells are typical of congestive heart failure and are often termed *'heart failure cells'*. Human alveolar phagocytes (macrophages) have been shown to produce both a collagenase and a collagenase inhibitor (Welgus et al 1985); they may thus produce a profound effect on the connective tissue matrix of the lungs and on any fibrous scar tissue produced in response to damage to the respiratory surface (vide infra). Other blood cells may invade the alveoli (and other parts of the respiratory tree) in pathological conditions, e.g. neutrophil leucocytes and lymphocytes in infections, giving sputum a characteristic yellowish appearance. The presence of these cell types in sputum is important in diagnosis.

PULMONARY DEFENSIVE MECHANISMS



The problems associated with the protection and maintenance of the respiratory tract are great. Such a huge exposed area is vulnerable to desiccation, microbial invasion and the mechanical and chemical effects of inhaled particles. Inhaled air is humidified chiefly in the upper respiratory tract where it passes, with some turbulence, over the nasal and buccopharyngeal mucosae. Secretions of the various glands of the bronchial tree also help to prevent desiccation. The composition of these secretions is hence important. Goblet cells secrete sulphated acid mucosubstances, whereas cells in mucous glands beneath the epithelial surface contain mainly carboxylated mucosubstances, particularly those associated with sialic acid, though sulphated groups also occur (de Haller 1969). In contrast, cells of serous glands contain neutral mucosubstances. Goblet cells respond mainly to local irritation and tubular glands, both mucous and serous, to neural and hormonal control. Excessive or altered secretions may obstruct the flow of air. In addition to mucosubstances secreted by bronchial glands, antibacterial and antiviral substances also appear in the secreted fluid, e.g. lysozyme, antibodies of the IgA type and possibly interferon (Havez et al 1966).

removed. However, particles small enough to reach the alveoli may be removed by alveolar phagocytes (vide supra); if particles are abrasive they may nevertheless damage the respiratory surface, with consequent fibrosis and reduction in the respiratory area, as in many industrial diseases, such as pneumoconiosis due to coal dust. Alveolar epithelium has limited powers of regeneration but normally is continually replaced. The life-span of alveolar squamous cells is about three weeks, that of alveolar phagocytes about four days (Bertalanffy 1966). Finally, numerous lymphoid nodules (bronchus-associated lymphoid tissue, BALT, see p. 832) occur in the bronchial lining, providing foci for the production of lymphocytes and giving local immunological protection against infection both by cell mediated (T cell) activities and the production of immunoglobulins (mainly IgA) from B cells to be passed on to gland cells for secretion to the epithelial surface.

In addition to these cellular mechanisms, coughing to clear pulmonary obstructions is, of course, essential. Initiation of such muscular responses to irritation involves stimulation of sensory endings. The identity of these afferent terminals is still somewhat uncertain except at the laryngeal aditus, where epithelial receptors similar to taste buds are considered responsible. However, at

least some of the 'brush cells' of the respiratory epithelium appear to have neural contacts and may represent sensory cells with basal synaptic outputs.

PERINATAL PULMONARY DEVELOPMENT

Histologically the lung changes much during development, which is divisible for description into three phases: glandular, canalicular and alveolar (Engel 1947, de Reuck & Porter 1967, Emery 1969, Reid 1976). In the *glandular period*, during the first 16 weeks (approximately) of embryonic development, the tubular epithelial outgrowth ducts of the pulmonary rudiments are lined by tall columnar epithelial cells rich in glycogen, the cells almost obliterating the ductual lumina; between these tubes are closely packed mesenchymal cells and vascular tissue, the whole lung bud being a concentrated mass of cells resembling glandular tissue. At about the sixteenth week a *canalicular period* commences, marked by a rapid proliferation of the ducts, which branch profusely and become canalized as many cells become cuboidal and often ciliated. Some cells become squamous and begin to associate with capillaries, a change predominant in the *alveolar period*, which lasts from about 24 weeks onwards to birth, during which alveoli and the bronchial tree finally differentiate. Expansion of the future respiratory spaces is associated with the passage of fluid from lung tissue into their lumina, although incipient respiratory movements, causing inhalation of amniotic fluid, may also aid expansion. By full term and indeed some time before, the lungs are able to support normal respiration once fluid is expelled by expiration in air. After birth minor structural changes continue, alveolar surfaces becoming more complex and alveoli more numerous with increase in body size. Alveolar surfactant is synthesized first and premature births, particularly, may give rise to difficulties in expanding the lungs (respiratory distress syndrome); this can usually be corrected by glucocorticoid administration, which stimulates the synthesis of surfactant.

PULMONARY VASCULATURE AND INNERVATION

The *pulmonary artery* returns deoxygenated blood to the lungs; it divides into branches which accompany segmental and subsegmental bronchi and lie mostly dorsolateral to them (**8**.24B). They end in the dense capillary networks in the walls of alveolar sacs and alveoli (**8**.37). The arteries of neighbouring segments are independent. Elliot & Reid (1965) have demonstrated a fairly constant relation between the luminal and mural dimensions in the pulmonary arterial tree, this ratio (total diameter: wall thickness) being less than in most systemic arteries, as might be expected from the pressure differences. No regional differences have been detected (Simons & Reid 1969), despite evidence suggesting a large difference between blood flow in the upper and lower pulmonary regions. (See Van Meurs-Van Woezik et al 1987 for changes in the internal diameters in the pulmonary arterial tree with increasing age in infants and children.)

The *pulmonary capillaries* form plexuses immediately outside the epithelium in the walls and septa of alveoli and alveolar sacs. In interalveolar septa the network is a single layer, with meshes smaller than the capillaries, whose walls are exceedingly thin (vide supra and Suarez 1979).

Arteriovenous shunts have been demonstrated in human lungs near the terminal bronchioles. Experiments show that such shunts may pass particles of 500 μm diameter; the functional implications of this are not clear (Tobin 1966).

Pulmonary veins, two from each lung, drain the pulmonary capillaries, the radicles coalescing into larger branches which traverse the lung independently of the pulmonary arteries and bronchi (vide infra). Communicating freely they form large vessels, which ultimately accompany the arteries and bronchial tubes to the pulmonary hilum, the bronchi often separating the dorsolateral artery and the ventromedial vein. The pulmonary veins open into the left atrium, conveying oxygenated blood for systemic distribution by the left ventricle.

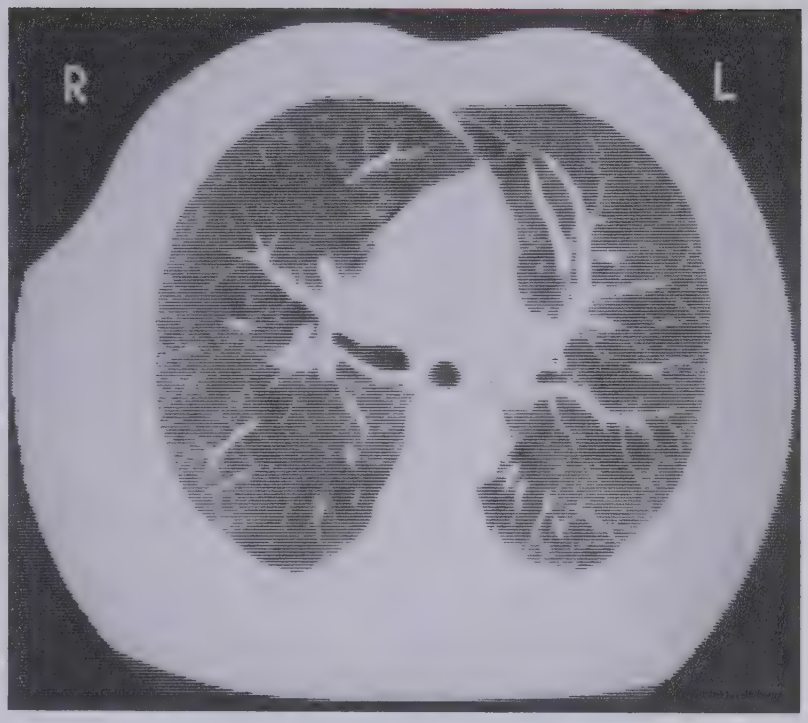
At the hilum the pulmonary arteries and veins accompany the main bronchial divisions but peripheral to this, in the bronchopulmonary segments, relations change (pp. 1261–1265). In general a bronchus and its branches in a segment are central and accompanied by branching arteries but many tributaries of the pulmonary veins run *between* segments, serving adjacent segments, which drain into more than one vein. Some veins also lie beneath the visceral pleura, including that in the interlobar fissures. Thus a bronchopulmonary segment is not a complete vascular unit, with an individual bronchus, artery *and* vein. In the resection of segments it is obvious that the planes between them are not avascular but crossed by pulmonary veins and sometimes by branches of arteries. This pattern of bronchi, arteries and veins varies much, the veins being the most variable and arteries more variable than bronchi (Brock 1942, 1943, 1944, 1954, Boyden 1955, Cory & Valentine 1959, Bloomer et al 1960, Volpe et al 1969). Therefore the following general account requires amplification by reference to the above classic and to later reports.

Arteries of the right lung. Before reaching the hilum, the right pulmonary artery (p. 726) sends a large superior branch to the upper lobe; this is at first in front of the superior lobar bronchus but soon passes posterolateral to it. The main artery continues laterally between the superior lobar bronchus and the continuation of the principal bronchus to become posterolateral to the latter in the oblique fissure, dividing into middle and lower lobar arteries. This superior branch of the right pulmonary artery gives off apical, anterior descending and ascending and posterior descending and ascending segmental arteries. The middle lobar artery arises from the stem of the right pulmonary artery close to (or at) the origin of the superior branch to the lower lobe and divides into lateral and medial segmental branches. The remaining stem of the right pulmonary artery supplies the lower lobe with superior (apical), subsuperior (subapical), medial basal (cardiac), anterior basal, lateral basal and posterior basal segmental arteries.

Arteries of the left lung. The left pulmonary artery (p. 726), having crossed anterior to the left principal bronchus to its posterolateral aspect at the hilum, gives off to the upper lobe apical, posterior, anterior descending and ascending segmental arteries and a lingular artery which subdivides into superior and inferior rami. Beyond this the pulmonary artery supplies the lower lobe with superior (apical), subsuperior (subapical), medial basal, anterior basal, lateral basal and posterior basal segmental arteries.

Although the pulmonary arteries rarely depart from the above mode of primary (lobar) branching, segmental branches vary much in their sites of origin and numbers, reduplication being frequent. From observations at 521 partial pneumonectomies, Cory & Valentine (1959) recorded many variations: the right and left upper lobes showed the greatest range of variation, with 14 types of pattern in 152 right-sided operations, and 29 types in 107 on the left; other lobes displayed less variation, the patterns noted being five in the right middle, six in the right lower and four in the left lower lobe. Only the commonest patterns will be noted here.

Right upper lobe: Type 1: 3 segmental arteries, the apical and anterior arising from a common branch (91 of 152 = 60%). Type 2: 3 segmental arteries from a common branch (26 of 152 = 17%). Type 3: like Type 1, but with a reduplicated posterior segmental artery (13 of 152 = 8.5%). Type 4: like Type 2, but with a second, separate, posterior segmental branch (9 of 152 = 6%). These accounted for 91.5% of the observed patterns; the remainder (13 of 152, classified as Types 5–14) were mostly single instances. Direct branches from the right pulmonary artery varied from one to four in number and actual segmental arteries (often by common trunks) varied from the classic three (118 = 77%) to six.



Right middle lobe: Type 1: 2 segmental arteries (25 of 51 = 49%). Type 2: a common stem for 2 segmental arteries (23 of 51 = 45%). Types 3–5 (1 instance each of 51) all showed multiplicity (numbering 3,4 and 5) of middle lobe segmental branches.

Right lower lobe: Type 1: 3 segmental branches, 1 superior, 2 basal (31 of 43 = 72%). Types 3–6 (8 of the 43 lobes): a reduplicated superior branch and its atypical origin from a basal branch. Segmental arteries always numbered three or four, individual basal segments usually sharing common trunks.

Left upper lobe: Types 1–7 (78 of 107 = 70%) showed 4 or 5 segmental branches, most displaying early bifurcation, the resultant vessels being almost always distributed to two segments (with much variation in those supplied). Remaining types (8–29)

8.41A Radiograph of chest: postero-anterior view of adult female. Note the difference in level of the right and left halves of the diaphragm. 1. Aortic 'knuckle'. 2. Pulmonary vessels of right side. 3. Edge of shadow caused by breast. 4. Position of trachea.

were single instances, showing variation in number (2–6 segmental branches) and sites of branching from the left pulmonary artery; bifurcation was less common than in Types 1–7 and trifurcation occurred in three lobes. A common pattern for this lobe cannot be defined.

Left lower lobe: Type 1: showed 1 apical and 2 basal segmental arteries (44 of 57 = 77%). Type 2: like Type 1 but with 2 apical branches (9 of 57 = 15%). Type 3: like Type 1 but with 3 basal branches (3 of 57). Type 4: showed 2 basal and 3 apical branches.

Veins of the right lung (see also p. 791). In the hilum the superior right pulmonary vein is formed by the union of apical, anterior and posterior veins (upper lobe) with a middle lobar vein (formed by lateral and medial tributaries). The inferior right pulmonary vein is formed by the hilar union of superior (apical) and common basal veins from the lower lobe, the common basal being formed by the union of superior and inferior basal tributaries.

Veins of the left lung (p. 791). In the hilum the superior left pulmonary vein, which drains the upper lobe, is formed by the union of apicoposterior (draining the apical and posterior segments), anterior and lingular veins, the last-named consisting of an upper and a lower part. The inferior left pulmonary vein, which drains the lower lobe, is formed by the hilar union of two veins, superior (apical) and common basal, the latter formed by the union of a superior and an inferior basal vein.

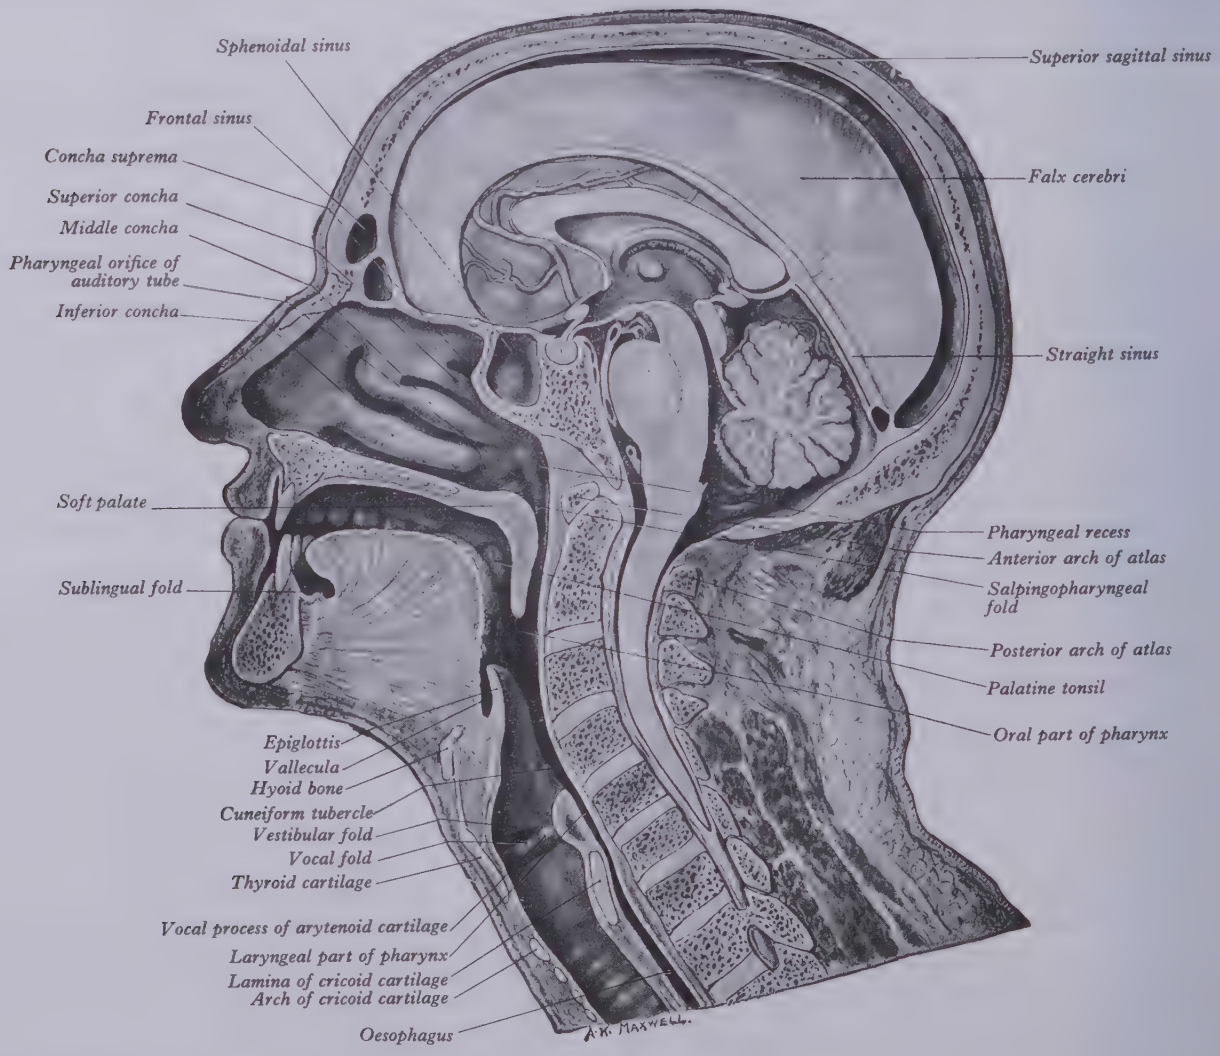
All the main tributaries of the pulmonary veins receive smaller tributaries, some intrasegmental and others intersegmental (p. 1284).

Bronchial arteries supply oxygenated blood to maintain the pulmonary tissues. They are derived from the descending thoracic aorta or the upper posterior intercostal arteries. They accompany the bronchial tree and supply bronchial glands and the walls of the bronchial tubes and larger pulmonary vessels. The bronchial branches form, in the muscular tunic of the air passages, a capillary plexus supporting a second, mucosal plexus which communicates with branches of the pulmonary artery and drains into the pulmonary veins. Other arterial branches ramify in interlobular areolar tissue and end partly in deep and partly in superficial, bronchial veins. Some also ramify on the surface of the lung, forming subpleural capillary plexuses. Bronchial arteries supply the bronchial wall as far as the respiratory bronchioles. They anastomose with branches of the pulmonary arteries in the walls of the smaller bronchi and in the visceral pleura. Such bronchopulmonary anastomoses may be more numerous in the newborn, then later obliterated to a marked degree (Wagenvoort & Wagenvoort 1967). In addition to the main bronchial arteries, smaller bronchial branches arise from the descending thoracic aorta; one of these may lie in the pulmonary ligament and may cause bleeding during inferior lobectomy.

Bronchial veins form two distinct systems (Marchand et al 1950). *Deep bronchial veins* commence as intrapulmonary bronchiolar plexuses, communicating freely with the pulmonary veins and eventually joining a single trunk which ends in a main pulmonary vein or in the left atrium. *Superficial bronchial veins* drain extrapulmonary bronchi, visceral pleura and the hilar lymph nodes; they also communicate with the pulmonary veins and end on the right in the azygos vein and on the left in the left superior intercostal or the accessory hemiazygos veins. Bronchial veins do not receive all the blood conveyed by bronchial arteries; some enters the pulmonary veins. The main bronchial arteries and veins run on the dorsal aspect of the extrapulmonary bronchi.

The pulmonary lymph vessels are described on p. 857. For reconstructions of the bronchial lymphatic networks consult Bastianini (1967,1968). Major ultrastructural features of pulmonary lymphatics include a thin basal lamina and abundant vesicles in the cytoplasm of the endothelial cells, with other evidence of pinocytosis, suggesting considerable passage of fluid across the lymphatic wall (Lauweryns & Boussaw 1967).

Pulmonary innervation. The anterior and posterior pulmonary plexuses are largely formed by sympathetic and vagal branches. Rami from these accompany the bronchial tubes, carrying efferent fibres to the bronchial muscles and glands and



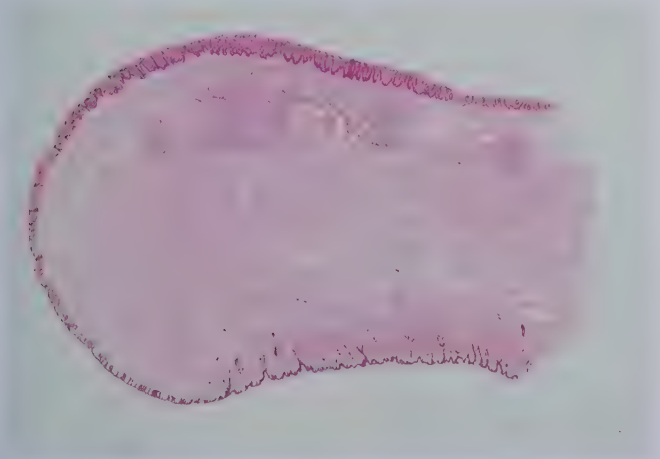
afferent fibres from the bronchial mucous membrane and alveoli. Small ganglia occur along these nerves. It is generally accepted that bronchoconstrictors are supplied by the vagus (pp. 1118, 1156), the sympathetic supply being inhibitory and relaxing the non-striated bronchial musculature, as does also the withdrawal or reduction of parasympathetic (vagal) stimulation. The actual stimulus for bronchodilatation is the pressure of inspired air. The innervation of the alveolar walls in the human lung has been studied at the ultrastructural level by Fox et al (1980).

Radiology. The trachea, because of its content of air, is more radio-translucent than neighbouring structures and hence visible in lateral and anteroposterior radiograms of the neck and upper thorax as a dark area in negatives (light in positive prints, **3**.63). Similarly, the lungs appear as dark areas in the thorax, flanking the central mediastinal opacity; they also appear darker at the end of inspiration and in diseased conditions in which the alveoli are permanently distended (emphysema), but are more radio-opaque in pathological states which reduce the air in them (e.g. pneumonia). Pulmonary shadows have superimposed on them the light shadows of pulmonary blood vessels branching from the hilum (see **6**.45 and Lodge 1946). These are sometimes mistaken for bronchi but the latter (because of contained air) obviously appear dark. Where a blood vessel is photographed end-on, it appears as a white circle (**8**.41A), a bronchus appearing as a dark circle surrounded by a white line (its wall). Hilar lymph nodes, if enlarged or calcified, appear as mottled areas near the mediastinum. The lumina of bronchi and bronchioles can be made radiologically visible by injecting a suitable radio-opaque oil into the trachea. Effusions of fluid into pleural cavities appear opaque in radiograms.

THE ALIMENTARY SYSTEM

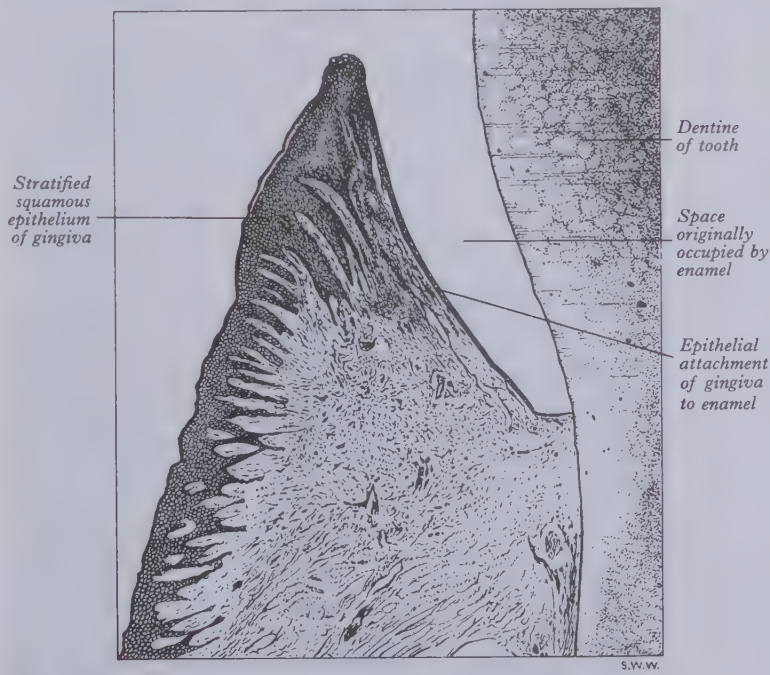
The alimentary system, also described as the *digestive* or *gastro-intestinal tract*, is not merely concerned with *digestion*, nor does it exclude the mouth, pharynx and oesophagus. It is a muscular canal, lined by a mucosa, extending from the lips to the anal orifice and displaying at successive levels a series of accessory structures, dental, glandular and muscular, for the ingestion, mastication, transport, digestion and absorption of foodstuffs of every kind and for the elimination of unabsorbed residues.

Throughout the *Chordata*, the alimentary and respiratory organs have shared a common history. In the primary aquatic era of



8.42A Median sagittal section through the head and neck. Where it divides the skull and the brain, the section passes slightly to the left of the median plane but, below the base of the skull, it passes slightly to the right of the median plane.

their evolution the two functions were intimately associated, as they still are in extant representatives. Dissolved oxygen and suspended particulate matter are absorbed or filtered from the same stream of water, entering through a single opening, the mouth, and escaping via a branchial apparatus of some kind, as in *Amphioxus*. The largest aquatic vertebrates of today, e.g. the basking shark *Cetorhinus* and baleen whales, the *Mysticeti*, still use filtration for food-gathering, though the filter is palatal in the latter. But many fishes, including some teleosts, have developed an ability to gulp in air to fill either a hydrostatic 'swim-bladder' or a respiratory 'air-bladder', which commonly loses continuity with the pharynx, deriving its contained gas from arterial blood (via the *dorsal* aorta). It is usually accepted that the respiratory system of terrestrial vertebrates is developed from a *ventral* 'air-bladder', supplied by the sixth branchial rami of the *ventral* aorta, as in extant *Dipnoi*, the lung fishes. *Amphibia* are similarly derived and they have the lungs and bronchial tree typical of terrestrial vertebrates, though many amphibians also depend on transcutaneous respiration. (Some urodeles, such as the newt *Necturus*, depend on this to such an extent that their lungs are said to have reverted to a flotation function!) Nevertheless, the buccal cavity and pharynx retain their initially dual function, even after division of the primitive mouth into definitive buccal and nasal chambers by palatal development in reptiles and in all subsequent vertebrates. Only with such specializations as the crocodilian larynx, which can be elevated into the nasopharynx during breathing, is complete *structural* separation of the upper respiratory and alimentary tracts achieved. In land vertebrates *functional* separation is nevertheless complete — into an apparatus conducting inspired and expired air with a regular periodicity, and another concerned in the intake and unidirectional passage of a highly varied pabulum, at intervals which vary enormously in different species and individuals. The early anatomical association persists, however; the dorsal position of the *respiratory* nasal chamber, relative to the *alimentary* buccal cavity, and the reversal of this relationship where the larynx diverges *ventrally* from the pharynx, entails a crossover between routes for air and food. Since both utilize the pharynx, except its nasal part, mechanisms have evolved to shut off the nasopharynx (by the soft palate) and respiratory tree (by the larynx) during swallowing. Because of their respiratory function, the nasal and oral parts of the pharynx, though muscular, are able to preserve their patency. (These complications are considered further on pp. 1248, 1328.)



The alimentary tract, being unidirectional, has a separate, caudal exit. This is essentially so even in the saccular urochordate *Ciona*, the sea-squirt, despite its sessile habit; its short gut with distinct mouth, pharynx and intestine opens into the atriopore, although this is, in fact, near the mouth. In the cephalochordate *Amphioxus*, differentiation of the gut has advanced, not only in the development of a caudal anus separate from the atrial chamber (into which the pharynx strains its aqueous intake) but also in the development of a diverticulum of the midgut, sometimes regarded as 'hepatic' but more probably a source of digestive enzymes. Both these chordates use the pharynx, with its numerous branchial clefts, to strain food particles from imbibed water, the concentrated solids being passed on into the intestine. Tracts of cilia and mucous glands aid this mechanism and transport in the intestine, a method still used in mammalian respiratory systems, though lost in the alimentary canal. These are examples of the ability of the lining epithelia (and associated mesoderm) of the alimentary tract to adapt most variously to the functions of its successive parts. Even in the Agnatha (e.g. *Petromyzon*, the lamprey) the buccal cavity has primitive teeth, a rasping tongue and salivary glands; the pharynx has a branchial complex and the gut is differentiated into oesophagus (foregut) and intestine (midgut) into which a liver delivers its secretion. There is no true stomach but, while no pancreas is identifiable, some epithelial cells in the proximal intestine resemble those in the exocrine pancreas of later forms of vertebrate. (Closed follicles of intestinal cells have also been described at the same level; these may represent the pancreatic endocrine element.) The lamprey's intestine also shows a surface-increasing specialization, the *typhlosole*, a helical fold of mucosa like the spiral valve of the elasmobranch intestine. Elasmobranchs also have a well-defined stomach, pepsin-producing and divisible into cardiac (glandular) and pyloric (muscular) parts. A definite pancreas also appears, secreting into the midgut, and a large liver. A rectum is also recognized. In teleostean fishes the chief advance is intestinal elongation and coiling, to a degree varying with feeding habits. In the amphibian alimentary tract the intestine is clearly separated into intestine proper and colon, a muscular valve intervening.

Except in *Eutherian* mammals, the vertebrate intestine ends in a *cloaca*, which also receives the urinary and usually the genital ducts. Complete separation of the end of the alimentary tube at an anus, though foreshadowed in Agnatha, was not achieved until the mammals appeared, though monotremes must be excluded. A similar peculiarity exists at the *commencement* of the tract, for salivary glands, considered present in Agnatha, are also characteristic of mammals but are absent from intervening classes.

It is not appropriate to amplify this superficial account of the evolution in the alimentary canal, even in mammals; but a few examples must be added to emphasize its adaptiveness to feeding habits. Birds, of course, display peculiar specializations: the teeth

8.42B Sagittal section through the lower lip of a neonate, showing thin non-hairy skin of the vermilion border (left) grading into thicker stratified squamous epithelium of the vestibule, with mucosal labial glands (above). Small fasciculi of circumoral muscles are also visible. Haematoxylin and eosin. Provided by A Hayward; photography: Sarah Smith.

8.43 A section across a tooth and the adjoining part of the gum. The enamel has been decalcified and removed, leaving a space between the dentine and the thin layer of stratified epithelium of the covering gum.

or their Jurassic ancestors (e.g. *Archaeopteryx*) have been lost; a hard, horny beak of highly variable form is the alternative feeding tool. The avian oesophagus is commonly dilated into a receptacle, the crop, and the stomach consists of a glandular proventriculus followed by a highly muscular gizzard, with a lining, often horny, and a content of swallowed stones to assist in grinding up hard foodstuffs. Among all mammals the general pattern of the alimentary tract is similar to the human; but the size and proportions of its different organs greatly vary. There is much variation in the relative size of the jaws and their musculature and even more marked differentiation in numbers, sizes and structure of teeth. All this reflects the plasticity of epithelial tissues and their associated mesodermal derivatives. Especially in the mucosa of the alimentary canal, this protean ability is manifest in production not only of varied epithelia (columnar, cuboidal, ciliated, stratified, keratinized and enamel-generating), but also a wide range of glandular structures, either as single cells or vast complexes such as the liver and pancreas, secreting a wide variety of digestive enzymes and hormones. Moreover, a range of endocrine cells is produced, including not only those of the thyroid gland and pancreatic islet tissue, long recognized, but also more recently identified systems of enterochromaffin and other endocrine cells (e.g. GEP and APUD series, p. 1376), scattered through much of the alimentary tract.

With these generalities in mind the detailed anatomy of the human alimentary tract must be considered seriatim at various levels, including its accessory organs, teeth, tongue, salivary glands, liver and pancreas. The microscopic structure of all these is included at appropriate points. It is also convenient and appropriate to describe the peritoneum with the subdiaphragmatic parts of the gut with which it is associated.

The alimentary canal is about 9 m long (see Underhill 1955 and p. 1355) and extends from mouth to anus, lined almost throughout by mucous membrane. It commences at the *mouth*, where provision is made for mechanical diminution of food (*mastication*) and admixture with the secretions of the salivary glands (*insalivation*); organs of swallowing (*deglutition*), the *palate*, *pharynx* and *oesophagus*, convey the mixture to the *stomach*, where the major digestive processes begin; the stomach empties into the *small intestine*, where digestion continues and many resulting products are absorbed into the blood and lymph. The small intestine leads to the *large intestine*, chiefly concerned in re-absorption of fluid, and opens finally at the *anus*. At many points the alimentary tube has sphincteric muscles, to be described seriatim (DiDio & Anderson 1968). For the general organization of the postpharyngeal alimentary tract see p. 1330. **The accessory digestive organs** are the *teeth*, which break up food, three pairs of main *salivary glands*—the *parotid*, *submandibular* and *sublingual*—whose secretion aids mastication in the mouth and the *liver* (with the *gallbladder*) and *pancreas*, large abdominal glands greatly concerned in digestion.

The Oral Cavity

The oral or buccal cavity, the 'mouth', consists of a smaller *vestibule* outside the teeth and an inner, larger *oral cavity proper*.

The *vestibule* is a slit-like space, bounded externally by the lips and cheeks and internally by the gums and teeth (**8**.42), communicating with the exterior by the *oral fissure*. Above and below, it is limited by the reflexion of the mucosa from the lips and cheeks on to the gums. When the teeth are apposed it communicates with the general oral cavity behind the third molar teeth and by clefts between adjacent teeth. On the cheek's internal surface, opposite the second upper molar crown, a small papilla bears the opening of the duct of the parotid salivary gland. The *oral cavity proper* (**8**.89, 90) is bounded anterolaterally by the alveolar arches, teeth and gums; behind, it communicates with the pharynx at the *oropharyngeal isthmus*, between the palatoglossal folds. Its roof is formed by the hard and soft palates, most of its floor by the anterior region of the tongue and the remainder by the reflexion of the mucosa from its sides and inferior surface to the gum on the internal mandibular surface. A median crescentic *frenulum linguae* connects the inferior surface of the anterior part of the tongue to the oral floor. Inferiorly, on each side of the frenulum, a small *sublingual papilla* bears the orifice of the duct of the submandibular salivary gland. From this papilla a ridge extends posterolaterally in the floor, produced by the subjacent sublingual salivary gland and hence termed the *sublingual fold*; minute openings of the gland's ducts appear on the edge of the fold. The oral *mucosa* is continuous with the skin at the labial margins and with the pharyngeal mucosa at the oropharyngeal isthmus; it is roseate pink and very thick where it overlies bone. It has a stratified squamous epithelium which, except on the anterior tongue, is never completely cornified and is in many places non-keratinized. The *lymph vessels* of the mouth are described on p. 844.

The lips (**8**.42B) are two fleshy folds around the oral orifice, formed externally of skin and internally of mucous membrane enclosing the orbicularis oris, labial vessels and nerves, fibro-adipose connective tissue and numerous small labial salivary glands secreting into the oral cavity. The line of contact between the lips (*the oral fissure*) is opposite the cutting edges of the superior incisor teeth; on each side a *labial commissure* forms the *angle of the mouth*, usually near the first premolar tooth. External and central in the upper lip is a shallow vertical groove, the *philtrum*, ending below in a slight *tubercle* and limited by lateral ridges. Internally each lip is connected to the gum by a median *labial frenulum*, the upper being the larger.

The *labial glands*, situated between the mucosa and orbicularis oris, are about the size of small peas and in structure resemble mucous salivary glands (p. 1290). Their ducts open into the vestibule.

The cheeks are continuous in front with the lips, the junction indicated externally by *the nasolabial sulcus*, which descends laterally from the side of the nose to each oral angle. They contain a muscular stratum and variable but usually considerable amount of adipose tissue, together with areolar tissue, vessels, nerves and buccal glands, covered externally by skin and internally by mucous membrane. The *mucosa* of the cheek is reflected on to the external surfaces of the maxilla and mandible and thence to the gums; it is continuous behind with the palatal mucosa. The parotid duct, as already noted, opens opposite the crown of the second upper molar tooth. The principal muscle is buccinator, but others are also involved, e.g. zygomaticus major, risorius and platysma (see p. 573). The *buccal mucous glands* lie mainly between the mucosa and buccinator. Four or five larger ones (*molar glands*) lie external to the buccinator around the termination of the parotid duct; their ducts pierce the buccinator to open opposite the last molar tooth. *Lymph vessels* of the cheeks and lips are described on p. 845.

The gums (*gingivae*) (**8**.43) are composed of dense, vascular fibrous tissue covered by stratified, parakeratinized squamous epithelium. They consist of free parts which surround the neck of each tooth like a collar and attached parts which are firmly anchored to the alveolar processes of the mandible and maxillae. The fibrous tissue is continuous with the alveolar periosteum. In young people the stratified squamous epithelium is attached to the enamel of the teeth (epithelial attachment) but later the gums recede from the enamel and are attached to the cementum. Near the teeth, the mucosa on the buccal aspect of the gums develops tall papillae but becomes smooth where related to the enamel (**8**.43). *The nerves* of the upper gum come from the maxillary nerve via its anterior palatine, nasopalatine and anterior, middle and posterior superior alveolar branches. The mandibular nerve innervates the lower gum by the inferior alveolar, lingual and buccal branches. The buccal nerve supplies the external aspects of the lower gum as far forwards as the mental foramen. Vessels usually accompany the nerves. Lymphatics of the upper gum drain to the submandibular nodes; those from the anterior part of the lower gum pass to the submental nodes and from its posterior part to the submandibular nodes.

The gingival stratified squamous epithelium, like that of skin, contains melanocytes which are more obvious in pigmented

races. Dendritic (Langerhans) cells are also present within the epithelium. The incidence of these two types of cells has been assessed (Barker 1967); the dendritic cells are more superficially located than the melanocytes and more frequent in the crevices between adjacent teeth. (For a detailed study of the oral cavity and tongue, consult Combelles 1972.)

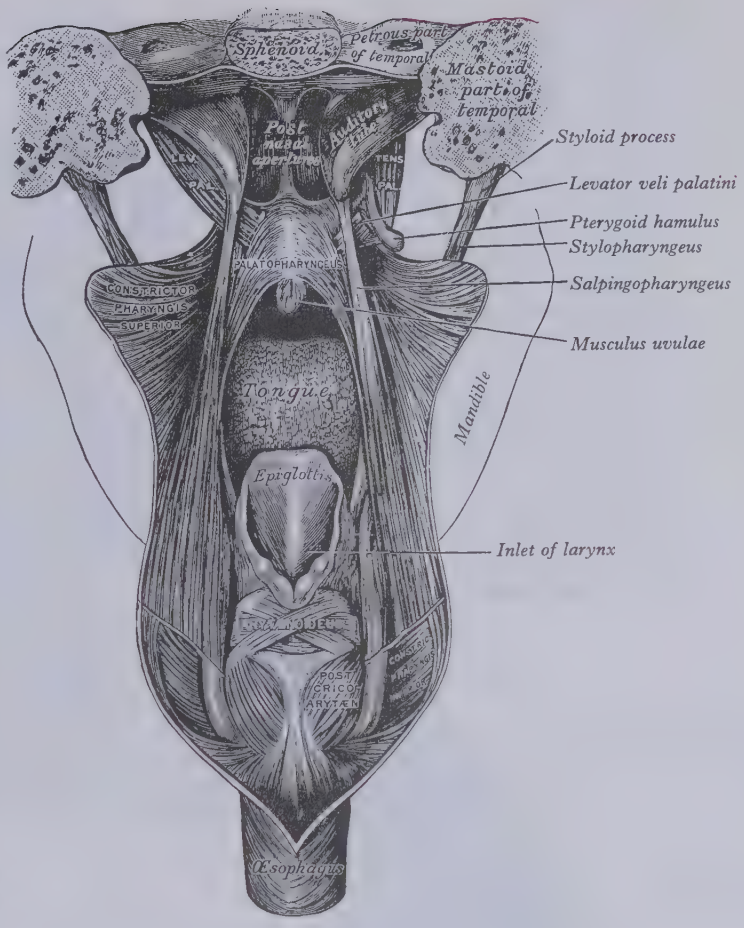
THE PALATE

The palate, or oral roof, is divisible into two regions: the *hard palate* in front and *soft palate* behind.

The hard palate (**8**.62) is formed by the palatine processes of the maxillae and the horizontal plates of the palatine bones. It is bounded anterolaterally by the alveolar arch and gums and is continuous posteriorly with the soft palate, being covered by a dense mucoperiosteum. It has a median, linear raphe, ending anteriorly in a small papilla over the incisive fossa, on each side of which the mucosa is thick, pale and corrugated; posteriorly it is thin, smooth and redder. Its epithelium is keratinized stratified squamous. It has numerous palatine mucous glands which lie between the mucosa and periosteum in its posterior half. The upper surface of the hard palate is part of the nasal floor and is covered by ciliated epithelium.

The soft palate (**8**.42), a mobile flap suspended from the posterior border of the hard palate, slopes down and back between the oral and nasal parts of the pharynx. It is a fold of mucosa enclosing an aponeurosis, muscular tissue, vessels, nerves, lymphoid tissue and mucous glands. In its usual position, relaxed and pendant, its anterior (oral) surface is concave, with a median raphe. Its posterior aspect is convex and continuous with the nasal floor. Its superior border is attached to the hard palate's posterior margin, its sides blended with the pharyngeal wall and its inferior border is free, hanging between the mouth and pharynx.

A median conical process, the *uvula*, projects from its posterior border; the palatal arches, two curved folds of mucosa containing muscle, descend laterally from each side of the uvular base (**8**.90). The anterior, *palatoglossal arch* contains palatoglossus and descends to the side of the tongue at the junction of its oral and pharyngeal parts, forming the lateral limits of the oropharyngeal isthmus. The posterior, *palatopharyngeal arch* containing the palatopharyngeus descends on the lateral wall of the oropharynx (p. 1321). The *isthmus of the fauces* includes both arches.



Flanking the median palatine raphe, near the junction of the hard and soft parts of the palate, there is often a pair of depressions, a few millimetres apart. These *palatine foveae* may extend into pits, a few millimetres deep, with openings sagittally elongated. They are the common superficial orifices of converging ducts from the palatine mucous glands. The thin *palatine mucosa* has non-keratinized, stratified squamous epithelium, except on its upper pharyngeal surface and near the orifices of the auditory tubes, where it is columnar ciliated ('respiratory epithelium'), as in the nasal cavities. Beneath the mucosa on both surfaces are palatine mucous glands; they are most abundant around the uvula and on the oral aspect of the soft palate, where taste buds also occur.

Vessels and Nerves

The *arteries* of the palate are the greater palatine branch of the maxillary artery, the ascending palatine branch of the facial artery and the palatine branch of the ascending pharyngeal artery. The *veins* end largely in the pterygoid and tonsillar plexuses. The *lymph vessels* pass to the deep cervical lymph nodes. The *sensory nerves* issue from the greater and lesser palatine, nasopalatine and glossopharyngeal nerves; the lesser palatine contain taste fibres from the oral surface of the soft palate.

The Palatine Aoneurosis

A thin, fibrous *palatine aponeurosis* supports the muscles and strengthens the soft palate; it is attached to the posterior border and inferior surface of the hard palate behind the palatine crest. It is thick in the anterior two-thirds of the soft palate but very thin further back. It is composed of the expanded tendons of the tensores veli palatini; near the midline it encloses the musculus uvulae. All the other palatine muscles are attached to it. The juxta-osseous part of the soft palate contains little muscle, consisting mainly of the palatine aponeurosis, inferior to which are many mucous glands; it is less mobile and more horizontal than the rest of the soft palate and the tensores veli palatini act mainly upon it.

8.44 The muscles of the palate, exposed from the posterior aspect.

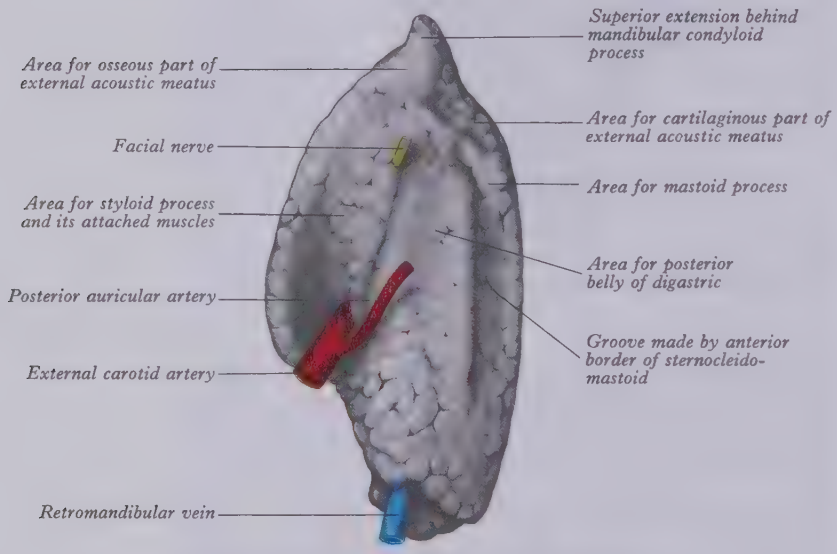
THE PALATINE MUSCULATURE

The palatine muscles (**8**.44) include levator veli palatini, tensor veli palatini, palatoglossus and palatopharyngeus and musculus uvulae. For their activities in swallowing and speech see p. 1328.

Levator veli palatini (**8**.44, 99, 100) is cylindrical and lies lateral to the posterior nasal aperture. According to Rohan & Turner (1956) it is attached: (1) by a small tendon to a rough area on the inferior surface of the petrous temporal bone in front of the lower opening of the carotid canal; (2) by muscle fibres to a sheet of fascia descending from the tympanic vaginal process to form the upper part of the carotid sheath; and (3) by a few fibres to the inferior aspect of the cartilaginous part of the auditory tube. At its origin the muscle is inferior rather than medial to the auditory tube and only crosses medial to it at the level of the medial pterygoid lamina. Passing above the upper margin of the superior constrictor and in front of the salpingopharyngeus, it spreads in the soft palate between the two strands of the palatopharyngeus, its fibres being attached to the upper surface of the palatine aponeurosis as far as the midline where they blend with those of its fellow.

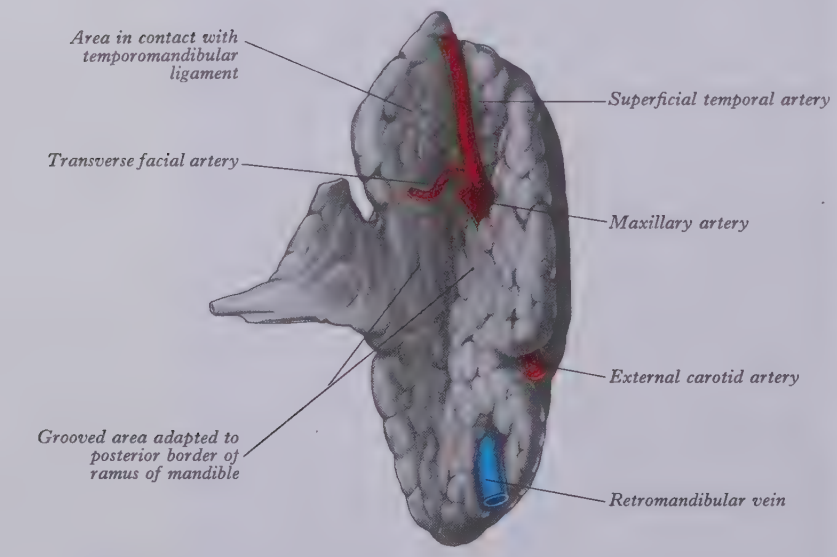
Action. The levator veli palatini elevates the soft palate.

The tensor veli palatini (**8**.44, 94, 100), a thin, triangular muscle, is lateral to the medial pterygoid plate, auditory tube and levator veli palatini. Its lateral surface contacts the upper anterior part of the medial pterygoid, the mandibular, auriculo-temporal and chorda tympani nerves, the otic ganglion and the middle meningeal artery. It is attached to the scaphoid fossa of the pterygoid process, the lateral lamina of the cartilage of the



auditory tube and the medial aspect of the sphenoidal spine; from this point it descends, its fibres converging into a delicate tendon turning medially round the pterygoid hamulus to pass through the origin of the buccinator to the palatine aponeurosis and the osseous surface behind the palatine crest on the horizontal plate of the palatine bone. Between the tendon and the pterygoid hamulus is a small bursa.

Actions. Alone, the muscle pulls the soft palate to one side; with its fellow it tautens the soft palate (principally its anterior part), depressing it by flattening its arch.



The musculus uvulae, a bilateral structure, is attached to the posterior nasal spine of the palatine bone and to the palatine aponeurosis, between the two laminae of which the uvular muscles lie; it descends to be inserted into the uvular mucosa.

Action: elevation and retraction of the uvula.

The palatoglossus is a small fasciculus narrower at its middle than at its ends and forming, with the mucosa over it, the palatoglossal arch or fold. From the oral surface of the palatine aponeurosis, where it is continuous with its fellow, it extends antero-inferiorly and laterally in front of the tonsil to the side of the tongue, some of its fibres spreading over the lingual dorsum, others passing deeply into its substance to intermingle with the transversus linguae.

8.45A The right parotid gland: posteromedial aspect.

8.45B The right parotid gland: anteromedial aspect.

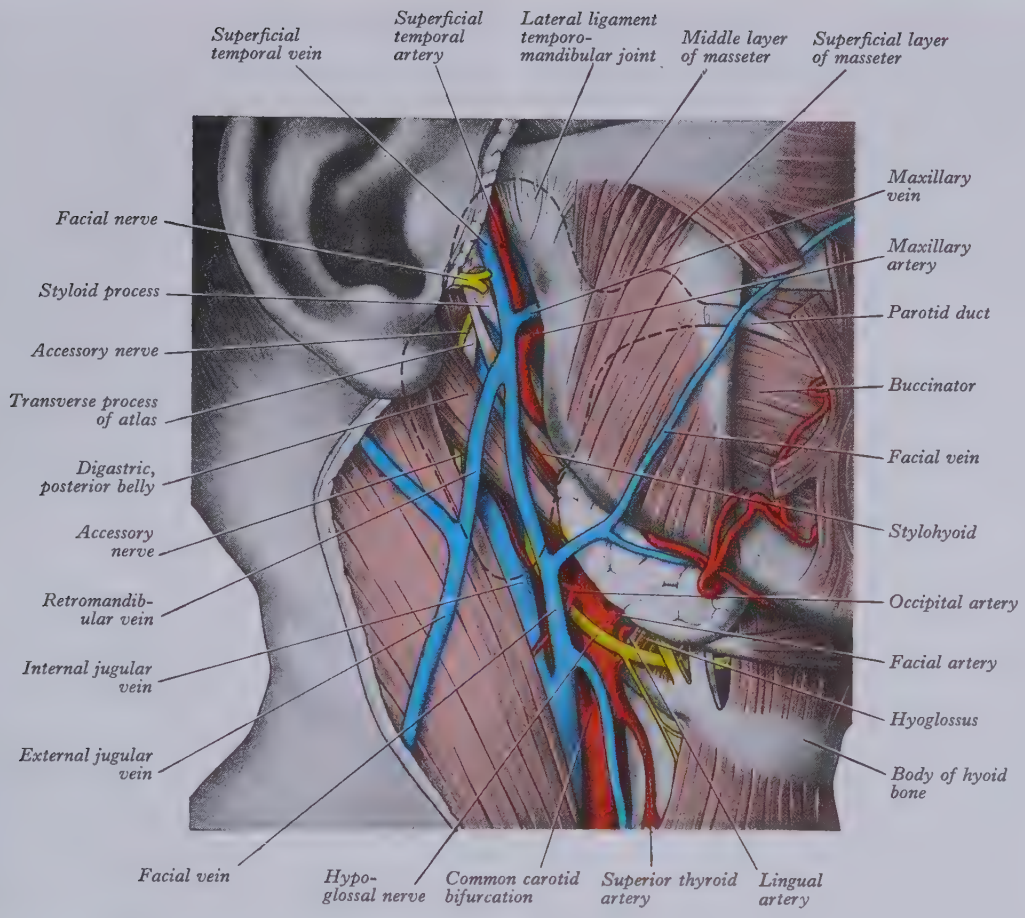
Actions. Palatoglossus elevates the root of the tongue and approximates the palatoglossal arch to its fellow, thus shutting off the oral cavity from the oropharynx.

The palatopharyngeus (8.44, 100) forms, with its overlying mucosa, the palatopharyngeal arch. In the palate its two fasciculi are separated by levator veli palatini. The *posterior* fasciculus is in contact with the mucosa of the pharyngeal aspect of the palate; it joins the posterior band of the opposite muscle in the midline. The thicker *anterior* fasciculus passes between the levator and tensor veli palatini and is attached to the posterior border of the hard palate and to the palatine aponeurosis, some fibres interdigitating with their fellows across the midline. Both fasciculi are attached to the upper aspect of the palatine aponeurosis in the same plane. At the soft palate's posterolateral border the two layers unite and are joined by fibres of salpingopharyngeus (p. 1324). Passing laterally and downwards behind the tonsil, the palatopharyngeus descends posteromedial to the stylopharyngeus, to be attached with it to the posterior border of the thyroid cartilage; some fibres end on the side of the pharynx, attached to pharyngeal fibrous tissue and others cross the midline posteriorly, decussating with those of the opposite muscle. The palatopharyngeus thus forms an incomplete internal longitudinal muscular layer in the wall of the pharynx.

Actions. The palatopharyngei pull the pharynx up, forwards and medially, shortening it during swallowing. They also approximate the palatopharyngeal arches drawing them forwards.

Nerve supply. Except for tensor veli palatini, which is innervated by the mandibular nerve (p. 1103), all the palatine muscles are supplied by nerve fibres which leave the medulla in the cranial part of the accessory nerve and reach the pharyngeal plexus via the vagus nerve.

In the soft palate the muscles are arranged as follows: the palatine aponeurosis (tendon of the tensores veli palatini) is intermediate, enclosing the uvular muscles near the midline; the levatores veli palatini and palatopharyngi are attached to its upper surface, the two fasciculi of the latter separated by the former; the palatoglossi are attached to the inferior surface of the aponeurosis. (For a description of *the palatopharyngeal sphincter*, see p. 1327.)



Applied Anatomy. The condition of congenital cleft palate has been noted already as a developmental defect (p. 168). Paralysis of the soft palate may follow diphtheria due to the action of the toxin on the nerve cells of the medulla oblongata; in this state, the voice becomes nasal and fluids regurgitate into the nose during swallowing; the palate is visibly flaccid and motionless and also anaesthetic. Other pathological processes involving the glossopharyngeal, vagus and accessory nerves or their nuclei in the medulla oblongata also cause palatal paralysis.

The Salivary Glands

A salivary gland is any cell or organ discharging a secretion into the oral cavity; but a distinction is customarily made between the *major salivary glands*, located at some distance from the oral mucosa, with which they connect by extraglandular ducts, and the *minor salivary glands* which lie in the mucosa or submucosa, opening directly through the mucosa or indirectly via many short ducts. In humans the major salivary glands comprise the paired parotid, submandibular and sublingual glands; the minor salivary group includes the anterior glands of the tongue, numerous small lingual glands (including von Ebner's glands, p. 1322) and small labial, buccal and palatal glands (p. 1298). Their functions include: lubrication of food to assist deglutition, moistening the buccal mucosa, aiding speech, provision of an aqueous solvent necessary for taste and as a fluid seal for sucking and suckling, secretion of digestive enzymes such as salivary amylase and of hormones and other compounds, such as a glucagon-like protein (Lawrence et al 1977) and possibly serotonin (Feyrter 1961) and secretion of antimicrobial agents (IgA and lysozyme).

THE PAROTID GLANDS

The paired parotid glands (8.45A, B) are the largest of the salivary glands; each has an average weight of about 25 g and is an irregular, lobulated, yellowish mass, lying largely below the external

8.46 Drawing of a dissection to show the principal immediate deep relations of the parotid gland. The outline of the parotid gland is indicated by the interrupted black line.

acoustic meatus between the mandible and sternocleidomastoid; it also projects forwards on the surface of the masseter, where a small, usually detached part lies between the zygomatic arch above and the parotid duct below, the *pars accessoria* or *socia parotidis*.

The glandular capsule is derived from the deep cervical fascia; its superficial layer is dense, closely adherent to the gland and attached to the zygomatic arch; medial to the gland it is attached to the styloid process, mandible and tympanic plate, blending with the fibrous sheaths of related muscles; the fascia extending from the styloid process to the mandibular angle forms a stylomandibular ligament between the parotid and submandibular glands. The parotid gland is like an inverted, flat, three-sided pyramid, presenting a small superior and superficial, anteromedial and posteromedial surfaces; it tapers inferiorly to a blunt apex.

The concave *superior surface* is related to the cartilaginous part of the external acoustic meatus and posterior aspect of the temporomandibular joint; here the auriculotemporal nerve curves round the mandibular neck, embedded in the gland's capsule. The *apex* overlaps the posterior belly of the digastric and the carotid triangle to a variable extent.

The *superficial surface* is covered by skin and superficial fascia, which contains facial branches of the great auricular nerve, superficial parotid lymph nodes (p. 843) and the posterior border of platysma. It extends upwards to the zygomatic arch, back to overlap the sternocleidomastoid, down to its apex postero-inferior to the mandibular angle and forwards superficial to the masseter below the parotid duct (**8**.46).

The *anteromedial surface* is grooved by the posterior border of the mandibular ramus. It covers the postero-inferior part of the masseter, the lateral aspect of the temporomandibular joint and the adjoining part of the mandibular ramus, passing forwards medial to the ramus to reach the medial pterygoid. Branches of the facial nerve emerge on the face from the anterior margin of this surface.

The *posteromedial surface* is moulded to the mastoid process, sternocleidomastoid, posterior belly of the digastric and the styloid process and its muscles. The external carotid artery grooves this surface before entering the gland. The internal carotid artery and internal jugular vein are separated from the gland by the styloid process and its muscles (**8**.46). The anteromedial and posteromedial surfaces meet at a medial margin which may project so deeply as to be in contact with the lateral wall of the pharynx.

Several structures traverse the gland partly or wholly and even branch within it. The external carotid artery enters the posteromedial surface, dividing into the maxillary artery which emerges from the anteromedial surface and the superficial temporal artery which gives off its transverse facial branch in the gland and ascends to leave its upper limit (**8**.45B). The posterior auricular artery may also branch from the external carotid within the gland, leaving by its posteromedial surface. The retromandibular vein (p. 794), formed by the union of the maxillary and superficial temporal veins (which enter near the points of exit of the corresponding arteries), is superficial to the external carotid artery and emerges behind the gland's apex to join the posterior auricular vein, forming the external jugular; it has a communicating branch which leaves anterior to the apex to join the facial vein. Most superficial is the facial nerve, entering high on the posteromedial surface (**8**.45A) and passing forwards and down behind the mandibular ramus in two main divisions, from which its terminal branches diverge (**7**. 118) to leave by the anteromedial surface, passing medial to its anterior margin.

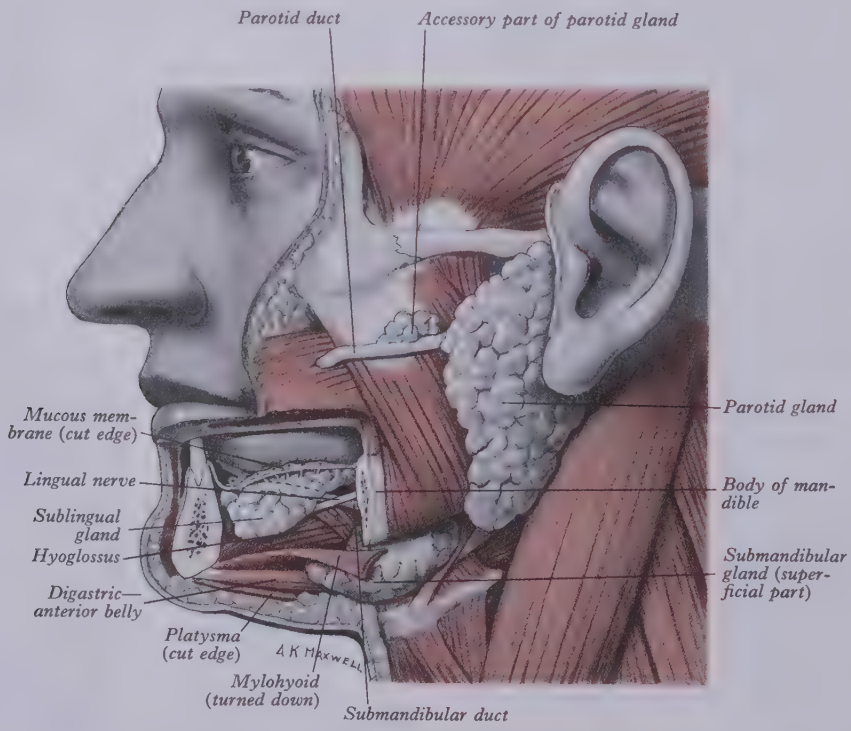
The parotid gland develops as an outgrowth from the buccal cavity (p. 227), spreading back towards the ear and covering the

facial nerve; prolongations penetrate medially between the branches of the nerve to form its deeper part, the largest part being between the nerve's main temporal and cervical divisions (Bailey 1947, McKenzie 1948). These processes finally engulf the nerve and its branches, which are sometimes considered to divide the gland into a superficial and a deep lobe.

The parotid duct (8.47, 54A), about 5 cm long, begins by the confluence of two main tributaries within the anterior part of the gland (p. 1298), then crosses the masseter and at its anterior border turns medially at almost a right angle, traversing the corpus adiposum (suctorial pad of infants) and the buccinator. It then runs obliquely forwards for a short distance between the buccinator and the oral mucosa to open upon a small papilla opposite the second upper molar crown. While crossing the masseter it receives the accessory parotid duct and here lies between the upper and lower buccal branches of the facial nerve; the accessory part of the gland and the transverse facial artery are above it. The buccal branch of the mandibular nerve, emerging from beneath the temporalis and masseter, is just below the duct at the masseter's anterior border.

The wall of the parotid duct is thick, with an external fibrous layer containing non-striated muscle and a mucosa lined by low columnar epithelium (vide infra). Its calibre is about 3 mm, but smaller at its oral orifice.

Surface Anatomy. The parotid duct can be felt on the face or more easily in the vestibule and rolled on the anterior border of the masseter, by pressing the finger *backwards* on it (with teeth clenched to make the muscle tense). The anterior border of the parotid gland is represented by a line descending from the mandibular condyle to about the middle of the masseter and then to a point about 2 cm inferoposterior to the mandibular angle. Its concave upper border corresponds to a curve from the mandibular condyle across the ear's lobule to the mastoid process. The posterior border is indicated by a straight line between the ends of the anterior and upper borders. The parotid duct corresponds to the middle third of a line drawn from the lower border of the tragus to a point midway between the nasal ala and upper labial margin.



Vessels and Nerves

The parotid *arterial supply* is from the external carotid and its branches in and near the gland. The *veins* drain to the external jugular, through local tributaries. The *lymph vessels* end in the superficial and deep cervical lymph nodes, interrupted by two or three nodes lying on and within the gland. The *efferent innervation* is autonomic, consisting of sympathetic fibres from the external carotid plexus and parasympathetic fibres which reach it via the tympanic branch of the glossopharyngeal nerve relaying in the otic ganglion and then travelling along the auriculotemporal nerve. Clinical observations suggest that the human gland also receives secretomotor fibres through the chorda tympani (Reichert & Poth 1933, Diamant & Wiberg 1965). Holmberg (1972) has shown that in *dogs* secretomotor fibres pass to the parotid gland from the maxillary plexus and the facial and auriculotemporal nerves, a supply unconfirmed in man. The termination of these supplies is still controversial. Studies in *cats* suggest that both parasympathetic and sympathetic fibres end in relation to glandular cells (Genvis-Galvey et al 1966, and vide infra).

THE SUBMANDIBULAR GLANDS

The paired submandibular glands (8.47) are irregular in shape and about the size of a walnut. Each consist of a large superficial and a smaller deep part, continuous with each other around the posterior border of the mylohyoid.

The *superficial part*, situated in the digastric triangle, reaches forward to the anterior belly of the digastric and back to the stylomandibular ligament, which separates it from the parotid gland. Above, it extends medial to the mandible's body; below, it usually overlaps the intermediate tendon of the digastric and the hyoidean attachment of stylohyoid. It has an inferior, a lateral and a medial surface and is partially enclosed between two layers of deep cervical fascia extending from the hyoid's greater cornu; one layer passes to the mandible's lower border, covering the gland's inferior surface, the other passes to the

8.47 Dissection showing the salivary glands of the left side. The cranial region of the superficial part of the submandibular gland has been excised and the cut mylohyoid has been turned down to expose a portion of the deep part of the gland.

mylohyoid line on the medial surface of the mandible and covers the gland's medial surface.

The *inferior surface*, covered by skin, platysma and deep fascia, is crossed by the facial vein and facial nerve's cervical branch; near the mandible the submandibular lymph nodes are in contact with the gland and some may be embedded in it (p. 844).

The *lateral surface* is in relation with the submandibular fossa (on the medial surface of the mandibular body) and the mandibular attachment of the medial pterygoid; the facial artery grooves its posterosuperior part, lying at first deep to the gland and then emerging between its lateral surface and the mandibular attachment of the medial pterygoid to reach the mandible's lower border.

The *medial surface* is related anteriorly to the mylohyoid, separated from it by the mylohyoid nerve and vessels and branches of the submental vessels. More posteriorly, it is related to the styloglossus, stylohyoid ligament and glossopharyngeal nerve, which separate it from the pharynx; in its intermediate part the medial surface is related to the hyoglossus, separated from it by the styloglossus, the lingual nerve, submandibular ganglion, hypoglossal nerve and deep lingual vein (sequentially from above down). Below, the medial surface is related to the stylohyoid and the posterior belly of the digastric.

The *deep part* of the gland extends forwards to the posterior end of the sublingual gland and lies between the mylohyoid inferolaterally and the hyoglossus and styloglossus medially; above it is the lingual nerve and, below it, the hypoglossal nerve and deep lingual vein.

The gland is palpable between an index finger placed on the floor of the mouth and a thumb placed anteromedial to the angle of the mandible, below the floor.

The submandibular duct (**8**.54B) is about 5 cm long and has a thinner wall than the parotid duct. It begins from numerous tributaries in the superficial part of the gland and emerges from the medial surface of this part of the gland behind the posterior border of the mylohyoid; it traverses the deep part, passing at first up and slightly back for 4 or 5 mm and then forwards between the mylohyoid and hyoglossus. Passing between the sublingual gland and genioglossus it opens in the oral floor on the summit of the sublingual papilla at the side of the frenulum of the tongue (**8**.89). On the hyoglossus it lies between the lingual and hypoglossal nerves, but at the muscle's anterior border it is crossed laterally by the lingual nerve, terminal branches of which ascend on its medial side (**8**.95). As it traverses the gland's deep part it receives small tributaries draining this part of the gland. Salivary calculi occasionally occur in the submandibular duct; they are radiopaque and may be palpable.

Vessels and Nerves

The *arteries* supplying the submandibular gland are branches of the facial and lingual; the *veins* correspond. The *lymph vessels* drain into the deep cervical group of lymph nodes, particularly the jugulo-omohyoid node, interrupted by the submandibular nodes, some of which are in close relation with the anterior end and medial aspect of the superficial part of the gland and may be embedded in it. The *nerves* are derived from the submandibular ganglion, through which it receives fibres from the chorda tympani (parasympathetic), the lingual branch of the mandibular nerve and the sympathetic trunk. In dogs and cats the gland receives its nerve supply through the subsidiary ganglion of Langley (p. 1155), but in humans the parasympathetic nerve supply (chorda tympani) relays mainly in the submandibular ganglion. Small parasympathetic ganglia may occur in the gland's hilum and in the branches of the submandibular ganglion passing to it. Garrett & Kemplay (1977), using catecholamine fluorescence and electron micrography, observed that in cats all adrenergic fibres are derived from the superior cervical sympathetic ganglion.

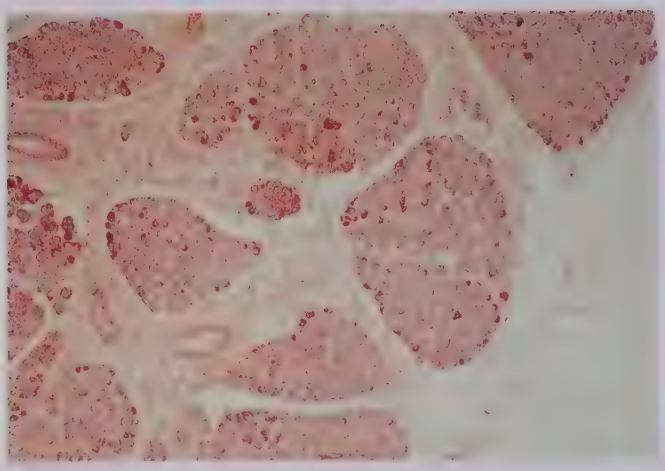
THE SUBLINGUAL GLANDS

The paired sublingual glands (**8**.47), the smallest of the main salivary glands, lie beneath the oral mucosa, each in contact with the sublingual fossa on the lingual aspect of the mandible, close to the symphysis. Each is narrow, flat, shaped like an almond, and weighs 3–4 g. *Above* it is the mucosa of the oral floor, raised as a sublingual fold; *below* the mylohyoid; *in front* the anterior end of its fellow; *behind*, the deep part of the submandibular gland; *lateral* is the mandible above the anterior part of the mylohyoid line and *medial* is the genioglossus separated from it by the lingual nerve and submandibular duct. It has 8–20 excretory ducts; of the *smaller sublingual ducts* most open separately on the summit of the sublingual fold and a few sometimes into the submandibular duct. From the anterior part of the gland small rami sometimes form a *major sublingual duct*, opening with or near to the submandibular duct.

Vessels and Nerves

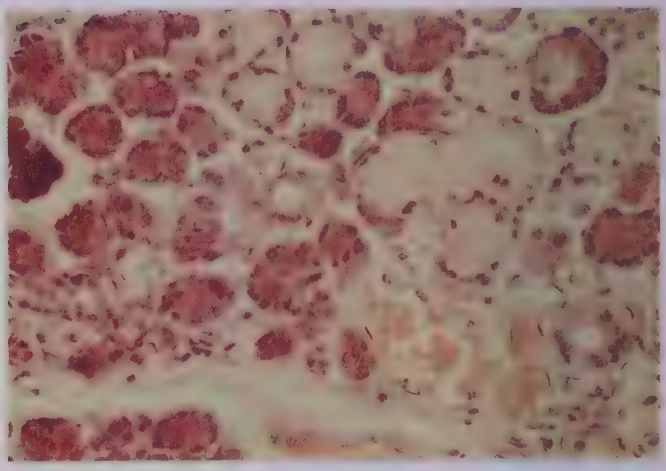
The *arterial supply* is by the sublingual and submental arteries. The *veins* correspond. *Innervation* is by the lingual nerve, chorda tympani and sympathetic fibres. The parasympathetic relay is in the submandibular ganglion; neurons may occur among its distal fibres to the lingual nerve forming a distinct sublingual ganglion. The precise terminations of the nerve supply are not fully known (vide infra).

STRUCTURE OF MAJOR SALIVARY GLANDS



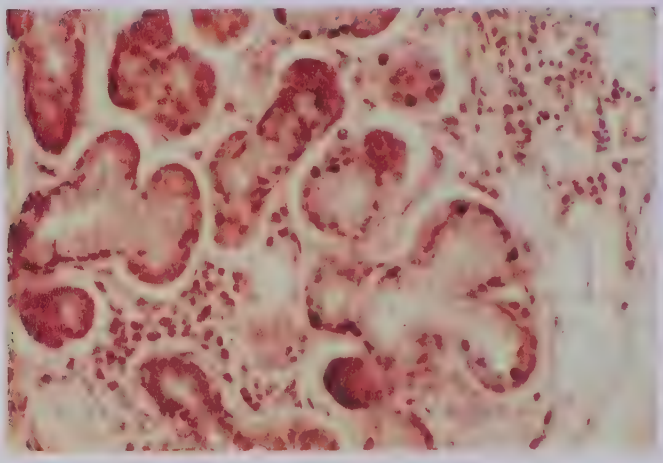
These compound racemose glands (**8**.48A,B, 49A,B, 50, 51, 52) have numerous lobes composed of lobules linked by dense connective tissue containing excretory (collecting) ducts, blood vessels, lymph vessels, nerve fibres and small ganglia. Each lobule has a single duct, whose branches end as dilated secretory 'endpieces' or acini. Their primary secretion is modified as it traverses intercalated, striated and excretory ducts into one or more main ducts which discharge saliva into the oral cavity.

Salivary Acini or 'Endpieces'



Variation in the terms describing the form and cytology of secretory acini or endpieces has caused much confusion. Garrett (1976) and Young & van Lennep (1978) have appraised the problems involved. (The official term is *portio terminalis*— of acinar, alveolar or tubulo-alveolar types—inelegantly translated as 'endpiece'.)

In the following description a secretory 'endpiece' is termed an *acinus* if approximately spheroidal, a *tubule* if elongate; *tubuloacini* are intermediate in shape. Secretory cells of acini are pyramidal, with narrow luminal apices and broad bases; those of tubules are more cylindrical. Such cells, the main producers of salivary protein and glycoprotein, are usually described as *serous*, *seromucous* or *mucous*, unfortunately without unanimity in use. A serous secretion of low viscosity and a highly viscous mucus were correlated initially with serous and mucous cells distinguished by simple staining. Improved techniques identified a seromucous variety. It is now established that products of these cells form an almost continuous series, from serous secretions with negligible amounts of protein-associated acidic carbohydrates to mucous secretions rich in them. Attempts to define the terms serous, seromucous and mucous histochemically (Leblond 1950, Munger 1964, Shackleford & Wilborn 1968) have proved indecisive. Though definition may be desirable, it is more convenient in practice to use observable cytological features, such as the appearance of the secretory granules. Applying the criteria of Young & van Lennep (1978) glandular cells are here dubbed: *serous* if the granules are small, discrete, homogeneous, generally eosinophilic and electron-dense; *mucous* if their granules are larger, close-packed and ill-defined, with low eosinophilia and a homogeneous, fairly electron-translucent matrix; or *seromucous* if they are intermediate in appearance, with granules either close-packed, eosinophilic and homogeneous, or more discrete, larger and heterogeneous. A gland or secretory acinus with only one type of cell is *homocrine*, while one containing more than one type is *heterocrine*.



The secretory 'endpieces' of the human *parotid gland* are mainly seromucous (or serous) acini; mucous acini are rare. In the *submandibular gland* acini are usually seromucous with some mucous. In the *sublingual gland* they are typically mucous tubules, but seromucous cells also occur, frequently as acini or as *demilunes*

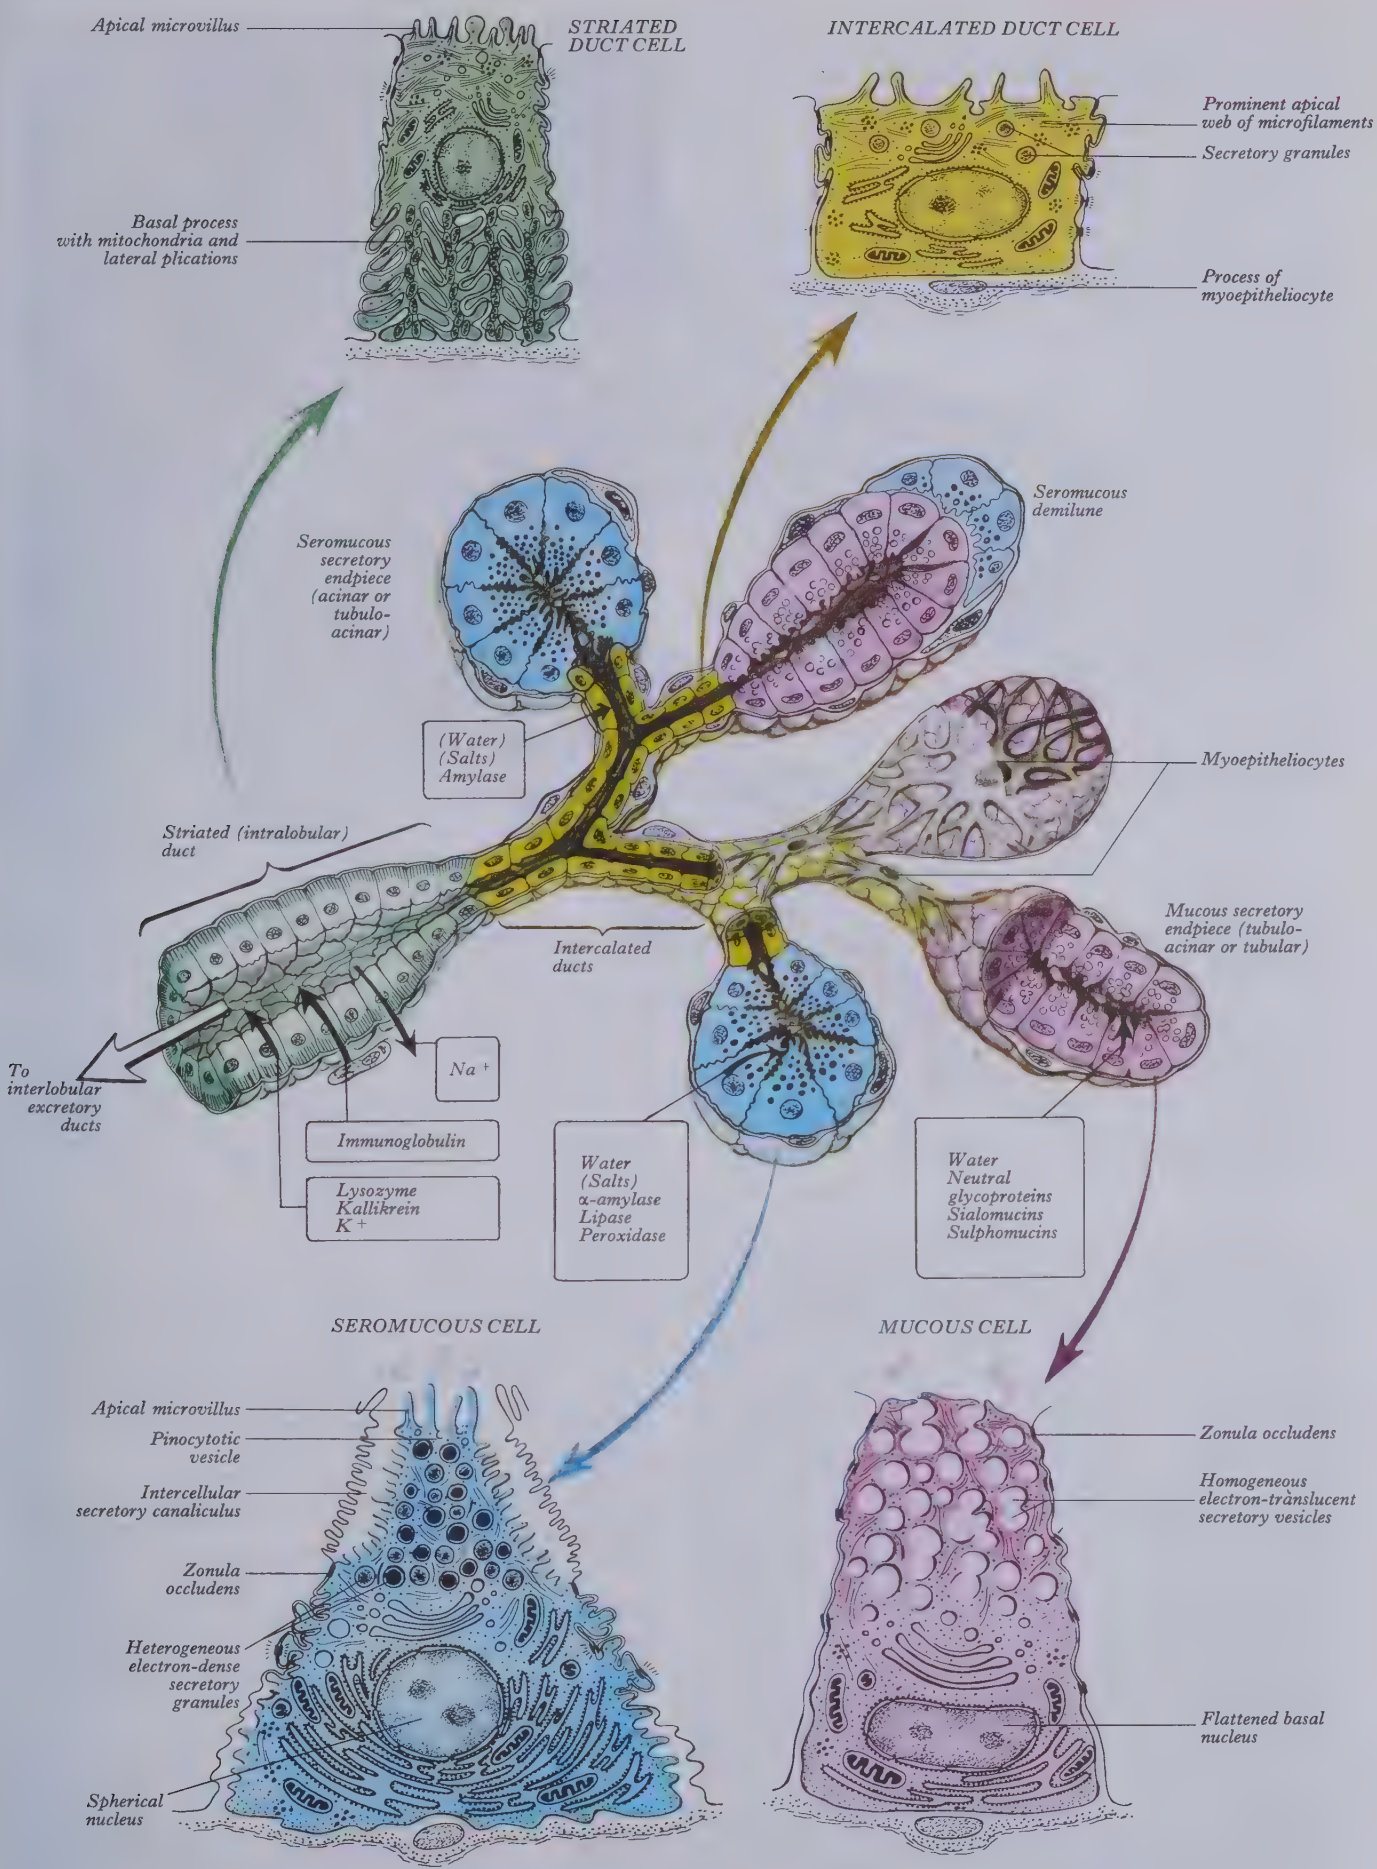
(Young & van Lennep 1978). Seromucous demilunes, which also exist in submandibular glands of many mammalian species, are crescentic groups of glandular cells found at the bases of some mucous endpieces (8.51); sited between the mucous cells and basal lamina, they apparently communicate with the lumen by fine canaliculi which pass between the mucous cells. Using the criteria described above all the major human salivary glands are thus heterocrine.



The ultrastructure of these glandular cells is shown diagrammatically in 8.51. *Seromucous* (and *serous) cells* are roughly pyramidal. The basal plasmalemma is usually smooth, while the lateral is plicated and interdigitates with that of the adjacent cells. The apical (luminal) plasmalemma commonly forms microvilli, between which are often pinocytotic vesicles. Discrete, secretory canaliculi lie between the cells; limited basilaterally by junctional complexes, they open into the lumen of the 'endpiece'; their zonulae occludentes are often assumed to form a continuous seal around each cell but freeze-fracture micrographs of parotid 'endpiece' tight junctions in rats (de Camilli et al 1976) suggest that the 'seals' may be incomplete. Nuclei vary in shape and position, but are more spheroidal and less basal than in mucous cells. Apical cytoplasm is filled by secretory granules of variable form (Tandler 1972, Riva & Riva-Testa 1973); a conspicuous feature of the infranuclear cytoplasm is an abundant granular endoplasmic reticulum arranged in stacks of parallel, flat cisternae. Golgi complexes are supranuclear with adjacent small coated and smooth vesicles. Elongated mitochondria, lysosomes, microfilaments and occasional large lipid droplets also appear. In contrast *mucous cells* are cylindrical; their luminal plasma membrane is smoother and secretory canaliculi between the cells are rare. The supranuclear cytoplasm is typically packed with large, electron-translucent, frequently fused, secretory droplets. Granular endoplasmic reticulum and Golgi complexes resemble those of serous and seromucous cells, but the nucleus is flatter and more basal.

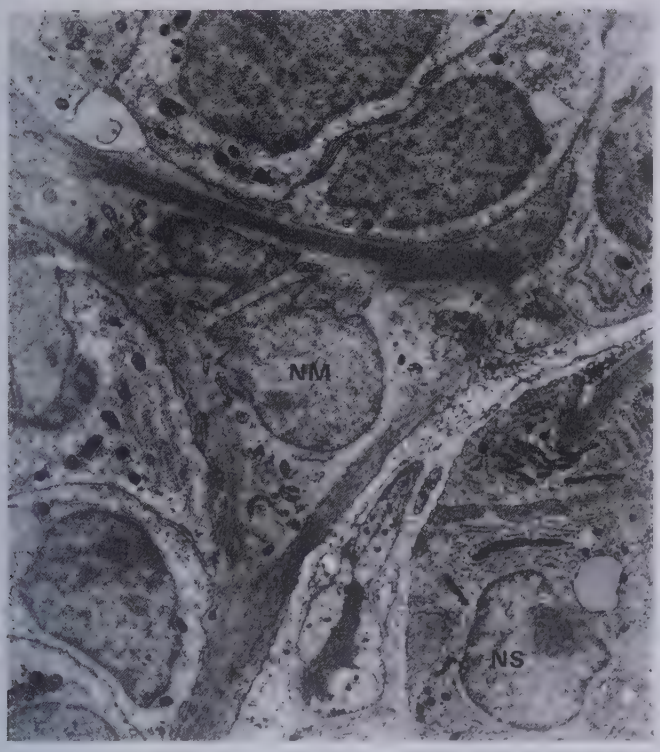
Ducts of Salivary Glands

Leading consecutively from the secretory 'endpieces' are *intercalated, striated* and *excretory ducts*.

8.51 Diagram of the architecture of a generalized salivary gland including ultrastructural details. Solid and outlined black arrows indicate direction of transport.

8.52 The innervation of the ducts, secretory units and arterioles in a generalized salivary gland.



The cells lining the intercalated ducts are cuboidal or flat. Their cytoplasm contains long mitochondria, a few cisternae of granular endoplasmic reticulum, juxtanuclear Golgi complexes, lysosomes and secretory granules. While this suggests little participation in protein synthesis, it does not preclude involvement in the addition of water and electrolytes to saliva; the cells responsible for this, in either 'endpiece' or duct, are unknown but, although this function is often assigned to glandular cells, cells of the intercalated ducts may also be involved.

Cells lining striated ducts are basally striated, 'like a thick lawn' according to Pfluger (1866). In 1909 Regaud & Mawas concluded that this is due to columns of packed, elongate mitochondria, as confirmed by ultrastructural studies (Pease 1956). Between the columns the cytoplasm is divided into basal processes by infolded basal plasmalemma, the lateral aspects of which may be extensively plicated to interdigitate with adjacent processes. Desmosomes often link adjacent plications. This folding and local abundance of mitochondria is typical of many epithelial cells engaged in electrolyte transport, as these cells certainly are; they transport potassium into saliva and by reabsorbing sodium ions in excess of water they render saliva hypotonic (Thaysen et al 1954). The lateral plasmalemmae of cells lining striated ducts are linked by slightly pervious junctional complexes (Garrett & Parsons 1974). The luminal plasmalemma forms microvilli and cytoplasm often extends into the lumen as apical blebs considered to enter saliva by this apocrine process (Garrett 1976). The supranuclear cytoplasm contains a few cisternae of granular endoplasmic reticulum, mitochondria, lysosomes, vesicles, microtubules and numerous microfilaments, the last conspicuous in the terminal web or 'separating zone' (Takano 1969). As well as modifying electrolyte composition, striated ducts secrete immunoglobulin A (Kraus & Mestecky 1971), lysozyme (Kraus & Mestecky 1971) and kallikrein (Garrett & Kidd 1975). Immunoglobulin A is produced by subepithelial plasma cells.

Few ultrastructural details of the excretory ducts have been recorded; they are lined in rats by simple columnar or pseudostratified epithelium, mainly of tall columnar cells with basal striations containing packed, elongate mitochondria (Tamarin & Sreebny 1965). These striations, and the more intimate relation to capillaries than elsewhere in the ductual system, suggest that excretory ducts are more than passive conduits; an involvement in electrolyte transport is possible (Young & van Lennep 1978).

Myoepitheliocytes of Salivary Glands

These contractile cells are associated not only with intercalated ducts and usually also with secretory endpieces, lying between the basal lamina and the epithelial cells proper, but also with intra- and extralobular ducts (Chaudhry et al 1987). Garrett & Emmelin (1979) summarized the effects of myoepithelial contraction as follows: outflow of saliva is accelerated, luminal volume of intercalated ducts and endpieces is reduced, secretory pressure is

8.53 Transmission electron micrograph of a myoepitheliocyte of a salivary gland. The superficial filamentous and juxtanuclear non-filamentous compartments of the cytoplasm can be seen. aided, underlying parenchyma supported, salivary flow is helped to overcome peripheral resistance and, in certain circumstances, discharge from associated secretory cells is aided.

The shape of salivary myoepitheliocytes depends on their location: in endpieces they are stellate, dendritic, with long overlapping processes which, with those of other such cells, form a reticulum around each endpiece. Those in ducts are fusiform, with fewer branches, and extend along the intercalated ducts longitudinally. 'Endpiece' myoepitheliocytes have a central perikaryon with four to eight radial processes, each with two or more successions of branches which cross but do not fuse or extend on to the ducts. In contrast, myoepitheliocytic processes in intercalated ducts seldom branch and often overlap on to the endpieces.

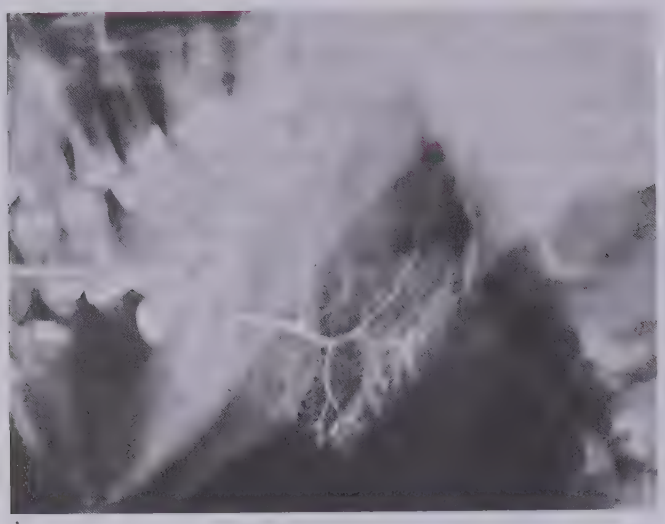
Myoepitheliocytic cytoplasm (**8.53**) may be divided into filamentous and non-filamentous compartments, the latter containing the nucleus, juxtanuclear Golgi complexes, lysosomal bodies and mitochondria. Globules of neutral fat may occur in human cells (Garrett 1963). The filaments, conspicuous in processes, and their rami resemble the myofilaments of non-striated myocytes (p. 546). Both thin (4 nm) and thick (10 nm) filaments are described, the former arranged longitudinally in processes, with the less numerous thick filaments scattered amongst them. Filaments often pass to attachment plaques on the basal plasmalemma, causing indentations. Basal lamina opposite the plaques appears thicker and may be linked to the cells at these sites. Bannerjee et al (1977) have shown that the basal lamina strengthens and supports the adjacent epithelium. When myoepitheliocytes contract, the basal lamina is probably tensed at the attachment plaques (Garrett & Emmelin 1979). Numerous caveolae are commonly associated with the stromal plasmalemma, but less frequently so with the plasmalemma adjacent to the epithelial cells. Myoepitheliocytes are linked to secretory and ductual cells by desmosomes and occasional cilia extend from them into indentations of the adjacent epithelial cells. Cilia were first observed by Tandler (1965) in myoepitheliocytes of human submandibular glands and subsequently described in other human salivary glands (Tandler et al 1970) and in glands of other species (Cutler & Chaudhry 1973, Kidd 1978). Garrett & Emmelin (1979) suggest that there may be a cilium on each salivary myoepitheliocyte, as proposed by Stirling & Chandler (1976), for human mammary myoepitheliocytes (p. 1447). The cilia may have a chemoreceptive and/or mechanoreceptive role.

Salivary myoepitheliocytes appear to have sympathetic and parasympathetic innervation (Garrett 1972, 1976), with several axons of either or both supplying a single cell. But in the sublingual gland of the rat myoepitheliocytes may have only cholinergic innervation (Templeton & Thulin 1978). Stimulation by sympathetic or by parasympathetic nerves may result in myoepitheliocyte contraction (Garrett & Emmelin 1979).

CONTROL OF SALIVARY GLAND ACTIVITY

The observed wide and rapid variation in the composition, quantity and rate of salivary secretion in response to various stimuli suggests an elaborate control mechanism (Emmelin 1972). In some glands salivary secretion is spontaneous; in others secretion follows different types of sensory stimulation: gustatory, nociceptive, olfactory and tactile. Secretion may be continuous, but at a low resting level, partly spontaneous but mainly in response to the drying of the oral and pharyngeal mucosae. A rapid increase can be superimposed on the resting level, e.g. during mastication or by autonomic stimulation. Controlled variation in the activity of the many types of salivary effector cells (serous, as well as seromucous and mucous secretory cells, myoepitheliocytes, epithelial cells of all the ductual elements and the non-striated myocytes of local blood vessels) affects the quantity and quality of saliva. The control of these is both hormonal and neural.

Hormonal Control



The effects of circulating hormones on salivary secretion were reviewed by Blair-West et al (1967). There is no clear evidence that they evoke secretion directly at physiological levels, but they may alter the response of glandular cells to neural stimuli. Local hormones, however, have profound effects in feline submandibular glands; e.g. vasodilatation, though neurally initiated, is maintained by plasma-kinins formed locally when kallikrein is released from secretory cells stimulated by sympathetic amines (Gautvik et al 1972). Vasodilatation and secretion are functionally related (Hilton & Lewis 1956).

Neural Control

Most salivary glands, except those secreting spontaneously, depend on autonomic nerves to evoke secretion and in all salivary flow is mainly under nervous control. The nerves involved are cholinergic (parasympathetic) and adrenergic (sympathetic); there is no evidence for any other neural involvement (Garrett 1976).

The typical pattern of innervation is shown in Fig. **8.52**, but this varies in different glands and species (Garrett 1972); variations may also occur with age (Yohro 1971). Only the more constant features are illustrated and described here. Cholinergic nerves often accompany ducts and arborize freely around secretory endpieces, but adrenergic nerves usually enter glands along arteries and ramify with them. The main glandular nerves contain largely non-myelinated axons, but a few myelinated axons occur, presumably either preganglionic efferent or afferent. Postganglionic efferent axons, like those elsewhere (Norberg 1967), show periodic dilatations containing mitochondria and vesicles, the latter electron-lucent in cholinergic axons and with electron-dense cores in adrenergic axons. Within the glands the nerve fibres intermingle, cholinergic and adrenergic axons often lying in the adjacent invaginations of one Schwann cell (Eneroth et al 1969, Garrett 1972, 1976).

At *neuro-effector junctions* (**8.52**) the synaptic regions of axons and the effector cells they supply are functionally related, the axonal surfaces closest to the effector cells being free of Schwann cell covering. Where effector cells are epithelial, the junctions may be *epilemmal* or *hypolemmal* (Garrett 1975), terms introduced by Arnstein (1889, 1895). At epilemmal sites axonal and effector

A

surfaces are separated by about 100 nm, with the basal lamina intervening. At hypolemmal sites the axon penetrates the basal lamina and is separated from the effector cell by only 20 nm. One axon may supply several effector cells directly and many more indirectly through electrical coupling of adjacent cells (Lowenstein & Kanno 1964); group activity thus occurs. One effector cell may also receive several axons, both cholinergic and/or adrenergic. Single axons may act on several types of effector. Although there are separate sympathetic axons for secretion and vasoconstriction (Emmelin & Engström 1960), the former may also induce myoepitheliocyte contraction and a single parasympathetic axon may, through serial neuro-effector junctions of the *en passant* type (p. 882), induce vasodilatation, secretion and myoepitheliocytic contraction (Emmelin 1972).

Secretory endpieces usually have the most innervation, cholinergic and adrenergic, individual cells often having both. Cholinergic axons have long been accepted as the secretomotor innervation; however, in 1974 it was shown that in the parotid gland of the rat, at least, sympathetic nerves are also secretomotor (Harrop & Garrett 1974, Hodgson & Spiers 1974). Adrenergically evoked saliva differs in quantity and composition but by what mechanism is uncertain. In heterocrine glands (p. 1293) adrenergic and cholinergic nerves might activate different types of cell but in homocrine glands (p. 1293), where all cells appear similar, they presumably affect the same cells differently (Garrett 1972). In some situations sympathetic activity may modify saliva produced in response to parasympathetic stimulation, rather than directly inducing flow.

The ductual elements of salivary glands can markedly modify saliva (p. 1296) and, though less intensely innervated than secretory endpieces, their activity is also under neural influences, in part at least. In 1958 Lundberg showed that cells, assumed to be ductual, in the feline submaxillary gland, responded electrically to both parasympathetic *and* sympathetic stimulation. Cholinergic fibres lie adjacent to the striated ducts of most species, occasionally hypolemmal in position, but more commonly so in intercalary ducts. In some species, including mankind, adrenergic nerves are also associated with striated ducts (Garrett 1967). The main excretory ducts appear to have only cholinergic nerves but Schneyer (1976) observed that sympathetic stimulation alters electrolyte transport across the epithelium of the submaxillary main duct in the rat, suggesting an adrenergic supply.

The innervation of myoepitheliocytes adjoining secretory endpieces and intercalary ducts is physiologically obscure, but electron microscopy suggests a sympathetic and parasympathetic hypolemmal supply (Kagayama & Nishiyama 1972). Myoepitheliocytes are stimulated to contract by adrenergic axons; they may respond to a single impulse, suggesting high sensitivity. The role of cholinergic axons is less certain, but they also may cause contraction (Garrett 1975), thus aiding salivation.

Structural evidence shows that salivary arterioles are innervated by both adrenergic and cholinergic axons (Young & van Lennep 1978). The former, the more numerous, maintain vasoconstrictor tone; the latter may induce vasodilatation but this is maintained by local plasma-kinins (vide supra).

Little information is available on the afferent nerves of salivary glands. Pain due to obstruction of salivary ducts and sialography suggests a nociceptive function, but this awaits anatomical investigation. Sensory endings occur in the main ducts and presumably elsewhere in the glands. Afferent axons are postulated to occur in the main parasympathetic and sympathetic nerve trunks to the glands. Increasing pressure in the submandibular ducts in dogs enhances afferent activity in the chorda typani (Garrett 1975); intraglandular baroceptors are presumed to be involved in this response. Detailed studies of salivary sensory innervation are clearly needed.

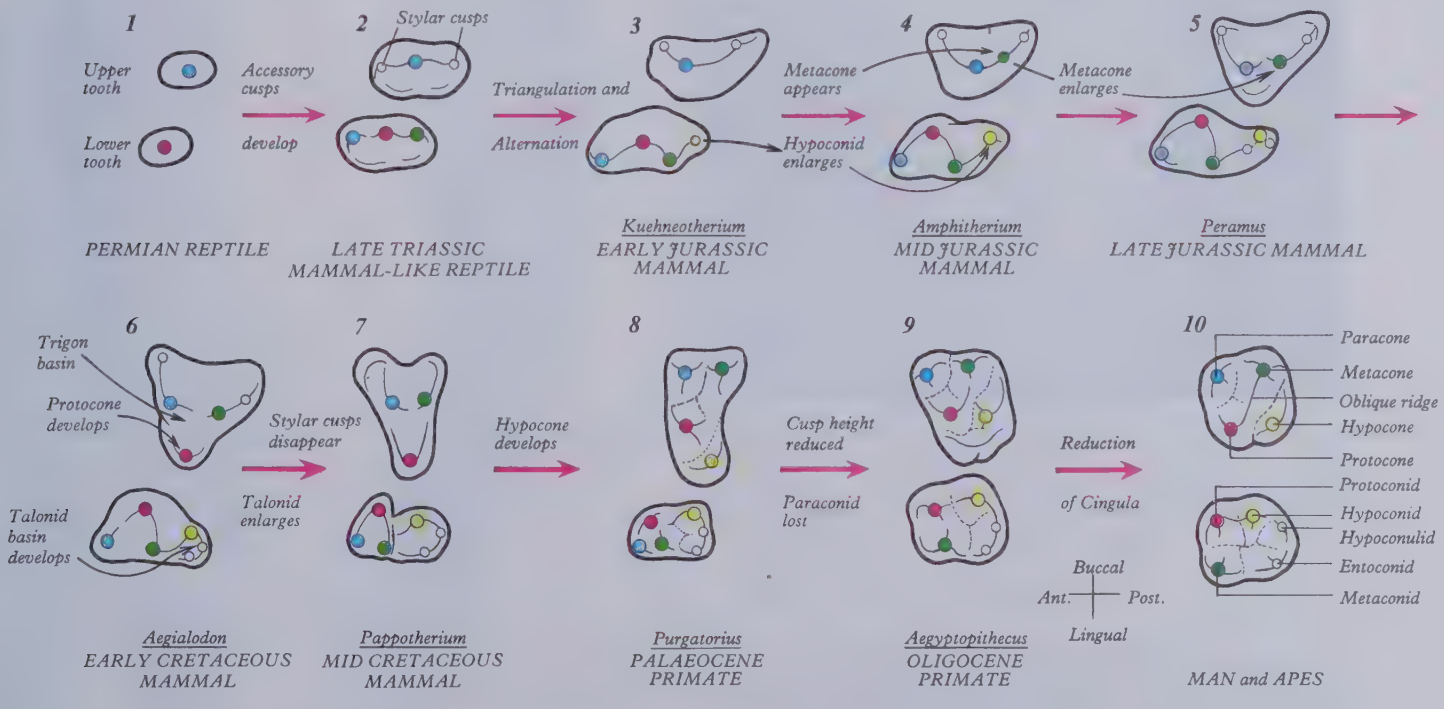
Accessory glands. Besides the main salivary glands many others exist: some in the tongue (p. 1322), others around and in the palatine tonsil between its crypts, and large numbers in the soft palate, the posterior part of the hard palate, the lips and cheeks. These are similar in structure to larger salivary glands and are mainly of the mucous type (p. 1293).

Sialography. Cannulae can be introduced into the parotid and submandibular ducts and used to inject radio-opaque substances (e.g. lipiodol) to outline the ramifications of the ductual systems of these glands. The pattern and calibres of the components of these systems are thus revealed. The *parotid duct*, as seen in lateral sialograms, is formed near the centre of the posterior border of the mandibular ramus by the union of two ducts which respectively ascend and descend at right angles to its course (8.54A). As it crosses the face, it receives from above five or six ductules from the accessory parotid gland; as it curves round the anterior border of the masseter it is often compressed, its shadow being attenuated here. The intraglandular part of the main duct receives an alternating series of descending and ascending tributaries, each formed from an arborization of fine ductules receiving acini. The acini usually do not show as dilatations in sialograms but are represented by the 'free' endings of the smallest ducts. The *submandibular duct* starts from that gland's lowest part, below the mandible in lateral views, ascends vertically above the mandible's lower border and turns sharply forwards, gradually ascending to its opening. The duct's vertical part receives anterior and posterior tributaries and, as it turns sharply forwards, it receives a large tributary from the posterior region (8.54B). Each tributary is formed from ductules (with their terminal acini) visualized as in the parotid gland. Contrast medium injected into the submandibular duct may also enter the major sublingual duct, revealing the ductules of the anterior part of the sublingual gland.

THE TEETH

Introduction

Teeth are vital to most mammals and other vertebrates, except mankind. Loss is incompatible with life; longevity is related to the endurance of the dentition under the abrasive process of mastication. In non-mammalian vertebrates, teeth are constantly replaced, a condition known as *polyphyodonty*, related to the need for successively larger teeth in animals which grow throughout life. Mammals of limited growth typically have two dentitions, *deciduous* and *permanent*, the condition of *diphyodonty*, although some, e.g. the rat, are *monophyodont*. The emergence and success of diphyodonty was probably related to the evolution of occlusion during mastication.



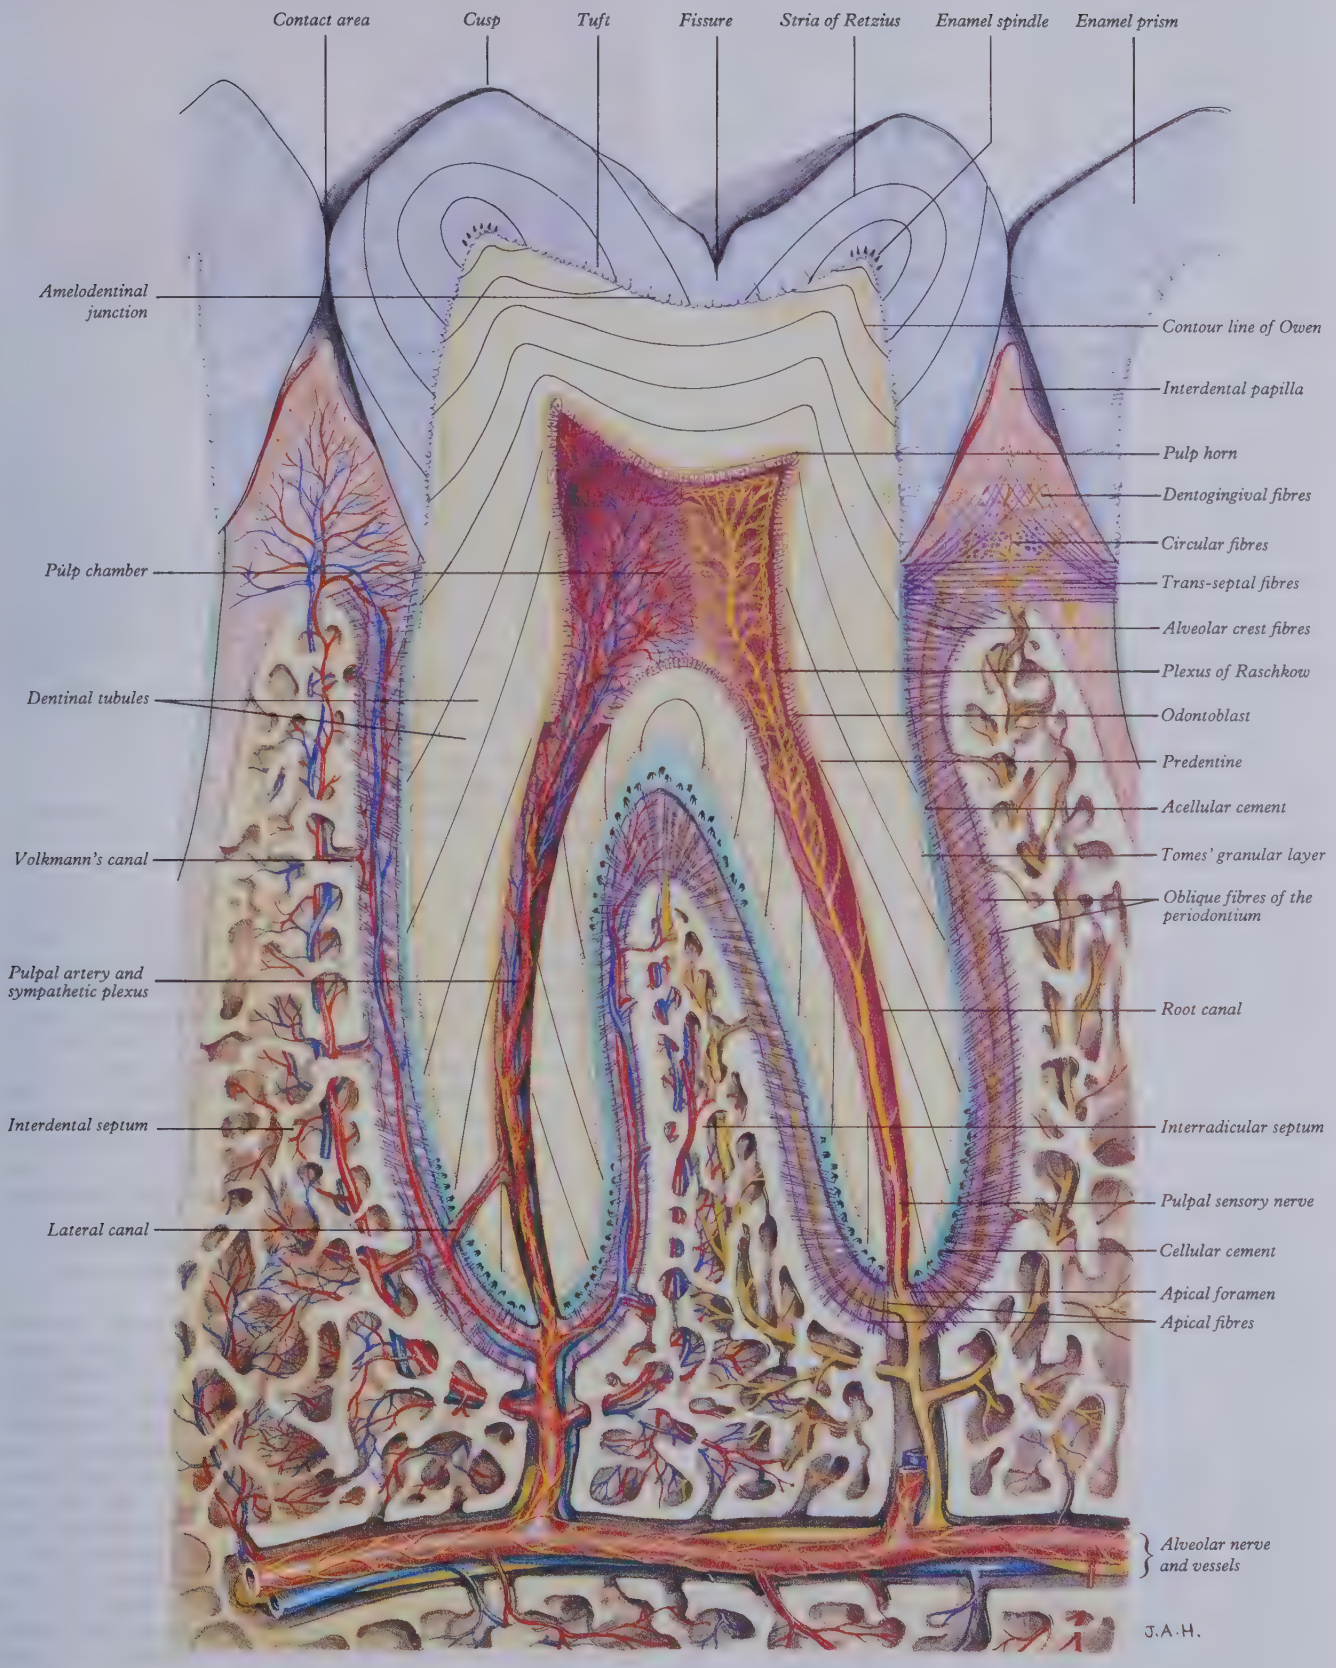
In non-mammalian vertebrates, the jaw joint is between the *quadrate* bone of the upper and the *articular* bone of the lower jaw, homologous respectively with the incus and malleus. The lower teeth are set on a curve so far inside the upper that, due also to restricted lateral movement, they cannot meet the upper teeth. The evolution of mammals was associated with the postero-superior growth of the *dentary* (one of several lower jaw bones existing in all non-mammalian vertebrates) towards the *squamosal bone*, homologous with the squamous temporal in most mammals. In accord with these skeletal changes, jaw muscles were also rearranged to move the mandible (dentary) transversely. Together with these trends there was a change in dental shape; from the simple conical teeth of reptilian ancestors, mammals evolved teeth with complex shearing planes. Lateral movements now possible in the new mandible allowed the lower teeth to grind across the upper, producing a more effective trituration. Although deficiencies in the fossil record make some details uncertain, the principal events in this evolutionary sequence are known and the cusps of human molars can be homologized with those of early mammals (8.55).

It has been argued that in reptiles ancestral to mammals the articular and quadrate bones of the jaw joint conducted sound vibrations to the stapes, received by a tympanum partly attached to the *angular bone* of the lower jaw (Allin 1976). Backward growth of the dentary had the selective advantage of reducing the mass of these post-dentary bones, which vibrated with the tympanum, thereby enhancing their auditory function. Finally, with evolution of a new jaw joint, the angular bone with its tympanum moved to the cranium, becoming the tympanic part of the temporal bone. The quadrate and articular bones remained in contact with each other and with the stapes, forming the incus and malleus. The three auditory ossicles then became encompassed by a definitive tympanic cavity. Evolution of a single-boned mammalian mandible was thus associated with an increasingly efficient auditory apparatus.

After a few months of active use, newly erupted mammalian teeth are worn to produce precisely matching upper and lower shearing edges. Continued eruption of new teeth would constantly disrupt this relationship and therefore be disadvantageous. However, because of the need to accommodate teeth in small, young jaws, a deciduous dentition is an almost universal requirement in mammals. With reduction of replacement, dental tissues evolved to minimize the effects of wear. Thus a harder, thicker *prismatic enamel* emerged in mammals to replace the thinner *non-prismatic enamel* of reptiles.

The teeth in all reptiles, apart from Crocodilia, are rigidly bound to the jaws, but in mammals each is suspended in a socket by a *periodontal ligament*. This allows further eruption and a degree of migration, impossible for ankylosed reptilian teeth, to compensate for wear. Innervation of the periodontal tissues also provides a more comprehensive flow of proprioceptive data to nervous centres concerned with control of masticatory patterns.

The introduction of refined carbohydrates made human teeth susceptible to caries and periodontal disease. Outside human culture such conditions would probably have led to extinction. But by appropriately preparing and in a sense predigesting food,



8.55 Occlusal views of the left upper and right lower teeth showing a series of steps in the evolution of complex molar occlusion. Large cusps (coloured) and smaller cusps are joined together by raised cutting edges. The cutting edges of opposing teeth pass each other during occlusion and certain cusps (e.g. the protocone and hypoconid) then crush into opposing basins (e.g. talonid and trigon basins).

8.56 An extracted upper right canine tooth viewed from its mesial aspect. Note the root covered by cement and the shiny enamel-covered crown. The sinuous cervical margin projects towards the cusp of the tooth both mesially and distally.

8.57 A bucco-lingual longitudinal ground section of a young lower first premolar tooth, photographed with transmitted light. Note the large buccal and small lingual cusps; the enamel tapers to a knife-edge at the cervical margin. The coarse dark lines perpendicular to the enamel surface are cracks produced during grinding; the fine lines parallel to the cracks indicate the long axes of the enamel prisms; the oblique lines which curve towards the apex of the cusp are the striae of Retzius (the incremental lines of enamel, compare with 8.70). The primary (S-shaped) curvatures of the coronal dentinal tubules become less pronounced in the root. A thin layer of cement covers the dentine. The apical foramen is wide open and the pulp cavity is large, as in this young tooth.

8.58 Diagram of a longitudinal section of a tooth and its environs.

mankind has overcome the problem of passing suitably fragmented material to the action of catabolic enzymes in the alimentary canal. Nevertheless, chewing does facilitate the digestion of most foods, including cooked meat and vegetables (Farrell 1956) and the natural dentition comminutes food much more efficiently than an artificial replacement (Lucas et al 1986). However, teeth are no longer vital to survival and therefore selective pressure leading to further evolutionary change in the human detition will be limited.

Because they are the hardest and most stable of tissues, teeth are selectively preserved and fossilized, providing by far the best evolutionary record. Hence teeth are excellent models for studying relations between ontogeny and phylogeny. In modern societies, the durability of teeth to fire and bacterial decomposition makes them invaluable in identification of otherwise unrecognizable bodies, a point of great forensic importance.

8.59 Anterior view of the dentition in centric occlusion, with the lips retracted. Note the pale pink, stippled gingivae and the red, shiny, smooth alveolar mucosa. The degree of overbite is rather pronounced and the gingiva and its epithelial attachment have receded on to the root of the upper left canine.

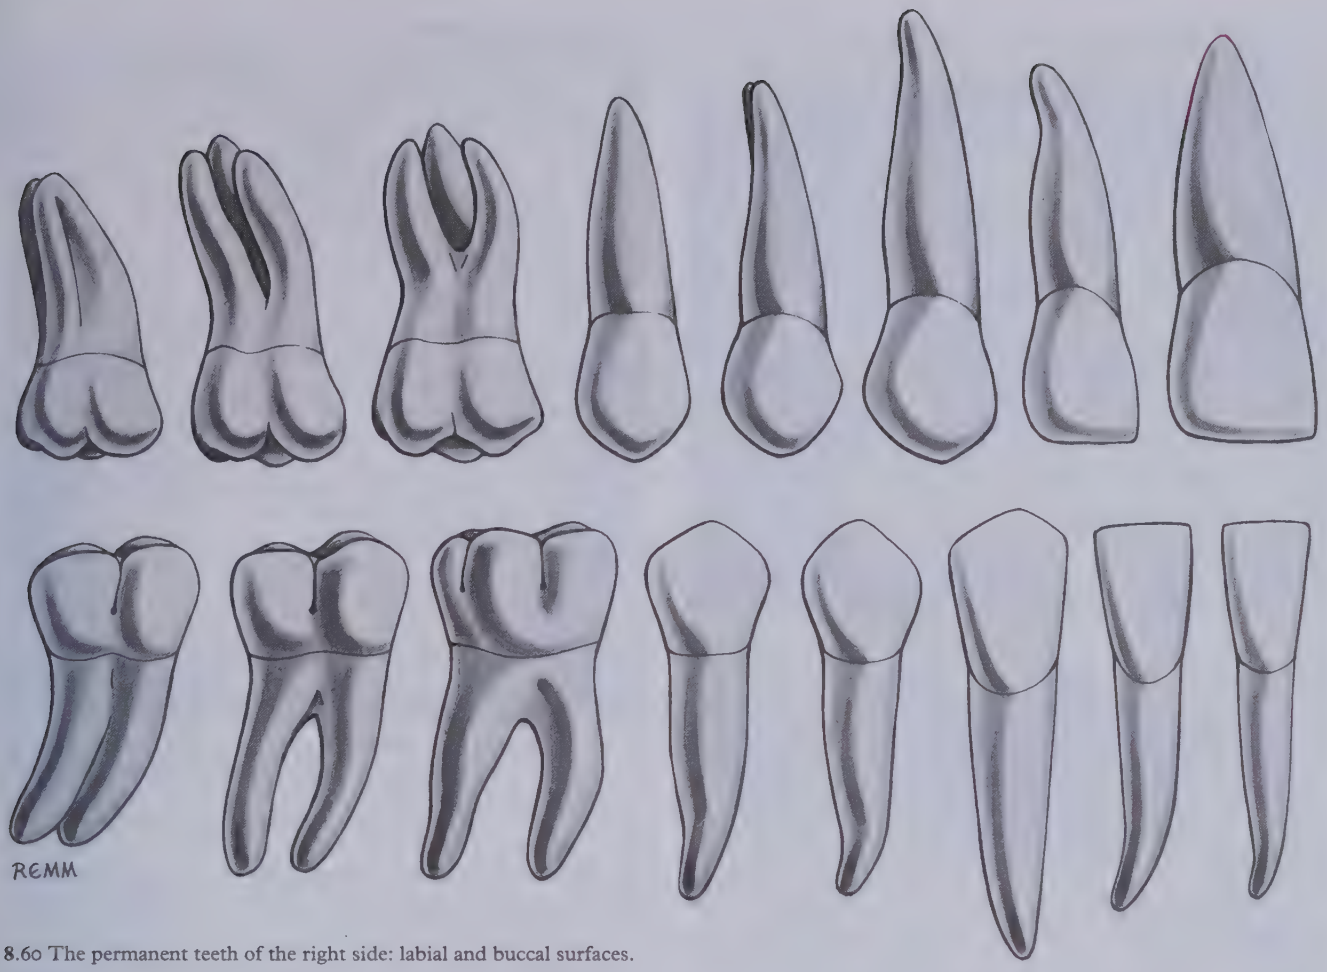
General Arrangement of Dental Tissues

A tooth (8.56) consists of a crown, covered by very hard translucent *enamel* and a root covered by yellowish bone-like *cement*. These meet at the neck or *cervical margin*. A longitudinal section (8.57, 58) reveals that a tooth is mostly *dentine* (ivory) with an enamel covering about 1.5 mm thick, while the cement is usually much thinner. The dentine contains a central *pulp cavity*, expanded at its coronal end into a *pulp chamber* and narrowed in the root as a *pulp canal*, opening at or near its tip by an *apical foramen*, occasionally multiple. The root is surrounded by *alveolar bone*, its cement separated from the osseous socket (*alveolus*) by the soft *periodontal ligament*, about 0.2 mm thick. Coarse bundles of collagen fibres, embedded at one end in cement, cross the periodontal ligament to enter the osseous alveolar wall. In most non-mammalian vertebrates (vide supra) teeth are rigidly connected (ankylosed) directly to bone, a rather brittle attachment. Only in mammals (and Crocodilia) does a periodontal ligament provide an independent, tough suspension for each tooth. Near the cervical margin, the tooth, periodontal ligament and adjacent bone are covered by the *gingiva* (gum), clearly recognizable in health by its pale pink, stippled appearance (8.59). This is continuous at the *mucogingival junction* with the red, smooth oral mucosa lining much of the oral cavity and is adherent to the tooth near the cervical margin by an *epithelial attachment*. The pulp is a connective tissue, continuous with the periodontal ligament via the apical foramen. It contains vessels for the support of the dentine and sensory nerves.

Dental Morphology

The curvature of the dental arches renders the terms of descriptive anatomy, such as anterior and posterior, inappropriate. The aspect of teeth adjacent to lips or cheeks is therefore termed *labial* or *buccal*, that adjacent to the tongue being *lingual* or *palatal*. Labial and lingual surfaces of an incisor meet medially at a *mesial* surface and laterally at a *distal* surface, terms also used to describe equivalent surfaces of premolar and molar (*postcanine*) teeth (8.62, 63). Mesial surfaces of postcanine teeth are, of course, directed anteriorly and distal surfaces posteriorly. Thus the point of contact between the central incisors is the datum point for *mesial* and *distal*. The biting or *occlusal* surfaces of postcanine teeth are tuberculated by *cusps* separated by *fissures* forming a pattern characteristic of each tooth. The biting surface of an incisor is the *incisal edge*.

THE PERMANENT TEETH



The names for teeth in all mammals are based on appearance, function or position of the equivalent human teeth: they are *incisors*, *canines*, *premolars* and *molars* (8.60, 61, 62, 63).

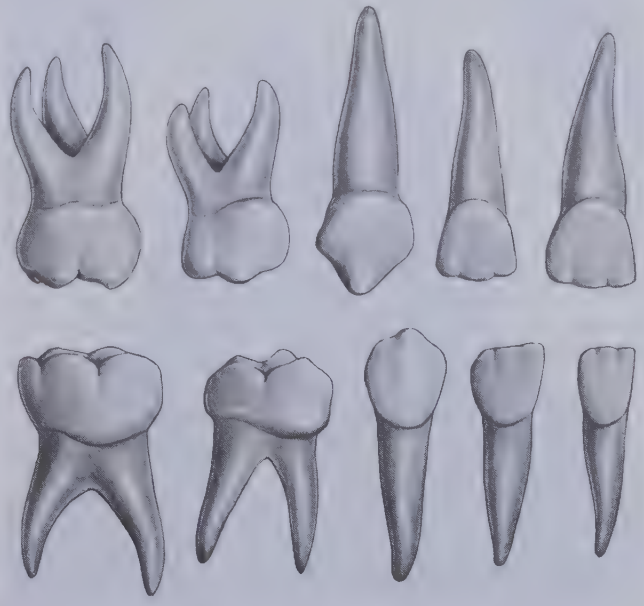
There are two *incisors*, central and lateral, in each half jaw or *quadrant*. In labial aspect, the crowns are trapezoid, the maxillary, particularly the central incisor, being larger than the mandibular. The incisal edges originally have three small tubercles or *mamelons* which are rapidly removed by wear. In mesial or distal view their labial profiles are convex; lingual surfaces are concavo-convex (ogival); the convexity near the cervical margin is due to a low horizontal ridge or *cingulum*, prominent only on upper incisors. The roots of incisors are single, being rounded in maxillary and flattened mesiodistally in mandibular teeth. The maxillary lateral incisor fails to develop in about 1% of people (Brothwell et al 1963) or it may be peg-shaped.

Distal to each lateral incisor is a rather larger *canine* with a single cusp (hence the term *cuspid*) instead of an incisal edge. Apart from this, canines resemble incisors, particularly when their cusps are worn flat. The canine root is the longest in the jaws and produces a bulge (*canine eminence*) on the bone externally, particularly of the maxilla. Although canines usually have single roots, triangular in cross section, that of the lower may be bifid (Kraus et al 1969).

Distal to the canines are two *premolars* each with a buccal and lingual cusp (hence the term *bicuspid*). Occlusal surfaces of upper premolars are oval (the long axis is buccopalatal) with a mesiodistal fissure separating the two cusps. In buccal view, premolars resemble canines but are smaller. The *upper first premolar* usually has two roots (one buccal, one palatal) but may have one and very rarely three roots (two buccal and one palatal). The upper second premolar usually has one root. The occlusal surfaces of lower premolars are more circular or square than those of the uppers. The buccal cusp of the *lower first premolar* towers above the lingual to which it is connected by a ridge separating mesial and distal occlusal pits. In the *lower second premolar* a mesiodistal fissure usually separates a buccal from two smaller lingual cusps. Each lower premolar has one root, but very rarely, the root of the first is bifid. Lower second premolars fail to develop in about 2% of individuals (Garn & Lewis 1962).

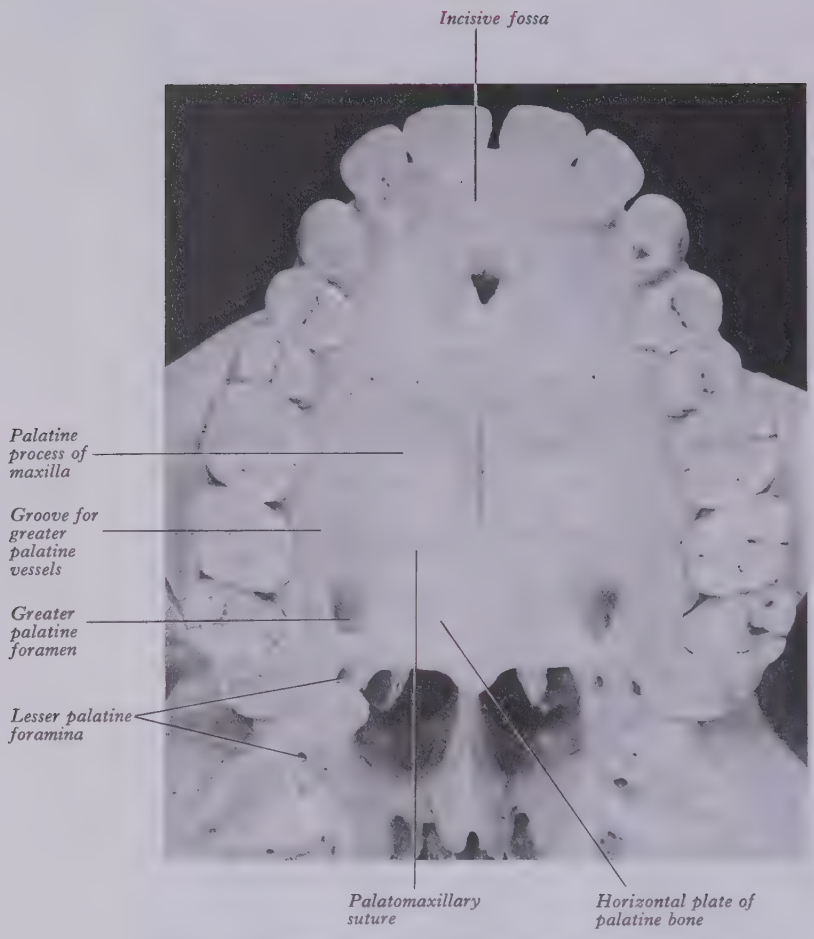
Posterior to the premolars are three *molars* whose size decreases distally; each has a large rhomboid (upper jaw) or rectangular (lower jaw) occlusal surface with four or five cusps. The *upper first molar* has a cusp at each corner of its occlusal surface and the mesiopalatal cusp is connected to the distobuccal by an *oblique ridge*, a primitive feature shared with many lower primates. A fifth cusp, the *cusp of Carabelli*, may appear on the mesiopalatal aspect, most commonly in Caucasoid races (Kraus 1959, Alvesalo et al 1975). The tooth has three widely separated roots, two buccal and one palatal. The smaller *upper second molar* may have a distopalatal cusp which is reduced or occasionally absent; its roots are divergent and two may be fused. The *upper third molar*, the smallest, usually has three cusps (the distopalatal being absent) and commonly one root. The *lower first molar* has three buccal and two lingual cusps on its rectangular occlusal surface, the smallest being distobuccal. The cusps are all separated by fissures. It has two widely separated roots, one mesial and one distal. The smaller *lower second molar* is like the first but usually lacks the distobuccal

8.60 The permanent teeth of the right side: labial and buccal surfaces.



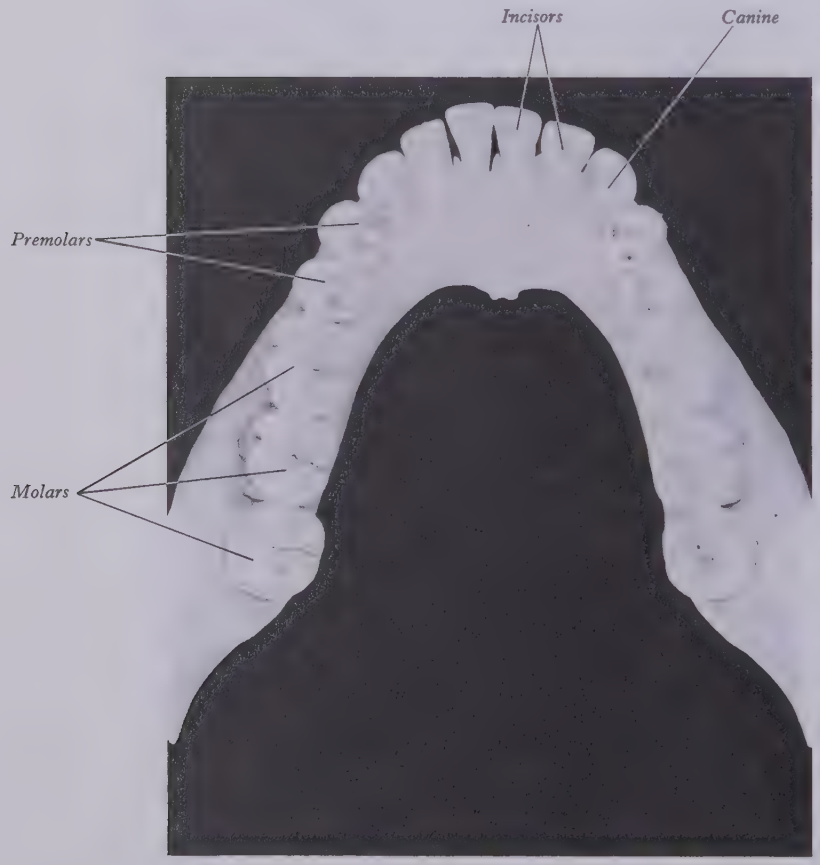
cusp and its roots are closer together. The *lower third molar* is smaller still and like the upper third molar it is variable in form. Its crown may resemble that of the lower first or second molar and its roots are frequently fused. Because it erupts anterosuperiorly it is often impacted against the second molar whereas the upper third molar erupts postero-inferiorly and is rarely impacted. In various populations, one or more third molars, upper or lower, fail to develop in 0.2–25% of individuals (Brothwell et al 1963). In general, absence of third molars is commoner in Mongoloid and Caucasoid than in Negroid races.

THE DECIDUOUS TEETH



The incisors, canine and premolars of the permanent dentition (**8**.60) replace two deciduous incisors, a deciduous canine and two deciduous molars in each jaw quadrant (**8**.61). The deciduous incisors and canine are shaped like their successors but are smaller and whiter and become extremely worn in older children. The deciduous molars resemble permanent ones rather than their successors, the premolars. Each second deciduous molar has a crown almost identical to that of the posteriorly adjacent first permanent molar. The *upper first deciduous molar* has a triangular occlusal surface (its rounded 'apex' being palatal) and a fissure separates a double buccal cusp from the palatal cusp. The *lower first deciduous molar* is long and narrow; its two buccal cusps are separated from the two lingual cusps by a zigzagging mesiodistal fissure. Like permanent molars, upper deciduous molars have three roots and lower deciduous molars have two roots; these diverge more than those of permanent teeth since each developing premolar is accommodated directly under the crown of its deciduous predecessor. The roots of deciduous teeth are progressively resorbed by osteoclasts prior to being shed. An extracted deciduous tooth may thus have very short roots.

DENTAL OCCLUSION



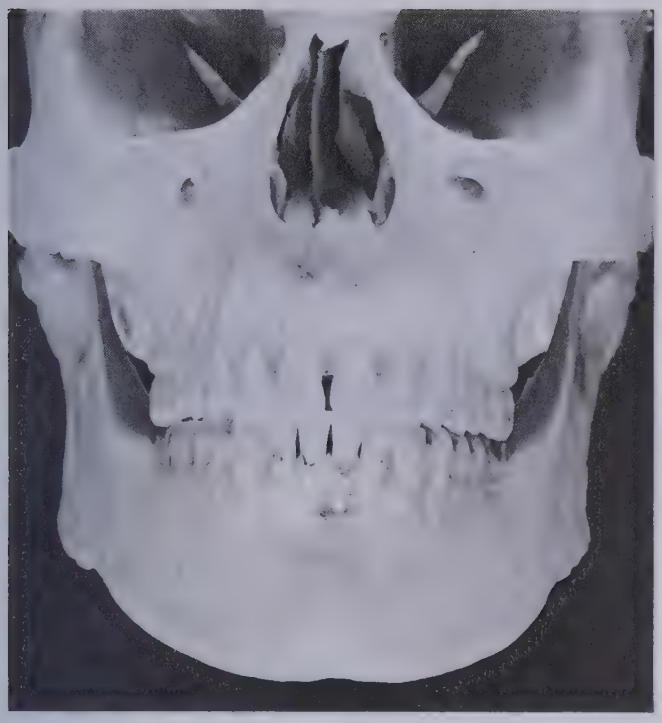
It is possible to bring the jaws together so that the teeth meet or *occlude* in many positions (Kraus et al 1969). When opposing occlusal surfaces meet with maximal '*intercuspation*' (i.e. maximum contact), the teeth are said to be in *centric occlusion* (**8**.64, 65). In this position the lower teeth are normally opposed symmetrically and lingually with respect to the upper.

8.61 The deciduous teeth of the right side: labial and buccal surfaces.

8.62 The permanent teeth of the upper dental arch: inferior aspect.

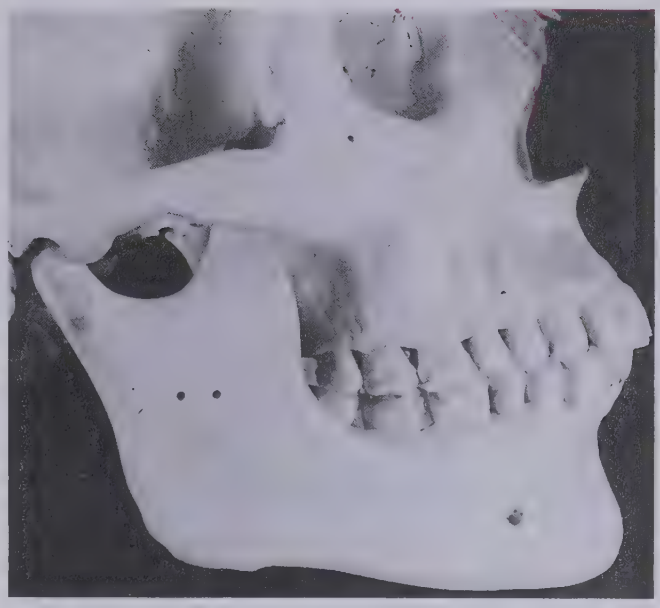
8.63 The permanent teeth of the lower dental arch: superior aspect.

Some important features of centric occlusion in a normal dentition must be noted. Each lower postcanine tooth is slightly in front of its upper equivalent and the lower canine is in front of the upper. Buccal cusps of the lower postcanine teeth lie between the buccal and palatal cusps of the upper teeth. Thus the lower postcanine teeth are slightly lingual and mesial to their upper equivalents. Lower incisors bite against the lingual surfaces of upper incisors, the latter normally obscuring about one-third of the crowns of the lower. This vertical overlap of incisors in centric occlusion is the *overbite*. The extent to which upper incisors are anterior to lowers is the *overjet*. In the most habitual jaw position, the *resting posture*, the teeth are slightly apart, the gap between being the *free-way space* or *interocclusal clearance*.



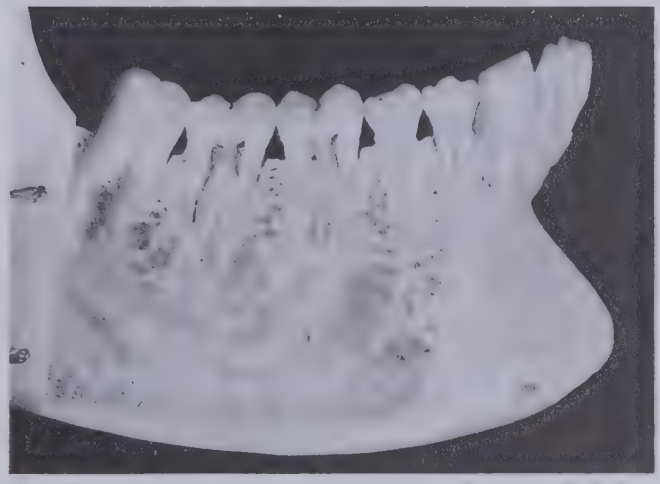
Each dental arch is approximately *catenary*, the form of a chain suspended at both ends (MacConaill & Scher 1949), the lower arch being slightly narrower (**8**.62,63). Viewed from the side, a line joining the buccal cusps of the upper postcanine teeth is curved (*curve of Spee*), concave upwards. The lower molar teeth are tilted slightly lingually so that a line joining the buccal and lingual cusps of the left and right lower first molars is curved (*curve of Monson*), concave upwards. These curvatures accord with movements of the mandible during mastication and are important in the construction of dentures.

DENTAL BLOOD AND LYMPHATIC VESSELS



The *inferior alveolar artery*, a branch of the maxillary artery, enters the mandibular foramen and travels forwards in its canal to divide into *incisive* and *mental* branches to supply the lower teeth, their supporting structures and the mandibular body, including its cortical bone (Saunders & Rockert 1967). About eight to 12 main rami and variable finer ones supply alveolar bone and teeth (Castelli 1963). Few anastomotic vessels cross the symphysis (Howkins 1963). Veins from alveolar bone and teeth collect either into larger vessels in the interdental septa or into plexuses around the dental apices and thence into several *inferior alveolar veins*; some of these drain through the mental foramen to the facial vein, others via the mandibular foramen to the pterygoid venous plexus (Cohen 1959). The upper jaw is supplied by *anterior* and *posterior superior alveolar arteries*. The latter, from the maxillary artery, ramify over the maxillary tuberosity, supplying alveolar bone, mucosa and teeth in the molar region and adjacent buccal mucosa, where they anastomose with the penetrating branches of the facial artery. Other rami supply the lateral wall of the maxillary sinus. The *anterior superior alveolar artery*, a branch of the infraorbital, curves through the *canalis sinuosus* (Wood Jones 1939), which swerves laterally from the infraorbital canal and inferomedially below it in the wall of the maxillary sinus, following the rim of the anterior nasal aperture, between the alveoli of canine and incisor teeth and the nasal cavity; it ends near the nasal septum where its termination emerges. The canal may be up to 55 mm long. Occasionally a small *middle superior alveolar artery* forms anastomotic arcades with the anterior and posterior vessels. On the palatal aspect of the upper teeth, the *greater palatine artery* supplies the palatal gingiva and its terminal branch ascends through the incisive canal to anastomose with septal branches of the nasopalatine artery. Veins accompanying the superior alveolar arteries drain anteriorly into the facial vein, or posteriorly into the pterygoid venous plexus.

The periodontal ligaments are supplied by *dental branches* of alveolar arteries (Melcher & Bowen 1969). One branch enters the alveolus apically and, of its small rami, two or three pass into the dental pulp through the apical foramen, others ascending in the periodontal ligament. *Interdental arteries* ascend in the interdental septa, sending branches at right angles into the ligament, and terminate by communicating with gingival vessels. Thus the ligament receives its blood from three sources: from the apical region, ascending interdental arteries and descending vessels from the gingiva; all anastomose with each other. Veins drain the periodontal ligament either into the *interdental veins* or into the *periapical plexus*. Longer vessels seen in the ligament are probably veins rather than anastomosing arteries (Folke & Stallard 1967).



Lymphatic drainage of human jaws and teeth is uncertain (Saunders & Rockert 1967). Injection techniques in monkeys

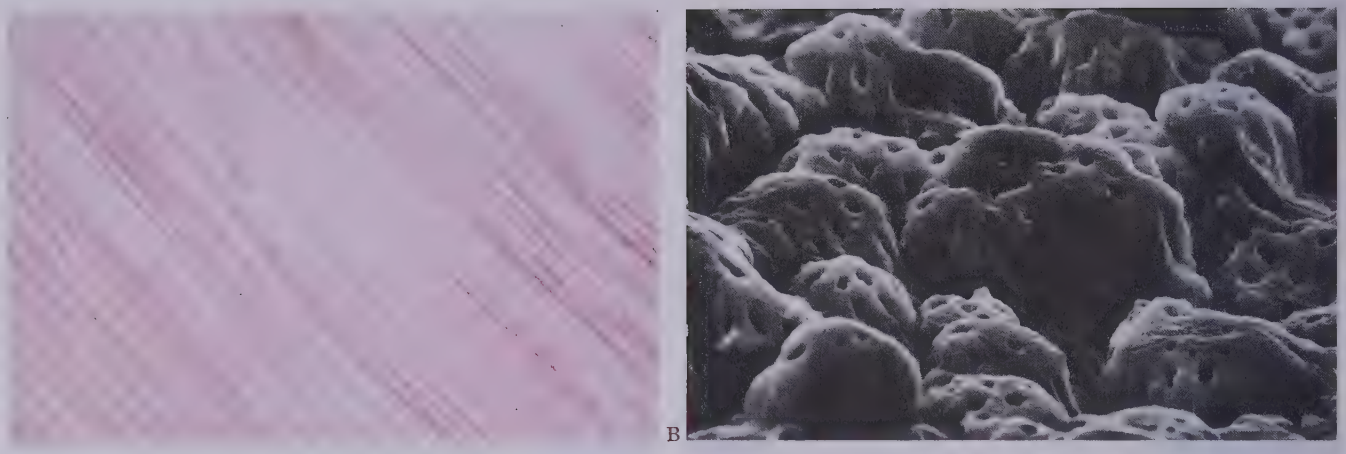
8.65 Lateral view of the dentition in centric occlusion.

8.66 Vertical section through the right half of the body of the mandible and its dentition. Note: (1) the pulp cavities in the molar teeth; (2) the flat table of bone surmounting the interdental bony septa; (3) the cancellous nature of much of the bone; (4) the cortical plate of compact bone lining the sockets of the teeth (the lamina dura of radiographs, see 8.85,86,87); (5) the compact bone forming the base of the mandible; (6) the inferior dental canal which, in this specimen, is widely separated from the roots of the teeth.

(MacGregor 1936) suggest that the upper jaw drains mainly to the submandibular and thence to supraclavicular lymph nodes, the lower to submental and on to the paratracheal nodes. Many dental abscesses lead to enlargement of the submandibular and upper deep cervical lymph nodes, indicating a common path for lymphatic drainage of the upper and lower teeth. Buccal lymph nodes may be affected by infection of the upper teeth. Lower incisors drain to the submental nodes and thence either to the submandibular or lower deep cervical nodes. It is presumed that alveolar bone, periodontal ligament and gingiva share the same route.

DENTAL INNERVATION

Upper teeth are supplied by the *superior alveolar nerves*, *anterior* and *posterior*; in 80% of individuals a *middle* nerve is also present (Fitzgerald & Scott 1958). These nerves supply a plexus lying above the apices of the teeth, partly on the posterior surface of the maxilla and partly within canals in the lateral and anterior surfaces of the bone. The *buccal nerve* provides a variable contribution to the buccal molar gingiva; the *greater palatine* and *nasopalatine* nerves pass to the palatal gingiva, overlapping in the region of the canine tooth.



The posterior superior alveolar nerves are two or three trunks from the postorbital section of the maxillary nerve. They divide into several rami within the periosteum and enter widely scattered foramina on the maxilla's posterior surface. Higher branches descend outside the antral mucosa to meet lower branches passing forwards above the teeth. The variable middle alveolar nerve, which may branch anywhere along the orbital part of the maxillary nerve, runs down the antral wall; the anterior alveolar nerve occupies the *canalis sinuosus* (p. 1304). The bony canals of the superior alveolar nerves also contain corresponding arteries forming the *superior alveolar neurovascular bundles*.

The **lower jaw** and its alveolar bone are largely supplied by the *inferior alveolar nerve*, with branches of the *buccal nerve* to the buccal gingiva of the molar and premolar teeth and branches of the *lingual nerve* to the lingual gingiva of all the lower teeth.

In its commonest form (six out of eight mandibles studied by Carter & Keen 1971), the inferior alveolar nerve is single, travelling through a well-defined osseous canal close to the dental roots, supplying individual branches to these and the interdental septa. Between the premolar teeth the mental nerve, often multiple, leaves via the mental foramen. Intra-osseous *incisive nerves* continue to supply the first premolar, canine and incisor teeth. Branches leave the mental nerve at its origin to form an *incisor plexus* labial to the teeth, probably supplying their labial periodontium and gingiva. From this plexus and the dental branches, rami turn down and then lingually to emerge on the lingual surface of the mandible on the posterior aspect of the symphysis or opposite the premolar teeth, probably communicating with the lingual or mylohyoid nerve.

Less commonly (two out of eight mandibles), the inferior alveolar nerve was close to the lower border of the mandible, well below the roots of the teeth (**8**.66) with a variable number of large rami passing anterosuperiorly towards the roots before dividing to supply the teeth and interdental septa.

In three out of eight dissected mandibles nerves passed from the temporal muscle to enter the mandible through the retromolar fossa, communicating with branches of the inferior alveolar

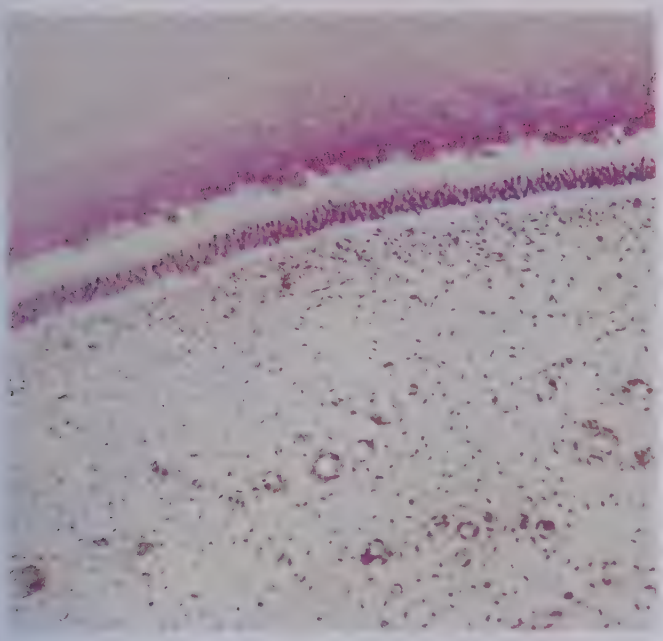
nerve. Foramina occur in about 10% of retromolar fossae (Azaz & Lustmann 1973) and infiltration in this region can abolish sensation occasionally remaining after an inferior alveolar nerve block. Similarly, branches from the buccal, mylohyoid and lingual nerves which enter the mandible may provide additional routes of sensory transmission from the teeth.

The lower central incisor teeth receive a bilateral innervation, fibres probably crossing the midline within the periosteum to re-enter the bone via numerous canals in the labial cortical plate (Rood 1977).

Dental Histology

DENTINE

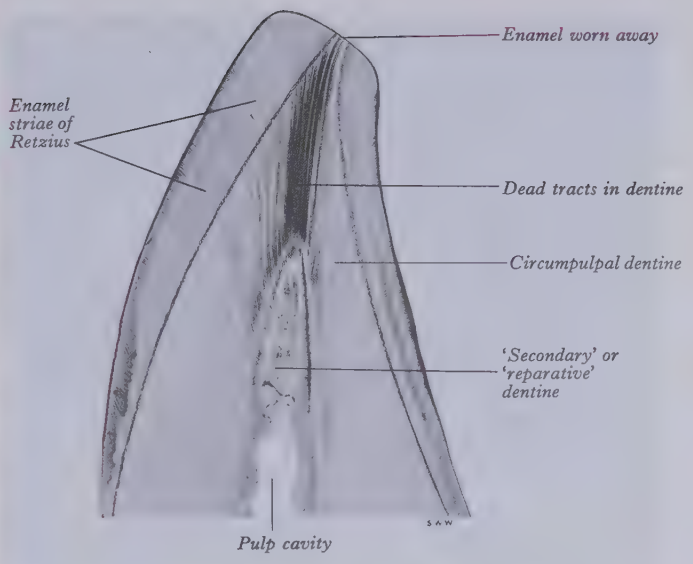


Dentine is yellowish avascular tissue forming the bulk of the tooth. It is a tough (work of fracture, Wf = 270–550 J/m²) and compliant (stiffness = 12 GN/m²) composite material, about 70% by weight mineral (largely crystalline hydroxyapatite and fluorapatite but some calcium carbonate) and 20% organic matrix (type I collagen fibres, glycosaminoglycans and phosphoprotein, Weinstock & Leblond 1973). Its conspicuous feature is the regular pattern of microscopic dentinal tubules, about 1–2 μm in diameter, extending from the pulpal surface (about 50 000 tubules per 1 sq mm cross-sectional area) to the enamel–dentine junction (about 20 000 per sq mm). Tubules have a single sinuous primary curvature (**8**.57) oriented apically and more pronounced in the crown. A spiral secondary curvature, less regular, has a periodicity and amplitude of a few microns. Near the enamel–dentine junction tubules bifurcate, some with short extensions into enamel. Abundant lateral branches interconnect adjacent tubules (**8**.67A). Each tubule encloses a single cytoplasmic process of an odontoblast, containing microtubules, microfilaments and mitochondria but few ribosomes. Odontoblast cell bodies are in a pseudostratified layer lining the pulpal surface. In newly erupted teeth, processes are believed to extend the full thickness of dentine (Sigal et al 1984, Holland 1985) but in older teeth may be partly withdrawn so as to occupy only the pulpal third, the outer regions containing extracellular fluid (Thomas 1979). Lining most tubules is a heavily mineralized cylinder of peritubular dentine, devoid of collagen fibres, separated from the plasma membrane of the process by a glycosaminoglycan-rich lamina limitans (Thomas & Carella 1983). It is uncertain whether the process directly abuts the lamina limitans or whether there is a fluid-filled periodontoblastic space separating them.

Between the odontoblasts and the dentine is a layer of non-mineralized matrix, the *predentine* (**8**.67B,68). The predentine-dentine border is irregularly scalloped (**8**.67B) because dentine mineralizes as microscopic spherical aggregates of crystals (calcospherites). The enamel–dentine junction is more regularly scalloped, with convexities towards the dentine, a pattern unrelated to mineralization. Next to the enamel–dentine junction is a 30–40 μm layer (mantle dentine) which is less mineralized and has collagen fibres arranged parallel to the tubules. In the remaining circumpulpal dentine, fine collagen fibres are perpendicular to and interwoven around the tubules.

Dentine, like enamel, is deposited incrementally and is not remodelled. Both tissues carry a permanent record of changing shape, rhythmical patterns of formation and disturbances during development. Dentine has two orders of incremental line. The *contour lines of Owen* are formed by the coincidence of exaggerated secondary curvatures of adjacent tubules and may also represent a brief period of lower mineralization. A prominent Owen line is formed in those teeth whose mineralization spans birth (all deciduous teeth and the first permanent molars); this is the neonatal line, a result of the abrupt change in environment and nutrition. Fine *incremental lines of von Ebner* record a diurnal rhythm in mineralization level; they are about 5–8 μm apart in the crown and 2–5 μm apart in the root. General slight disturbances during dentinal development result in failure of fusion of calcospherites and produce interglobular areas of unmineralized matrix, so common in a layer 100–300 μm deep near the enamel–dentine junction that they must be considered normal.

The outermost 1 μm of root dentine, the hyaline layer (Owens 1972), may incorporate enamel matrix proteins secreted by the epithelial root sheath (Schonfeld & Slavkin 1977). Internal to this is the granular layer of Tomes (**8**.69), whose granularity may be due to minute interglobular areas or to small terminal expansions and anastomoses of adjacent odontoblast processes (Ten Cate 1972).



Primary dentine formation proceeds at a steady but declining rate as first the crown and then the root is completed. Further reduction in the size of the pulp chamber continues throughout life with the very slow and intermittent deposition of secondary dentine, sometimes distinguished from primary dentine by an Owen line and by a sudden change in direction of dentinal tubules. If dentine receives a severe stimulus (e.g. rapidly advancing caries or wear, tooth breakage) the odontoblasts of the affected region die, leaving a dead tract. This is sealed pulpally by a thin zone of sclerosed dentine and the deposition by newly differentiated pulp cells of reparative dentine, a poorly mineralized and sporadically formed tissue with few and irregular tubules. A less severe stimulus results in the odontoblasts increasing the deposition of peritubular dentine so as to fill the tubules. In ground sections this dentine appears translucent because it has assumed a near uniform refractive index. Translucent dentine also develops with age near the root apices.

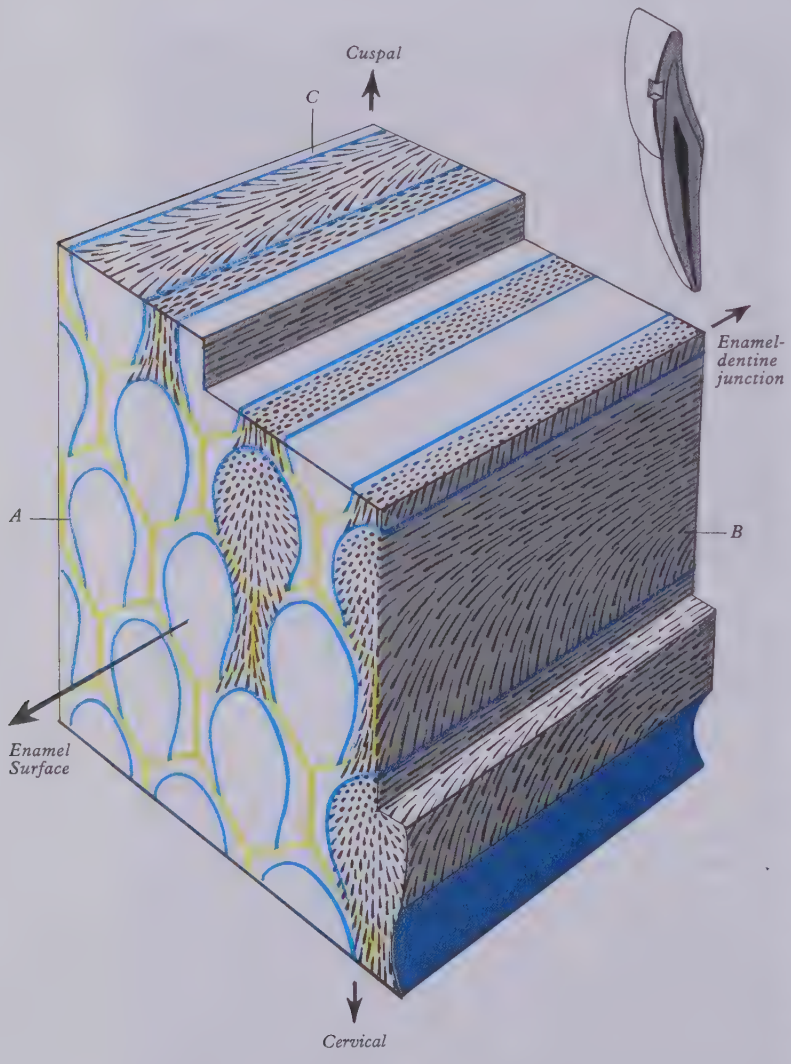
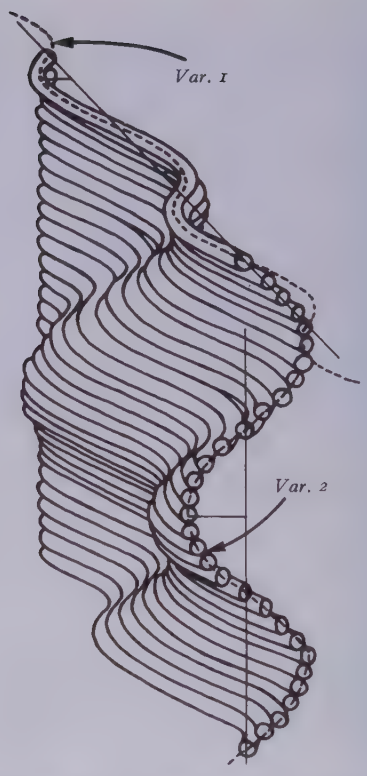
8.71 Longitudinal demineralized section of a tooth stained with a silver impregnation technique. Note the vertical nerve trunk (left of centre) within the pulp, with fine nerve fibres, one of which crosses transversely to pass between the odontoblasts lining the surface of the predentine (the pale-staining vertical layer, right of centre).



THE DENTAL PULP

The pulp is a well-vascularized loose connective tissue, enclosed by dentine. It is continuous with the periodontal ligament via the apical and accessory foramina. Several arterioles enter by the apical foramen to run longitudinally, giving branches to a subodontoblastic plexus in young teeth (Kramer 1960). Capillaries loops are seen in the odontoblast layer. The arterioles have thin walls, possibly related to their inclusion within a rigid cavity whose interstitial pressure is high (Van Hassel & McMinn 1972). Several small veins and lymphatic vessels (Bernick & Patek 1969) emerge from the pulp. Unmyelinated postganglionic sympathetic nerve fibres from the superior cervical ganglion enter the pulp with arterioles. Myelinated and unmyelinated sensory nerve fibres from the trigeminal ganglion traverse the pulp (8.71) longitudinally giving branches to ramify in the *plexus of Raschkow* (Scheinin & Light 1969) in the cell-rich parietal zone. Here fibres lose their myelin sheaths and continue into the odontoblast layer, some entering the dentinal tubules. Intratubular nerves are distinguishable from odontoblast processes because they contain numerous mitochondria (Frank 1968); they are more numerous beneath the cusps (where one in four tubules is occupied) than elsewhere (Lilja 1979). Ultrastructural studies have failed to reveal nerve fibres beyond 100 μm into human dentine but autoradiography of rats' teeth following injection of tritiated proline into the trigeminal ganglion and axonal transport of labelled proteins has revealed innervation in dentinal tubules near the enamel–dentine junction (Pimendis & Hinds 1977).



Stimulation of dentine by thermal, mechanical or osmotic stimuli evokes a diffuse pain response. The mechanism of stimulus transduction is unknown but is unlikely to involve the

8.72 Scanning electron micrograph of enamel prisms. Each prism is about 5 μm wide and separated from adjacent prisms by interprismatic material which has been removed from this specimen by acid etching. A thick structureless surface layer is present. Provided by D Whittaker, The Dental School, University of Wales, Cardiff.

8.73 Diagram of a block of enamel showing how the orientation of the crystallites determines their appearance when the prisms are cut transversely (face A), longitudinally (face B) or at right angles to both these planes (face C). Prism boundaries or sheaths (blue) are formed wherever crystallites meet at highly discordant angles. Superimposed on the transversely cut face (A) are cross-sectional outlines of the ameloblasts (yellow).

8.74A Diagram illustrating the relationships existing between a vertical stack of enamel prisms. Each prism undulates in the transverse plane of the tooth but its undulations are out of phase with those of vertically adjacent prisms. Hence, when a section is viewed by reflected light, the undulations are responsible for the characteristic alternation of dark and light bands which cross the prisms obliquely (the Hunter-Schreger bands). Var. 1 and 2 indicate the sine-wave undulations in the transverse and vertical planes, which vary in amplitude and periodicity in the enamel of different species. (From Osborn 1970 with permission of the author and publishers, Springer.)

direct stimulation of nerve endings in dentine. Newly erupted teeth are equally sensitive yet do not have a plexus of Raschkow or intratubular nerves. Pain-producing chemicals and local anaesthetics show little ability to stimulate or anaesthetize exposed dentine. One possibility is that the odontoblast process is capable of propagating some kind of impulse and of exciting nerve endings in contact with the proximal region of the process or the cell body. Gap junctions, known to give electric coupling, have been identified between adjacent odontoblasts and between odontoblasts and nerve fibres (Koling & Rask-Andersen 1983). Vesiculated terminal boutons have been noted in close (20 nm) apposition to odontoblast cell membranes (Arwill 1968), suggesting the possibility of a chemical synapse. An alternative hypothesis suggests that stimuli generate movement of intra- or extracellular fluid along the dentinal tubules, causing in turn a local distortion of the pulp, sensed by free nerve endings in the plexus (Gysi 1900, Anderson et al 1970, Brannstrom 1964). Recent evidence that odontoblasts are joined by continuous tight junctions (Bishop 1985) suggests that the odontoblast may be directly involved in relaying intratubular fluid movements to nerve endings. This 'hydrodynamic' theory would explain the ineffectiveness of neuroactive agents and why pain is produced by drying and by solutions of high osmotic pressure. Solutions equally effective at producing pain, however, create very different rates of fluid flow (Anderson & Matthews 1967, Horiuchi & Anderson 1973).

THE ENAMEL

Enamel (Osborn 1973, Boyde 1976) is an extremely hard (Knoop number = 300+) and rigid (stiffness = 40–80 GN/m²) ceramic material covering the crowns of teeth. It is a heavily mineralized cell secretion, containing 95–96% by weight crystalline apatites

8.74B Reconstruction of enamel prisms in the dog. Each prism is represented by a thread. Note the gradual change in direction between vertically adjacent prisms which are viewed from the cuspal aspect in this photograph. Only a part of one complete prism undulation is shown in each case. Compare with **8**.74A. Preparation by J W Osborn, Department of Anatomy, Guy's Hospital Medical School, London.

8.75 Scanning electron micrograph of the enamel surface showing perikymata. The holes (about 4 μm wide) were occupied by Tomes' processes of ameloblasts when the development of the enamel was completed. Provided by D Whittaker, The Dental School, University of Wales, Cardiff.

(88% by volume) and less than 1% organic matrix. Since its formative cells are lost from the surface (**8**.75) during eruption it is incapable of further growth or repair. It reaches a maximum thickness of 2.5 mm over cusps and thins to knife edge at the cervical margins. Enamel is composed of closely packed enamel *prisms* (or rods), U-shaped in cross section (**8**.72), extending from close to the enamel–dentine junction to within 6–12 μm of the surface. Each prism is partially delineated by a matrix-rich *prism sheath*, 70 nm thick, and is separated from neighbouring prisms by a continuous *interprismatic region*. Prisms are about 3–4 μm wide in inner enamel, increasing to about 6 μm near the surface. Prisms are packed with flattened hexagonal hydroxyapatite crystallites, 26 nm × 68 nm in cross section (Daculsi & Kerebel 1978). Hexagonal transverse profiles of ribbon-like crystallites are randomly oriented. In the cuspal region of a prism (plane C in **8**.73) these are almost parallel to the prism's long axis and may be as long as the enamel is thick (i.e. up to 2.5 mm); but in the cervical region of a prism (plane B in **8**.73) and in interprismatic regions, the crystallites have a pronounced cervical inclination and end at the cervically-adjacent prism sheath. A sudden change always exists between crystallite orientation on the two sides of a prism sheath. In surface enamel, crystallites are packed with their long axes parallel so that prism sheaths do not form.

At intervals of about 4 μm along its length, each prism is crossed by a dark *striation*, the light microscope manifestation of a rhythmic swelling and shrinking of prism diameter during one day's growth. Higher order incremental lines in enamel are *striae of Retzius* (**8**.70), passing from the enamel–dentine junction obliquely to the surface where they end in shallow furrows, *perikymata*, visible on newly erupted teeth. Each stria represents a period of 7–8 days' enamel growth (Bromage & Dean 1985). Striae are produced by a sudden double right-angle translocation of the prisms in the longitudinal plane (Weber et al 1974) and may be clear or brown in transmitted light. Tyndall scattering of short wavelengths is due to accumulations of matrix in the prism translocations. A prominent stria, the *neonatal line* (Whittaker & Richards 1978), is formed in teeth whose mineralization spans birth. Neonatal lines in enamel and dentine are of forensic importance, indicating that an infant has survived for a few days.

Each prism is sinuous in the tooth's transverse plane with a wavelength of about 1.5 mm, undulations of one prism matched by those lateral to it but slightly (2°) out of phase with those above or below (**8**.74). Prism sheaths are comparatively weak interfaces in enamel (work of fracture, Wf = 200 J/m² perpendicular to prisms but only 13 J/m² parallel to prisms, Waters 1980). Decussation of prisms in the tooth's longitudinal plane is an adaptation which increases the toughness of enamel by enlarging the surface area of potential cracks between prisms in that plane. Similar regular undulations over cusps produce the appearance of gnarled enamel in sections.

Prism sheaths in the inner enamel are considerably thickened to form tuft-like projections from the enamel–dentine junction, extending for a considerable distance in the longitudinal plane of the tooth. Longitudinal sheets of organic material penetrating the full thickness of enamel are *enamel lamellae*. Extensions into the enamel of dentinal tubules are *enamel spindles*, prominent over cusps.

THE CEMENT

Cement is a bone-like tissue covering the dental roots, about 50% by weight hydroxyapatite and amorphous calcium phosphates (Selvig 1965, Frank & Steuer 1977). In newly erupted teeth, the cement generally overlaps the enamel slightly but may just meet the cervical margin or fall short, leaving dentine exposed at the periodontal ligament. All three situations may prevail around the

8.76 Demineralized vertical section of a young rat's molar tooth in situ. Note: (1) the alveolar bone with marrow spaces; (2) the fibres of the periodontal ligament which connect the alveolar bone to the cement of the root; (3) the large pulp cavity typical of a young tooth; (4) the absence of enamel in this demineralized section; (5) the gingiva adjacent to the enamel space at the neck of the tooth.

neck of a single tooth. In older teeth, when the root becomes exposed in the mouth through occlusal drift and gingival recession, cement is often worn away and dentine revealed.

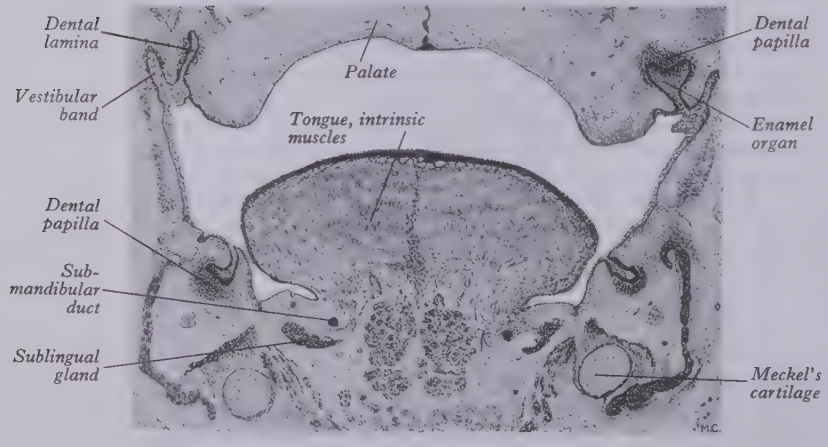
Cement is perforated by *Sharpey's fibres*, attachment bundles of periodontal ligament collagen fibres (extrinsic fibres). New layers of cement are deposited incrementally throughout life to compensate for tooth movements, incorporating new Sharpey's fibres. Incremental lines (of Salter) are irregularly spaced.

The first formed cement is thin (up to 200 μm), acellular and contains only extrinsic fibres; but cement formed later is produced more rapidly and contains cementocytes in lacunae joined by canaliculi mainly directed towards the periodontal ligament. This cement contains both extrinsic fibres and matrix (intrinsic) fibres of cementoblastic origin. With increasing age cellular cement may reach a thickness of a millimetre or more around the apices and at the furcations of the roots, where it compensates for the loss of the periodontal attachment area through occlusal drift. Cement is not usually remodelled but will repair both small areas of resorption and fractures of the dentine. Cement deposition within the apical foramen is a cause of vascular strangulation of the pulp which progresses with age.

THE PERIODONTAL LIGAMENT (MEMBRANE)

The periodontal ligament (Melcher & Bowen 1969) is a dense connective tissue (50% dry weight is collagen types I and III) between 0.15 and 0.3 mm wide. It contains cell types typical of connective tissue with the addition of a network of epithelial cells, the *epithelial debris of Malassez*, remnants of the root sheath. These have no evident function but may produce commonly occurring *dental cysts*.

The principal functions of the periodontal ligament are to attach teeth in sockets and to provide sensory information about tooth movements (Anderson et al 1970). The majority of collagen fibres are arranged in a number of *principal groups* which connect alveolar bone and cement. *Horizontal fibres* at the alveolar crest and near the apex restrict tilt; between these groups are the *oblique fibres*, restricting intrusive movement. Radiating from the apex are apical fibres, resisting extrusive movement. Gingival fibres pass from the cervical region of the root and from the osseous alveolar crest into the gingival lamina propria, anchoring it firmly to the tooth, aided by a *circular group* arranged concentrically around the central neck. The collagen fibres compartmentalize the proteoglycan-rich hydrophilic ground substance (Sloan 1978) which provides a compressive visco-elastic support (Melcher & Walker 1976).



Each periodontal ligament has a nerve supply from several sources (vide supra); the chief role of the innervation seems to be proprioception. Various endings have been described: irregularly branched, knob-like, Meissner's corpuscle-like and spindle-shaped. Structural variations of the mechanoreceptors appear to be less important than their spatial arrangement in determining the response (Hannan 1976). Impulses from such endings probably provide an input to many brain-stem centres and the cerebellum, where masticatory cycles may, in part, be integrated.

Turnover of collagen in periodontal ligaments is remarkably rapid. Fibroblasts are involved in both fibre synthesis and degradation, processes which may occur simultaneously within the same individual cell (Ten Cate & Deporter 1975).

THE GINGIVAE (GUMS)

The gingiva is a specialized region of the oral mucosa surrounding the necks of the teeth (Squier et al 1976). In a healthy mouth it is distinguished from the oral mucosa by its pale pink, stippled appearance (8.59), the adjacent alveolar mucosa being red, shiny and smooth; gingival, palatal and dorsal lingual epithelia are keratinized (or parakeratinized), while alveolar epithelium is non-keratinized. Gingival lamina propria is firmly connected to the underlying alveolar bone, forming a virtually immovable mucoperiosteum.

At the gingival crest, the epithelium is reflected towards the root so that its outer surface is attached to the tooth, forming the *epithelial attachment*. Surrounding the tooth there may be a shallow *gingival sulcus* between tooth and gingiva, its floor being the epithelial attachment. The epithelium attached to the tooth is termed the *junctional epithelium*, that lining the sulcus is the *sulcular epithelium*. Junctional epithelium is non-keratinized, has wide intercellular spaces, few tonofilaments and few desmosomes (Schroeder & Listgarten 1971); it is permeable, weakly cohesive and easily ruptured. Its superficial cells (equivalent to the prickle cells of normal keratinized epithelium) adhere tightly by hemidesmosomes to an outer basal lamina covering the adjoining dental surface (Listgarten 1970) to which they are firmly bonded; this is enamel in newly erupted teeth but in older individuals the junctional epithelium extends onto the cement. Junctional epithelial cells have a very high turnover and move rapidly up the dental surface, whence they are shed into the sulcus.

Early Dental Development

DECIDUOUS TEETH

At the 9 mm embryonic stage primitive oral epithelium (8.78A) begins to bulge into the underlying mesenchyme where teeth will form (8.77–81). From these separate ingrowths and the mesenchyme associated with them, the four anterior deciduous teeth (central and lateral incisors, canine and first molar) will arise (Ooe 1957, Nery et al 1970). In amphibian embryos, odontogenic

mesenchyme originates from the mesencephalic levels of the cranial neural crests, migratory ectomesenchyme entering and expanding the branchial arches (de Beer 1947, Chibon 1967) under the inductive influence of oral epithelium (Wagner 1949, 1955, Henzen 1957). The tooth inductive potency of mandibular arch ectoderm on cranial neural crest cells has been demonstrated in the mouse embryo (Lumsden 1987).

At about the 20 mm stage the ingrown epithelial dental laminae have expanded into knob-like swellings (Ooe 1956), each surrounded by a dense aggregate of vascular mesenchyme (Gaunt 1959). The combined organ rudiment is the *tooth bud*. Ectoderm starts to grow around the mesenchymal aggregate; the ectodermal part is now an *enamel organ*, the mesenchymal part a *dental papilla*. Peripheral cuboidal cells of the enamel organ are soon distinguished from central polygonal cells. At this stage (48 mm) the bud of the second deciduous molar appears on the posteriorly growing dental lamina.

The spherical dental papilla enlarges but the encircling edge of the enamel organ (the *cervical loop*) continues to surround more of its periphery until it sits on the papilla like a cap, the *cap stage* of development (8.78C). Meanwhile the central polygonal cells of the enamel organ have been secreting glycosaminoglycans into intercellular spaces, which attract water, swelling the enamel organ and compressing the cells. Since desmosomal connections persist, the central cells become stellar, forming a *stellate reticulum* (8.78E, 79). The originally cuboidal cells adjacent to the dental papilla lengthen to form the columnar cells of the *inner enamel epithelium* (8.78E). Cells forming the outer surface of the enamel organ are the *outer enamel epithelium* (8.78E), continuous via the dental lamina with the oral epithelium. By continued growth the cervical loop surrounds about three-quarters of the enlarging dental papilla, the *bell stage* of tooth development. Now a layer of flatter cells develops between the inner enamel epithelium and the stellate reticulum; this *stratum intermedium* (8.78E, 79) derives from the original polygonal cells of the enamel organ (the *enamel knot*). Tissue interactions between the peripheral cells of the dental papilla and the adjacent cells of the inner enamel epithelium (Thesleff & Hurmerinta 1981) result in the differentiation of odontoblasts from the former and of ameloblasts from the latter.

8.80 Part of a sagittal section through the head of a human embryo (CR length 60 mm), passing through the right lower central incisor tooth germ. Drawn from a photomicrograph given by C H Tonge, Anatomy Department, King's College, Newcastle-upon-Tyne. Stained with haematoxylin and eosin. Magnification × 12.

The development of a nerve supply to deciduous teeth has attracted little attention. Alveolar nerves enter into maxillary and mandibular processes during the fifth week, before the dental laminae form (Pearson 1977). A close association has been noted between peripheral nerve branches and the sites of prospective tooth development in the mouse (Kollar & Lumsden 1979) but initiation of tooth development does not appear to depend on innervation (Lumsden & Buchanan 1986). At cap and bell stages bundles of nerve fibres have entered the dense mesenchyme of dental papillae and follicles.

The Dental Follicle

The *dental follicle* (8.78E) is the layer of cells which surrounds the tooth germ ultimately to adjoin developing alveolar bone (8.78D, 81); the bony cavity containing the tooth germ and follicle is the *dental crypt*. The follicle cells adjacent to the outer enamel epithelium form a dense *investing layer* from which develops the cement of the root. The periodontal ligament and bone develop respectively from the loose intermediate layer and outer osteogenic layer of the follicle.

The Vestibular Band

As the dental laminae appear, a similar but continuous horseshoe-shaped ingrowth of epithelium develops external (buccal) to them. This *vestibular band* (8.77, 80) grows deeply into the

mesenchyme of the primitive jaws, separating prospective lips and cheeks from the tooth forming regions. It subsequently thickens and cleaves (**8**.80) to form the *oral vestibule*. In contrast to the dental lamina, the vestibular lamina is not associated with an aggregation of mesenchyme cells.

PERMANENT TEETH

As the jaws lengthen the dental lamina grows posteriorly from the distal aspect of the second deciduous molar germ as a solid cord of epithelium, not connected with the surface. From the deep border of this 'burrowing' lamina, buds for the three permanent molars develop in mesiodistal sequence, the first molar bud appearing in the 16-week fetus, the second at about one year and the third at five years. Each bud is initiated in the ramus of the lower jaw but, with progressive resorption of the anterior border of the coronoid process, they come to occupy the body of the mandible.

From each deciduous tooth germ at its bell stage (about 16 weeks) a lingual *successional lamina* grows from the site of continuity between outer enamel epithelium and dental lamina (**8**.81). Each grows down into mesenchyme lingual to a deciduous tooth and from its end a bud develops for a permanent successor which becomes surrounded by its own follicle and crypt. The follicle maintains fibrous continuity with the lamina propria of oral mucosa by *gubernacular cords*, whose original positions are visible in young skulls as *gubernacular canals*. Gubernacular canals are said to guide erupting permanent teeth into their correct positions (Scott 1967).

The Fate of the Dental Laminae

As dentine and enamel start to develop, the dental laminae begin to degenerate (**8**.78E), separating into clumps, many with a whorled appearance over developing deciduous teeth. These persist as epithelial rests but may sometimes proliferate to form cystic cavities, known as *eruption cysts*, recognizable as bluish swellings over erupting teeth.

Crown Pattern Morphogenesis

During the late bell stage the amelodentinal membrane, formed by the inner enamel epithelium, the peripheral cell layer of the dental papilla and the interposed basement membrane, folds in a genetically determined pattern to assume the definitive outline of the future enamel–dentine junction. Because regional variations in enamel thickness are slight, this folding determines the ultimate shape of a tooth, i.e. the number and positions of cusps. Cap stage incisor and molar tooth germs of mouse embryos separated into their epithelial and mesenchymal components and reciprocally recombined in organ culture develop the morphology expected of the mesenchyme (Kollar 1972). How the dental papilla mesenchyme acquires positional specification and how the information for shape is encoded and relayed to the apparently indifferent enamel epithelium are unknown.

DEVELOPMENT OF DENTINE

At the tip of a presumptive cusp, cells of the inner enamel epithelium lengthen and mesenchyme cells of the adjacent dental papilla extend fine processes through the reticular lamina of the basement membrane to contact the epithelial basal lamina. An extracellular matrix-mediated cell to cell interaction (Thesleff 1977) induces the mesenchyme cells to differentiate into odontoblasts, which will lay down dentine (**8**.78F, 82). Newly differentiated odontoblasts, with well developed endoplasmic reticulum and Golgi apparatus, secrete dentine matrix into the space between the basal ends of the inner enamel cells and their own secreting ends. Collagenase-containing vesicles in this early matrix (Sorgente et al 1977) may be involved in digestion of the epithelial basal lamina which permits the odontoblast processes to push up between the inner enamel epithelial cells where they may form direct cell contacts, mediating the differentiation of ameloblasts. Accumulating matrix pushes the odontoblasts back, their processes lengthening as their perikarya recede, becoming enclosed within tubules of the matrix. As soon as a few microns of matrix are formed, the matrix adjacent to the inner enamel epithelium begins to mineralize (Silva & Kailis 1972), possibly with the agency of alkaline phosphatase-rich matrix vesicles (Bernard 1972, see also p. 302).

From this region, the summit of a presumptive dentine cusp, a wave of differentiation of odontoblasts from papillary cells slowly spreads to the growing cervical loop. As soon as each differentiates, the matrix is formed, pushing the layer of odontoblasts, united by desmosomes, into the papilla. The layer of unmineralized matrix adjacent to the odontoblasts is termed predentine (**8**.82). First-formed collagen fibres lie parallel to the odontoblast processes; after this thin layer of *mantle dentine* (vide supra) is formed, fine collagen fibres of *circumpulpal dentine* are elaborated, interlacing at right angles to the processes. In mantle dentine each odontoblast has two or more processes but, as it recedes from the enamel–dentine junction, its processes unite into a single main process. This accounts for the bifurcation of the tubules near the junction. During circumpulpal dentinogenesis odontoblasts constantly extend short lateral processes at the base of the main process; these are later embedded by mineralized dentine to become fine lateral tubules. Dentinal tubules are much thinner in mineralized dentine than in predentine; this constriction starts at the level where predentine mineralization is beginning and is due to the deposition of a highly mineralized cylinder of *peritubular dentine* around the inside of the tubule, progressively reducing its lumen. It does not develop in interglobular areas (vide supra) where the tubule is walled by unmineralized intertubular dentine matrix.

DEVELOPMENT OF ENAMEL

Ameloblasts differentiate from cells of the inner enamel epithelium under the inductive influence of newly differentiated odontoblasts; the interaction between these cells is thought to involve direct cell contacts and/or the extracellular matrix. The first signs of differentiation are the manufacture of organelles required for enamel matrix production and the reversal of cell polarity; ameloblasts secrete from their original basal ends. Mitochondria, originally dispersed throughout the cytoplasm, congregate at the non-secreting pole where they cluster around the nucleus. The Golgi apparatus is located centrally; cisternae of the extensive endoplasmic reticulum are stacked in rows parallel to the cell's long axis. The mature cell is about 40 μm long and about 5 μm wide. In cross section ameloblasts are regular hexagons, accounting for the classic honeycomb appearance, and are interconnected by junctional complexes at both secreting and non-secreting poles. Their non-secreting poles are attached by desmosomes to the stratum intermedium cells, which may elaborate and transport materials to the ameloblasts (Kurahashi & Yoshiki 1972). Alkaline phosphatase, found in other hard-tissue forming cells, exists in the stratum intermedium but not in secretory ameloblasts.

Enamel matrix is secreted between mineralizing dentine and ameloblasts; a rise or potential rise in hydrostatic pressure produced by the accumulation of enamel matrix in this enclosed region probably provides the force to push ameloblasts away from the enamel–dentine junction (Osborn 1973). Since ameloblast differentiation depends on and shortly follows odontoblast differentiation, developing enamel spreads down the sides of the presumptive enamel–dentine junction in the same way as developing dentine, just behind it (**8**.82).

At the start of amelogenesis, in each region of the tooth germ, adjacent stellate reticulum seems to collapse, the enamel organ being progressively reduced in thickness until it has only three layers (outer enamel epithelium, stratum intermedium and ameloblast layer). It is widely assumed that this brings the ameloblasts, inside an avascular enamel organ, closer to the capillaries which have invaded the investing layer of the follicle adjacent to the external enamel epithelium. Meanwhile, cells of the latter, originally cuboidal, become squamous, throwing the outer surface of the enamel organ into microscopic folds to increase the area for diffusion.

When ameloblasts have moved about 10 microns from the enamel–dentine junction they develop conical extensions into the

8.82 Vertical section through the neck of a developing tooth with the crown above and the developing root below. Note above, from right to left: (1) the columnar ameloblasts; (2) enamel matrix (red); (3) mineralizing dentine (pale mauve); (4) predentine (pale blue); (5) odontoblasts; (6) the fibroblasts of the pulp. The columnar ameloblasts terminate at the tooth neck where the latter is continuous with the developing root. In this region note from right to left: (7) the fibrous tooth follicle; (8) the layer, two cells thick, of Hertwig's root sheath; (9) the developing dentine; (10) the odontoblasts. Beneath this the root sheath extends to the left beneath the dental papilla.

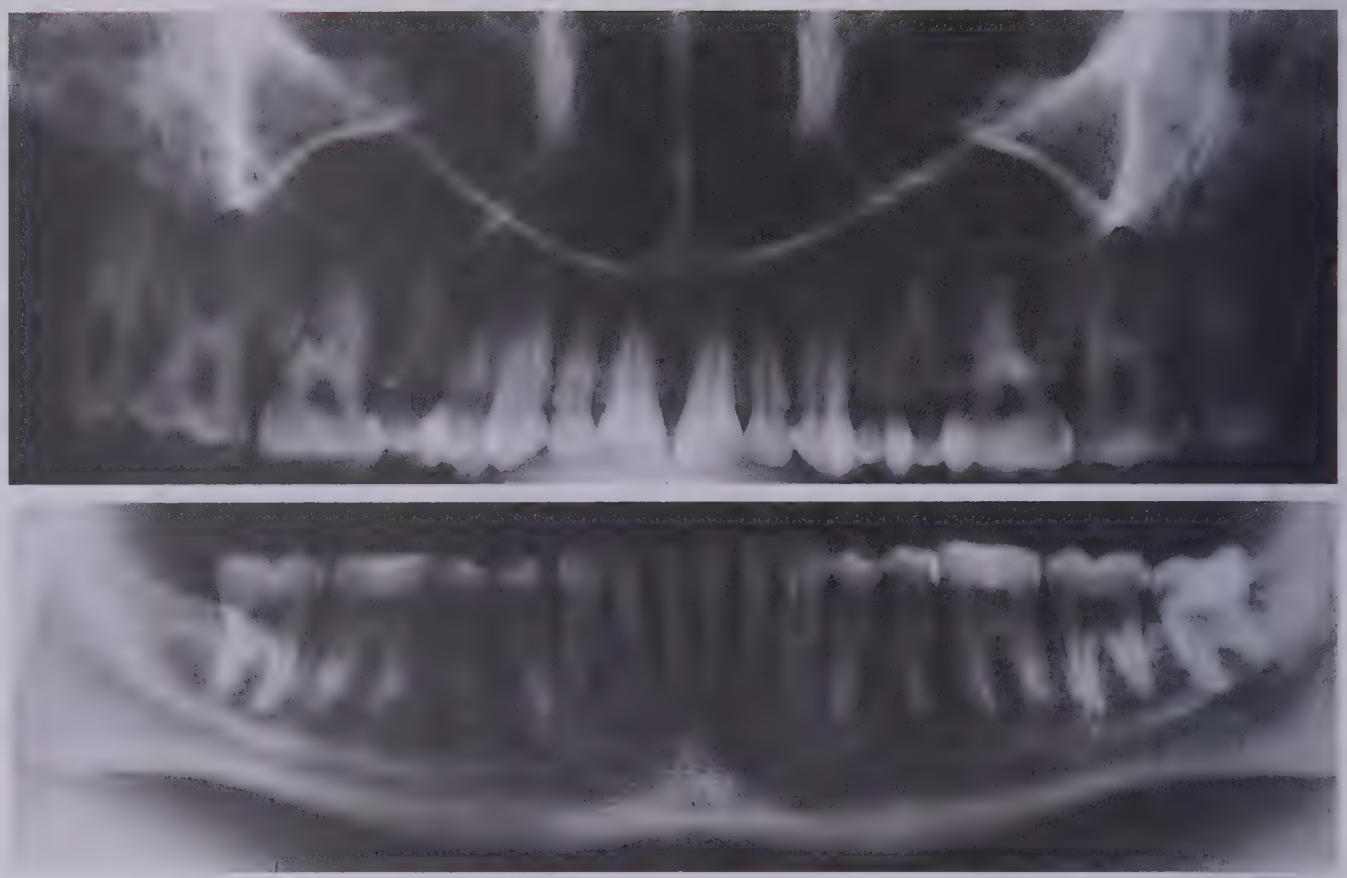
accumulating enamel. These *Tomes' processes*, whose bases are limited by the junctional complex at the secreting pole of the cell, bear a peripheral collar of microvilli (see Reith 1970). Tomes' processes give the developing front of enamel a pitted appearance (Boyde 1969); adjacent to each is an unmineralized layer about 50–100 nm thick, the *enamel matrix*. This is stippled under the electron microscope and similar material is seen in membrane-bound vesicles within Tomes' processes. On the enamel side of this stippled material are long ribbon-like crystallites. First formed enamel is non-prismatic or contains irregular prisms. At the enamel-dentine junction, enamel (recognized by long crystallites) is intermixed with dentine (recognized by collagen fibres and small crystallites).

The mineralizing enamel front shows little change until nearly the full thickness of enamel has been secreted. This is immature enamel, containing narrow crystallites about 3 nm × 29 nm in cross section, and has a composition of about 40% mineral by weight. As ameloblasts approach the final surface, deeper crystallites thicken by accretion of ions from the surrounding matrix. Diminishing calcium-rich matrix is replenished by ameloblasts, water and protein being resorbed. The matrix can travel long distances through the developing enamel. Ultimately the crystallites can widen no more, no further space being available between them. Theoretical analysis suggests that about 12% by volume of unmineralized enamel matrix and water would thus remain (Carlstrom 1964), according well with the observation that mature enamel is 96% by weight mineral (i.e. 88% by volume). No new crystallites appear to be added to the enamel except at the mineralizing front (Ronnholm 1962); crystals therefore grow in length as the enamel is deposited and achieve their final length as maturation begins. As secretion ends the ameloblast shortens, withdraws its previously conical Tomes' process and forms a ruffled membrane with numerous microvilli which endocytose the matrix (Reith 1967a,b). The maturative ameloblast contains numerous lysosomes. Over some of the enamel surface developed at this time, crystallites are parallel and prism sheaths are not formed (vide supra). This non-prismatic surface layer is about 6–12 μm deep (Gwinnett 1967, Osborn 1973) and is about 1% by weight more mineralized than the rest, possibly because of closer packing of crystallites permitted by parallel orientation.

ROOT DEVELOPMENT



As enamel maturation proceeds towards completion of the tooth crown, the cervical loop of the enamel organ starts to recede from the cervical margin as a double-layered cylinder, Hertwig's root sheath, around the lengthening dental papilla. The outer layer of this sheath is continuous with the outer enamel epithelium (8.82). The inner layer, like the inner enamel epithelium with which it is continuous, induces the differentiation of odontoblasts from contiguous mesenchyme cells. Odontoblasts now deposit a layer of dentine against the basal surface of the epithelium (8.83). The sheath continues to grow, outlining the final shape of the roots and inducing differentiation of odontoblasts, surrounding vessels and nerves supplying the dental papilla. These vessels remain and it is because of them, particularly those located centrally near the future apex, that the foramina open through canals in the dentine into the pulp of a fully developed tooth.

8.84B Normal dentition of a child aged seven years (deciduous teeth: blue, permanent teeth: yellow). The lower permanent central incisors have replaced the deciduous central incisors and the first permanent molars have erupted. The upper permanent lateral incisor appears to be congenitally missing from this skull. Drawn from a photograph by F Harrison, Dental Department, University of Sheffield and reproduced from Pedley & Harrison by permission of Blackie.

8.84A Development of the deciduous (blue) and permanent (yellow) dentitions from birth to maturity. Modified from Schour & Massler (1941).

8.85 Pan-oral radiographs of the whole dentition of the upper and lower jaws of a mature human skull. Note the right lower third molar is missing. To achieve these radiographs, an X-ray source is introduced into the buccal cavity, directed towards the palate for the upper jaw and towards the floor of the cavity for the lower jaw. The X-ray beam is deflected magnetically to disperse anterolaterally and the film is wrapped around the external aspect of the jaws. The clarity of the radiographs is much greater than that possible during clinical radiography of the living head. The radiographs were prepared by D White of the X-ray Department of the Royal Dental Hospital, London.

During crown development the capillaries are most numerous beneath the cuspal growth centres. The papilla grows more rapidly near the capillaries, less rapidly elsewhere. In the latter regions a growing tip of root sheath is able to penetrate under the papilla to meet a growing tip from the other side, separating the two roots. They may, however, just fail to meet, in which case a single flattened root is formed with two root canals. Thus the principal cusps of a multicusped tooth are each supported by a root, which is either separate or incompletely separated from its neighbours.

8.86 A lateral radiograph of the jaws of a newborn child. Note the state of development of the jaws and teeth.

THE DEVELOPMENT OF CEMENT

Shortly after initial dentinogenesis in the root, the adjacent root sheath epithelium becomes fenestrated (vide infra), exposing the unmineralized exterior of the dentine to the vascularized follicular mesenchyme, from whose investing layer cementoblasts are differentiated. These early cementoblasts do not synthesize collagen but secrete ground substance onto the dentine matrix and around bundles of collagen fibres developed in the follicle which have fanned out on the dentine surface. This composite matrix (which may also include epithelial cell secretions, vide supra) is mineralized under the influence of cementoblasts (Owens 1975). The collagen fibre bundles are about 6 μm wide and their cores mineralize more rapidly than their peripheries. Because it is unmineralized at the time of its formation, the junction between dentine and cement has crystalline continuity and is hence not easy to define in electron micrographs.

First-formed cement, containing only extrinsic collagen fibres, develops while the tooth is erupting and is therefore present on the cervical third of the root dentine. Cementoblasts differentiating over the remainder of the root and, in all later cement, contribute collagen fibres to the matrix (Boyde & Jones 1972). This mixed fibre cement therefore contains both *extrinsic* (Sharpey's) *fibres* of periodontal origin and *intrinsic fibres* from cementoblasts, the former being perpendicular to the developing surface, the latter parallel. Intrinsic fibres are mineralized first. Sharpey's fibres are then mineralized around their peripheries,

while the cores are unmineralized. In later or more rapid cementogenesis, the cementoblasts are frequently trapped within the matrix; cellular cement is most commonly formed around the apical two-thirds of the root surface.

DEVELOPMENT OF THE PERIODONTIUM

During the cap and bell stages of tooth development some cells of the dental papilla are displaced by the growing cervical loop to lie adjoining the outer enamel epithelium. Cementoblasts and fibroblasts of the tooth-related periodontal ligament are probably derived from these cells (Ten Cate 1974, Palmer & Lumsden 1987). The remaining, bone-related, periodontal ligament and alveolar bone are developed from the outer layers of the follicle.

The principal oblique fibre group of the ligament becomes organized at the time of root development and eruption, with an orientation which is visible first as an oblique array of fibroblasts. Once formed, their oblique orientation is maintained as the tooth moves relative to the alveolar bone. Based on its appearance in sections, it was formally considered that the principal fibres were formed, broken and reformed at an intermediate plexus in the central zone of the ligament (Hindle 1967). Autoradiographic studies following tritiated proline uptake, together with ultrastructural studies of collagen phagocytosis suggest, however, that fibres are replaced more rapidly close to alveolar bone (Melcher 1976).

The epithelial debris of Malassez is formed by the remains of Hertwig's root sheath which, following its fenestration and the translocation of presumptive cementoblasts from the follicle to the dentine surface, moves away from cement into the tooth-related periodontal ligament.

DENTAL ERUPTION

When the deciduous dentition is initiated, the five tooth germs in each quadrant occupy jaws which are about 1 mm long. By the time the teeth have erupted into the oral cavity they occupy about 3 or 4 cm of jaw; during development the teeth have migrated apart. It is not known how this movement is brought about.

Very soon after root formation starts, the teeth begin to move towards the oral cavity (Darling & Levers 1976). The origin of the forces which move teeth is not certainly known. A tooth could be *pushed* by growth of its root, proliferation of cells in the pulp or tissue hydrostatic pressure. In support of the latter, van Hassel & McMinn (1972) have shown in the dog that the tissue pressure above an erupting tooth is about 10 mmHg and within the tooth it is about 23 mmHg, creating an eruptive pressure of 13 mmHg. Alternatively, a tooth could be *pulled* out of its socket by shrinkage of the obliquely placed collagen fibres (Thomas 1976) or by the movement of fibroblasts within the periodontal ligament (Beertsen et al 1974). It has also been suggested that the remodelling of alveolar bone may cause eruption (Marks & Cahill 1984). In reality, several of the above factors are likely to co-operate in the eruptive process (Moxham & Berkovitz 1983).

The permanent incisors and canines initially develop lingual to their predecessors (**8**.81) but erupt along labially-inclined paths. This movement is associated with the intermittent but progressive osteoclastic resorption of the roots of deciduous teeth (Furseth 1968). In periods of quiescence, the resorbed tissues are temporarily repaired by the deposition of cement.

Early in its development, each premolar moves directly deep to its predecessor to become lodged between widely-divergent roots (**8**.61). As the premolar erupts it induces resorption of the deciduous molar. The enamel of the underlying permanent tooth is protected from resorption by its *reduced enamel epithelium* (see p. 1313).

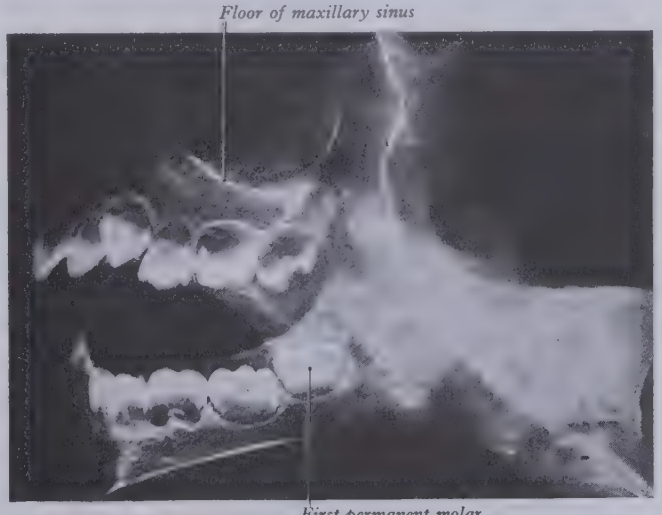
Usual times of eruption of deciduous teeth. (These vary. See **8**.84A,B.)

Central incisors	6–8 months
Lateral incisors	8–10 months
First molars	12–16 months
Canines	16–20 months
Second molars	20–30 months

Calcification of permanent teeth proceeds as follows: first molars at birth, incisors (except upper lateral) and canines about 4 months, upper lateral incisors about 1 year, premolars about 2 years, second molars about 3 years and third molars about 8 years.

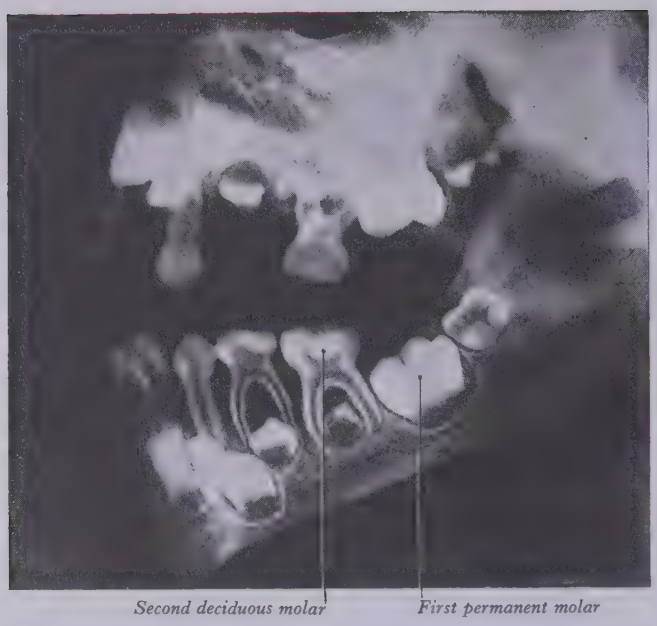
Usual times of eruption of permanent teeth. (Upper teeth erupt a little later than lower. See **8**.84A,B.)

First molars	6–7 years
Central incisors	6–8 years
Lateral incisors	7–9 years
Canines	9–12 years
First and second premolars	10–12 years
Second molars	11–13 years
Third molars	17–21 years



ALVEOLAR DEVELOPMENT

Jaws begin to develop when the dental lamina is forming. In the mandible the growing margin of membrane bone lateral to Meckel's cartilage passes back caudal to the inferior alveolar nerve; from it lateral and medial plates grow upwards (Dixon 1958, Melcher & Bowen 1969). Developing teeth thus appear to descend between the plates (**8**.81). An osseous horizontal partition divides the teeth from the inferior alveolar nerve and vertical septa later isolate each tooth in its own crypt. Bone does not develop over deciduous teeth and in skeletonized neonatal jaws teeth are usually lost. A similar process is involved in the development of maxillary crypts.



When the teeth start to move towards the oral cavity, their sockets also grow, deepening the crypts and increasing the height of the jaw. The rate of eruption outstrips the rate of upward bone growth until the teeth meet their opponents. Developing roots have wide open apices but these later close around nerves and vessels to form foramina. The lengthening of osseous sockets for the teeth much increases the depth of the face up to and during puberty (Scott 1967).

CUTICLES AND EPITHELIAL ATTACHMENT

At the end of amelogenesis, the cells of the enamel organ revert to a squamous shape, becoming a thin stratified layer covering the whole surface of the enamel. This is referred to as the *reduced enamel epithelium*. During eruption it fuses with the oral epithelium to provide an epithelium-lined path for the tooth. The reduced enamel epithelium is rapidly worn away from the exposed surface of the tooth except at the neck where it forms the

8.87A Radiograph of the jaws of an infant, nine months old (from Symington & Rankin *Atlas of Skiagrams*). Only the lower central incisor has erupted; the roots of the first lower deciduous molar are just beginning to form; the crown of the first lower permanent molar faces inwards.

8.87B Radiograph of the teeth of a boy, aged five years (from Symington & Rankin *Atlas of Skiagrams*). In the maxilla the lateral deciduous incisor and the first deciduous molar have been lost, but all the deciduous teeth are present in the mandible. No absorption of the roots of the deciduous teeth has occurred. No permanent teeth have erupted.

epithelial attachment (**8**.43,83) at the dentogingival junction. The reduced enamel epithelium is separated from the enamel surface by a structureless layer, the *primary enamel cuticle*, about 1 μm thick, which may be the final, unmineralized product of ameloblasts. This cuticle together with the reduced enamel epithelium is called *Nasmyth's membrane*. A form of cement known as *afibrillar cement* has been observed over the enamel around the necks of teeth (Listgarten 1966). Afibrillar cement is only about 100 nm thick, contains no banded collagen and is probably produced by cementoblasts following premature disruption of part of the reduced enamel epithelium. Occasionally a cuticle about 4 μm thick is found between the epithelial attachment and the tooth. This is the *secondary enamel cuticle*. It may be a product of the epithelial cells or it may be the remains of blood which has leaked through the epithelial attachment following some slight trauma (Hodson 1966). Finally, salivary protein and carbohydrate form an adherent film on tooth surfaces. This is known as the *pellicle* and is the foundation of *dental plaque*.

APPLIED ANATOMY

The cortical plate of bone in each jaw is continuous over the alveolar crest with the cortical plate lining the tooth socket (the *cribriform plate* or *lamina dura* of radiographs). On the labial and buccal aspects of *upper teeth*, these two cortical plates usually fuse with very little trabecular bone between them, except where the buccal bone thickens over the molar teeth near the root of the zygomatic arch (DuBrul 1980). It is easier and more convenient to extract upper teeth by fracturing the buccal than the palatal plate. Anteriorly in the *lower jaw*, labial and lingual plates are thin but in the molar region the buccal plate is thickened as the external oblique line. Near the lower third molar, the lingual bone is much thinner than the buccal and it is mechanically easier to remove this tooth, when impacted, via the lingual plate. However, the lingual nerve is here exposed to damage.

Abscesses developing in relation to the apices of roots ultimately penetrate the surrounding bone where it is thinnest. The position of the resultant swelling in the soft tissues is largely determined by the relationship between muscle attachments and the sinus (the path taken by the infected material) in the bone. Thus, in the lower incisor region, because the labial bone is thin, abscesses generally appear as a swelling in the labial sulcus, above the attachment of the mentalis. But the abscess may open below the mentalis and point beneath the chin. If an abscess from a lower postcanine tooth opens below the attachment of the buccinator, the swelling is in the neck; if it opens above, the swelling is in the buccal sulcus. If an abscess opens lingually above the mylohyoid, the swelling is in the lingual sulcus; if it is below, the swelling is in the neck. Because the mylohyoid ascends posteriorly, third molar abscesses tend to track into the neck rather than the mouth.

Apart from canine teeth, which have long roots, abscesses on upper teeth usually open buccally below, rather than above the attachment of buccinator. Because its root apex is occasionally curved towards the palate, abscesses of the upper lateral incisors may track into the palatal submucosa. Abscesses of upper canines often open facially just below the orbit. Here the swelling may obstruct drainage in the angular part of the facial vein (p. 793) which has no valves; it is therefore possible for infected material to travel via the angular and ophthalmic veins into the cavernous sinus. Abscesses on the palatal roots of upper molars usually open on the palate.

Upper second premolars and first and second molars are related to the maxillary sinus. When this is large, the root apices of these teeth may be separated from its cavity solely by the lining mucosa. Sinus infections may stimulate the nerves entering the teeth, simulating toothache. Upper first premolars and third molars may be closely related to the maxillary sinus.

With loss of teeth, alveolar bone is extensively resorbed. Thus in the edentulous mandible the mental nerve, originally inferior to premolar toots, may lie near the crest of the bone. In the edentulous maxilla, its sinus may enlarge to approach the bone's oral surface. Lingual to the lower premolars or molars, the upper molars and in the midline of the palate, there are occasional bony prominences termed the *torus mandibularis*, *torus maxillaris* and *torus palatinus* (pp. 367, 354, 389). They may need surgical removal before satisfactory dentures can be fitted.

Severe systemic infections during the time the teeth are developing may lead to faults in enamel, visible as horizontal lines (cf. Harris's growth lines p. 283).

DENTAL RADIOLOGY

Due to dense mineralization, enamel and dentine are radio-opaque whereas pulp appears as a radiolucent region (**8**.85A,B, 86,87A,B). Caries, which attacks teeth through the enamel or root surface, is easily diagnosed by intra-oral radiographs because it demineralizes teeth. The root of a tooth is separated from cortical bone (*lamina dura*) by the radiolucent periodontal ligament. Chronic infections of the pulp spread into this ligament, leading to resorption of the lamina dura around the dental apex. Thus continuity of the lamina dura around the apex of a tooth usually indicates a healthy apical region, except in acute infections where resorption of bone has not yet begun.

Anteriorly, interdental septa form sharp crests between the teeth; between molariform teeth they form tables. In periodontal disease, the eventual sequel to gingival disease, bony crests or tables are resorbed and the extent of the condition can therefore be determined radiographically.

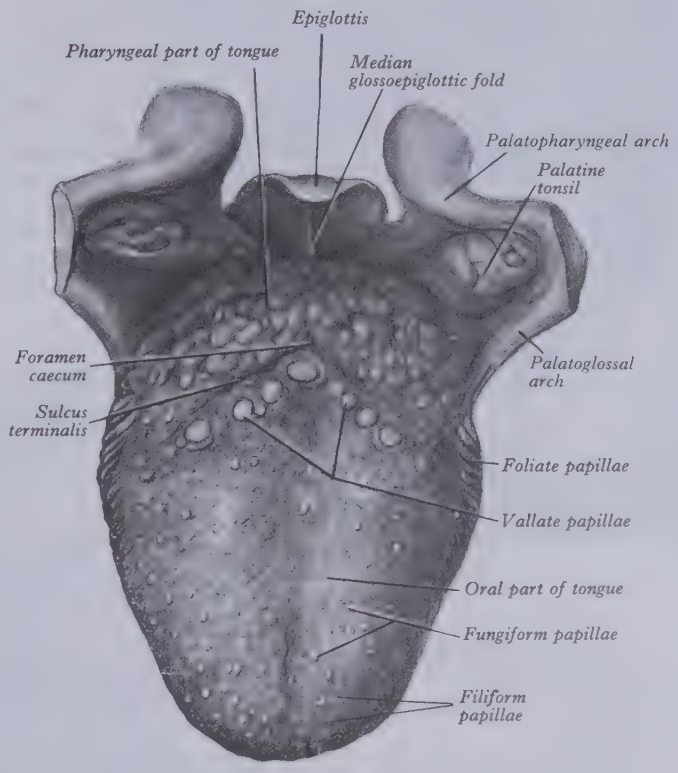
Radiographs are commonly used to estimate separation between the roots of maxillary teeth and the sinus; roots of the second premolar and first and second molar often project into the sinus. Mandibular third molars are commonly prevented from erupting by impaction against the second molars and radiographs are indispensable in assessing the degree of difficulty in extracting such teeth. Superior to the mental spines (genial tubercles), many mandibles exhibit a well-defined pit ending in a canal, presumably containing a median blood vessel or perhaps penetrating collagen fibres connected to the lingual frenulum. This pit, together with a radio-opaque ring of compact bone, can usually be seen in radiographs of incisors and is a useful median landmark in an edentulous mandible.

THE TONGUE, PHARYNX AND OESOPHAGUS

The Tongue

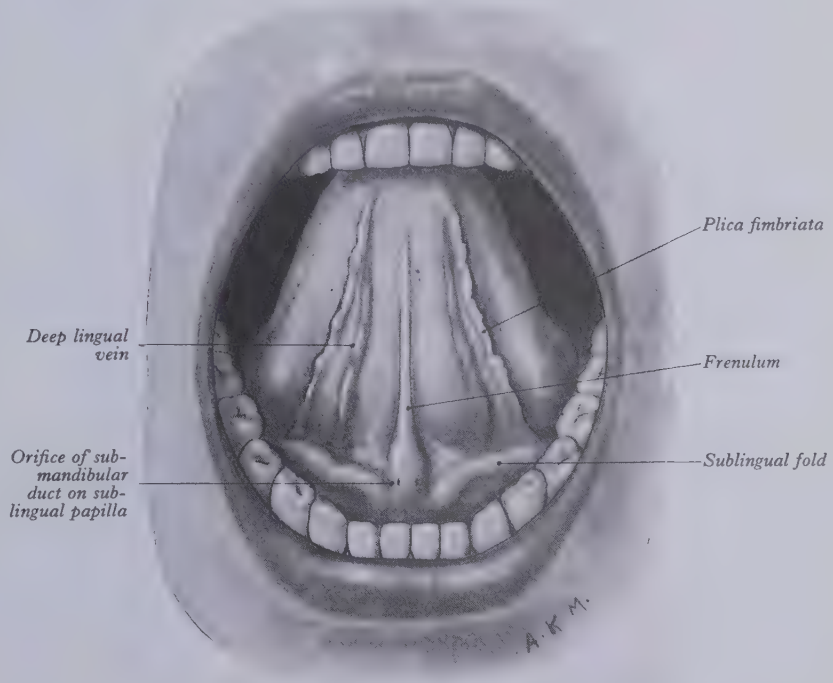
The tongue (**8**.88–90) is a highly muscular organ of deglutition, taste and speech; it is partly oral and partly pharyngeal in position. It is attached by its muscles to the hyoid bone, mandible, styloid processes, soft palate and pharyngeal wall. It has a root, an apex, a curved dorsum and an inferior surface. Its mucosa is normally pink and moist.

The *root of the tongue* (**8**.89) is attached to the hyoid and mandible and between them it is in contact inferiorly with the geniohyoid and mylohyoid muscles. The *dorsum* (posterosuperior surface) is generally convex at rest and is divided into an anterior part facing upwards and a posterior part facing posteriorly. These are separated by a V-shaped *sulcus terminalis*, whose limbs run anterolaterally from a median *foramen caecum* to the palatoglossal arches (**8**.88). The foramen indicates the site of the upper end of the thyroid diverticulum (p. 228) and the sulcus separates the oral (anterior two-thirds) and pharyngeal (posterior one-third) regions of the tongue, which differ in their mucosa, nerve supply and development (pp. 228, 1322). They are more suitably referred to as the *presulcal* and *postsulcal* parts.



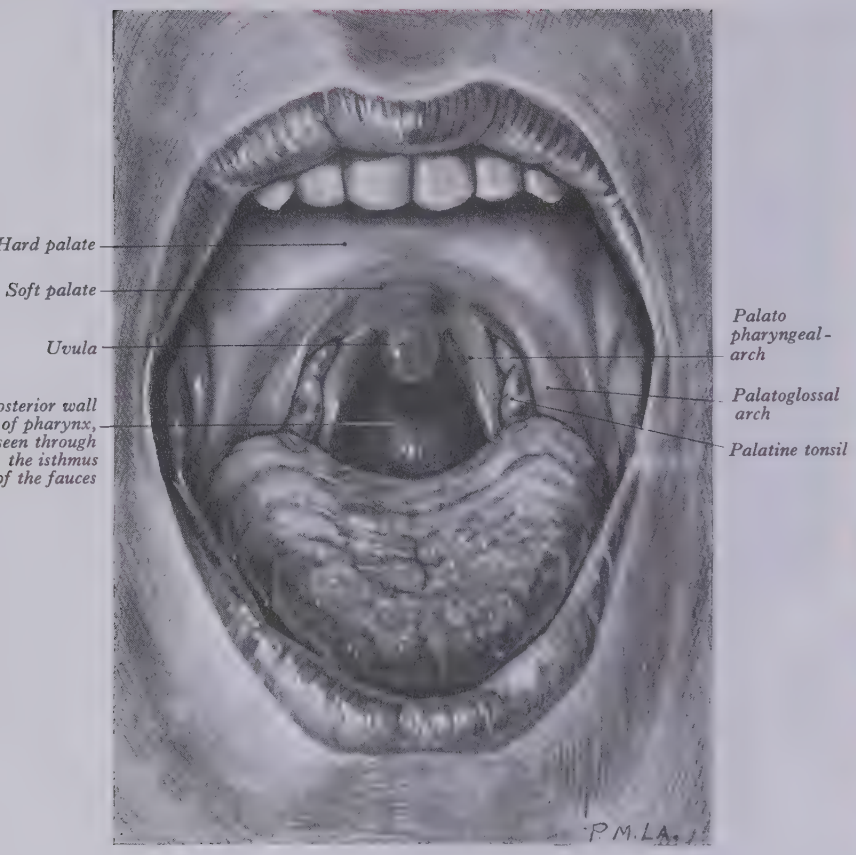
The oral (presulcal) part (**8**.88,89), located in the oral cavity and on its floor, has an *apex* touching the incisor teeth; its *margin* is in contact with the gums and teeth; its *superior surface* (dorsum) is related to the hard and soft palates. On each side, in front of the palatoglossal arch, are four or five vertical folds, the *foliate papillae* (**8**.88). The dorsal mucosa has a median sulcus (**8**.88,89), is adherent to the subjacent muscle of the tongue and is papillated. The inferior mucosa is smooth, purplish and reflected on to the oral floor and gums, being connected to the former by the median *frenulum linguae* (**8**.89); lateral to this, the deep lingual vein is visible, and lateral to the vein is a fringed *plica fimbriata*, directed anteromedially towards the lingual apex. The oral part of the tongue develops from lingual swellings of the mandibular arch and also the tuberculum impar (p. 228). Its general sensory nerve is the lingual, the chorda tympani mediating taste. (For the origin of lingual musculature see p. 175.)

The pharyngeal (postsulcal) part (**8**.88) lies posterior to the palatoglossal arches (the *base* of the tongue) and forms the anterior wall of the oropharynx. Its mucosa is reflected laterally on to the palatine tonsils and pharyngeal wall and posteriorly on to the epiglottic folds. Devoid of papillae, it has low elevations, due to lymphoid nodules embedded in the submucosa, collectively termed the *lingual tonsil*. The postsulcal tongue develops from the hypobranchial eminence (p. 228). Its sensory nerve, including taste, is the glossopharyngeal, whose rami also extend anterior to the sulcus terminalis to supply taste organs in the vallate papillae, an arrangement explained by the anterior extension of the hypobranchial eminence (derived from the third pharyngeal arch) over part of the lingual swellings (p. 228).



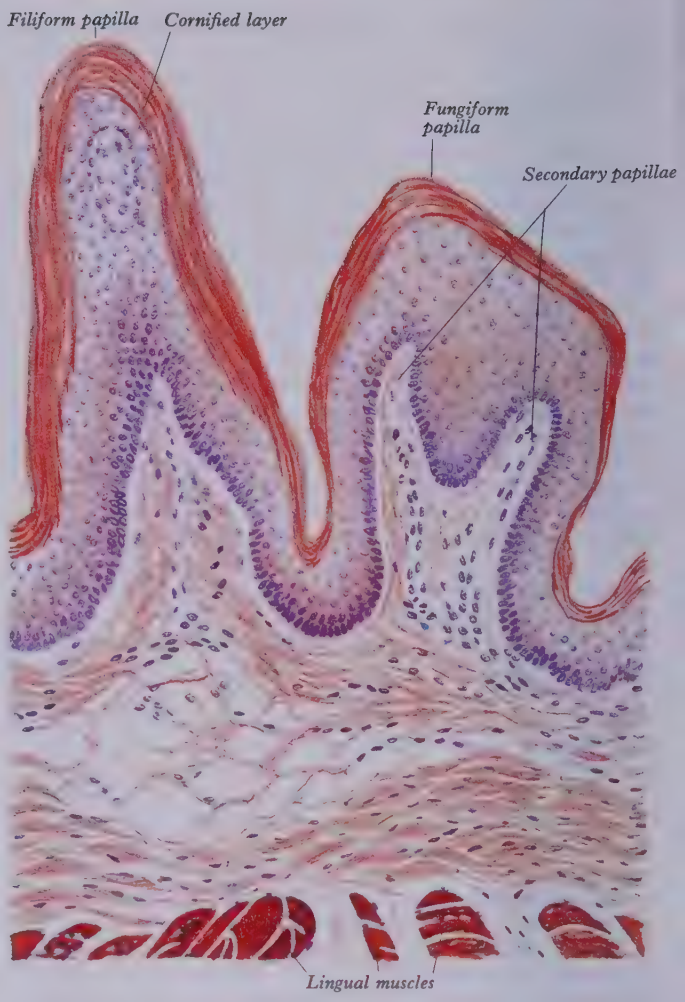
The lingual papillae (**8**.88) are projections of lamina propria which elevate the epithelium above the general level. They are numerous but limited to the presulcal part of the dorsum, producing its characteristic roughness; there are *papillae vallatae, fungiformes, filiformes* and *simplices*. *Foliate* papillae (**8**.88) lie laterally. Papillae are visible modifications of mucous membrane which increase the area of contact between the tongue with the contents of the mouth. *Taste buds* (see p. 1169) are microscopic specialized cellular arrangements around the gustatory nerve endings; they are much more widespread than papillae, being scattered over the entire lingual dorsum and sides, epiglottis and lingual aspect of the soft palate; each region is hence innervated by the appropriate gustatory nerves (facial, glossopharyngeal or vagus). The papillae are more visible in the living when the tongue is dry.

Vallate papillae (**8**.88) are large, varying in number from eight to 12 on the dorsum of the tongue; they form a V-shaped row immediately in front of the sulcus terminalis. Each papilla, 1–2 mm in diameter, is encompassed by a circular depression of mucosa and surrounded by a wall (*vallum*) separated from the papilla by a circular sulcus (**8**.91). The papilla is a truncated cone, its smaller end attached, its broader superficial aspect projecting and bearing numerous small secondary subepithelial papillae. The entire structure is covered with stratified squamous epithelium; in both sulcal walls taste buds abound.

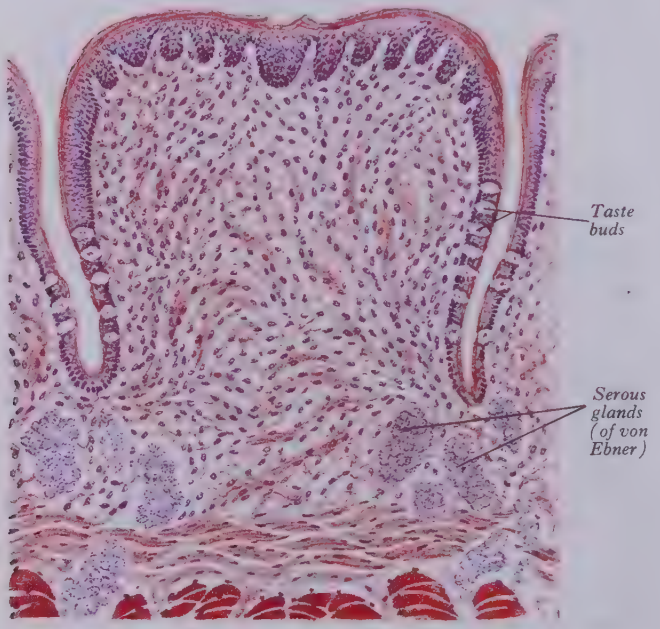


Fungiform papillae (**8**.88,92), more numerous than vallate, occur mainly on the lingual margin but also occur irregularly on the

8.88 The dorsum of the tongue.



8.89 The cavity of the mouth. The tip of the tongue is turned upwards. In the person from whom the drawing was made the two sublingual papillae formed a single median elevation (see p. 1293).



8.90 The cavity of the mouth.

dorsum, where they may occasionally be numerous. They differ from filiform papillae by their larger size, round shape and deep red colour; each has secondary subepithelial papillae and bears taste buds.

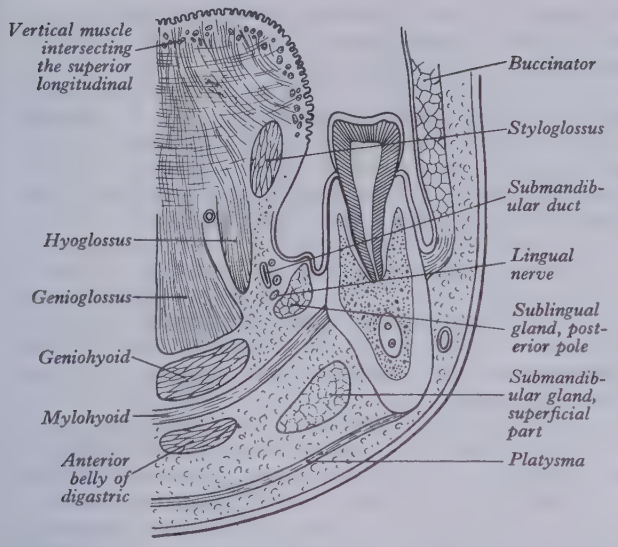
Filiform papillae (8.92) cover most of the presulcal dorsal area (Kullaa-Mikkonen et al 1987). They are minute, conical or cylindrical and arranged in rows parallel with the vallate papillae, except at the lingual apex where they are transverse. They bear many secondary papillae, which are more pointed than those of vallate and fungiform papillae. Their epithelium, which is keratinized, may split into fine processes, each being the apex of a secondary papilla; these processes are whitish, owing to thickened epithelium, its elongated cells being keratinized. These papillae do not bear taste buds but increase the friction between the tongue and food, facilitating the movement of particles by the tongue within the oral cavity.

8.92 Section through a filiform papilla and an adjoining fungiform papilla. Stained with haematoxylin and eosin. Drawn from a preparation lent by E E Hewer. Magnification × 30.

8.91 Section through a vallate papilla. (after Sobotta). Stained with haematoxylin and eosin. Magnification × 32.

Papillae simplices are like those of the dermis (p. 79) and cover the whole mucous membrane of the tongue, including the larger papillae.

Foliate papillae (8.88) or *folia linguae* are red, leaf-like projections found at the sides of the tongue near the sulcus terminalis. Their epithelium contains taste buds.



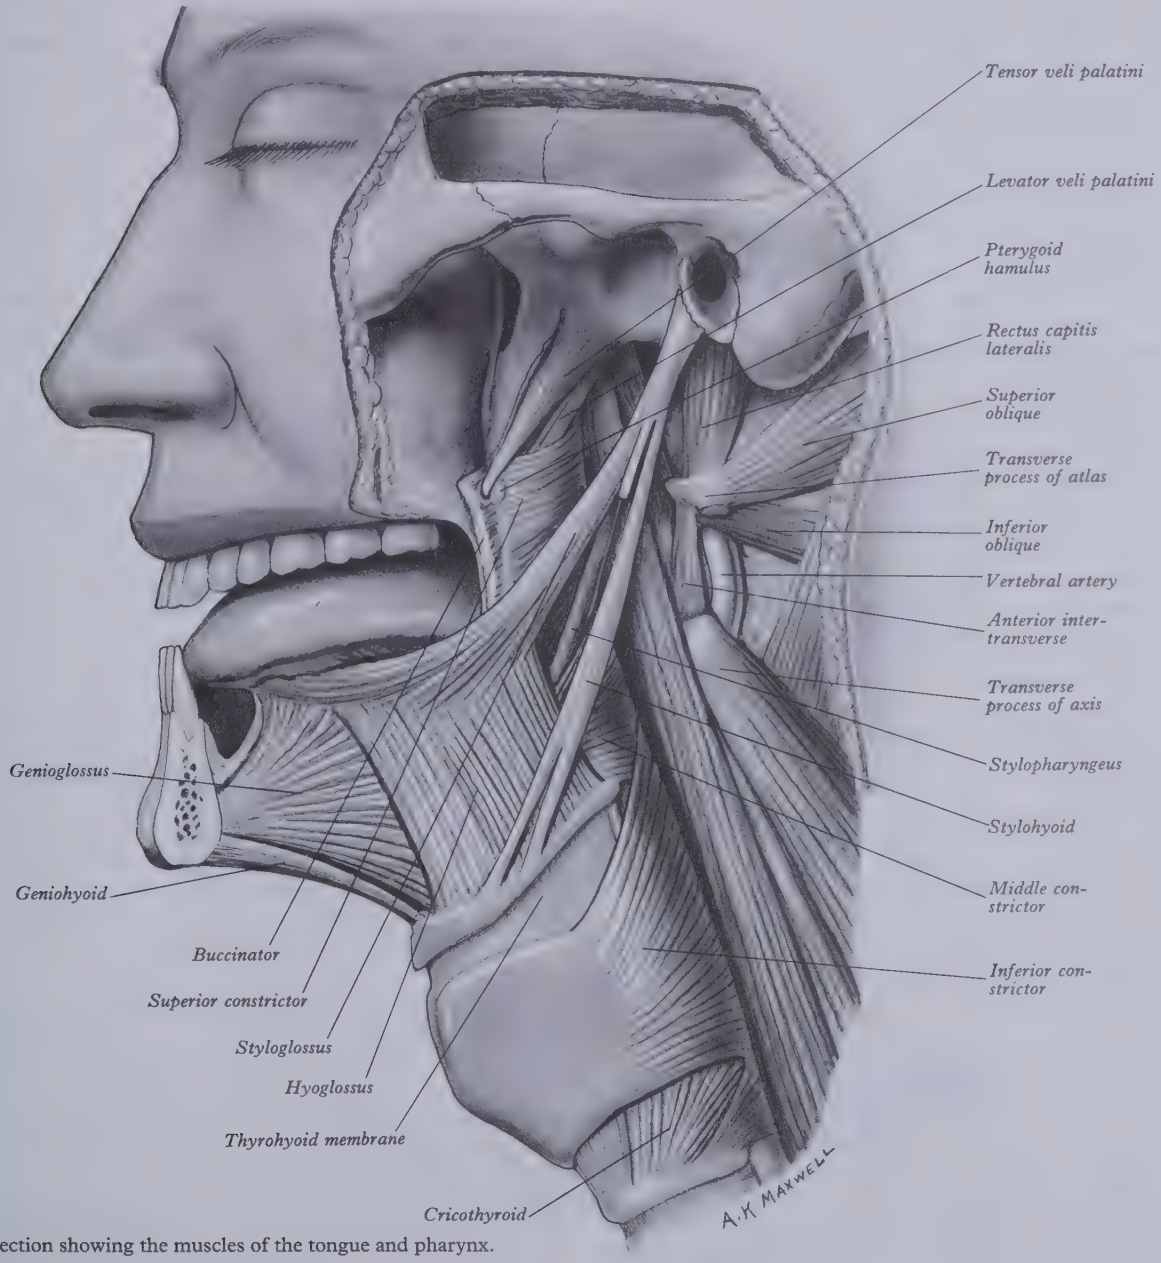
THE LINGUAL MUSCULATURE

The tongue is divided by a median fibrous septum, attached to the body of the hyoid bone. In each half are both the extrinsic and intrinsic muscles (8.93,94), the former extending outside the tongue, the latter wholly within it.

Extrinsic Muscles

These (8.94) include the genioglossus, hyoglossus, styloglossus, chondroglossus and palatoglossus. The palatoglossus, closely associated with the soft palate in function and innervation, is described with the other palatal muscles (p. 1289).

The genioglossus is triangular, lying near and parallel to the midline; it arises from a short tendon attached to the superior genial tubercle behind the mandibular symphysis above the origin of the geniohyoid. From this it fans out backwards and



8.93 Diagram of a coronal section through the tongue, the mouth and the body of the mandible opposite the first molar tooth.

upwards. The inferior fibres of genioglossus are attached by a thin aponeurosis to the upper anterior surface of the hyoid body near the midline, a few passing between hyoglossus and chondroglossus to blend with the pharyngeal middle constrictor; intermediate fibres pass backwards, and superior fibres ascend forwards to enter the whole length of the ventral surface of the tongue, from root to apex, intermingling with the intrinsic lingual muscles. The muscles of opposite sides are separated posteriorly by the lingual septum (p. 1322); anteriorly they are variably blended by decussation of fasciculi across the midline. Doran & Baggett (1972) considered that no fibres reach the lingual apex in man or other mammals.

Actions. Genioglossus brings about the forward traction of the tongue to protrude its apex from the mouth. Acting bilaterally, the two muscles depress the central part of the tongue, making it concave from side to side.

The hyoglossus, thin and quadrilateral, is attached to the whole length of the greater cornu and the front of the body of the hyoid bone, passing almost vertically up to enter the side of the tongue between the styloglossus laterally and the inferior longitudinal muscle medially. Fibres arising from the hyoid body overlap those from the greater cornu.

Relations. Hyoglossus is related at its *superficial surface* with:

8.94 Dissection showing the muscles of the tongue and pharynx.

the digastric tendon, stylohyoid, styloglossus and mylohyoid, the lingual nerve and submandibular ganglion, the sublingual gland, the deep part of the submandibular gland and duct, the hypoglossal nerve and the deep lingual vein. By its *deep surface* it is related with: the stylohyoid ligament, genioglossus, inferior longitudinal muscle, lingual artery and glossopharyngeal nerve. Postero-inferiorly it is separated from the middle constrictor by the lingual artery; this part of the muscle is in the lateral pharyngeal wall, below the palatine tonsil. Passing deep to the muscle's posterior border are, in descending order: the glossopharyngeal nerve, stylohyoid ligament and lingual artery.

Action. The hyoglossus depresses the tongue.

The chondroglossus, sometimes described as a part of hyoglossus, is separated from it by fibres of the genioglossus which pass to the side of the pharynx. It is about 2 cm long, arising from the medial side and base of the lesser cornu and the adjoining part of the hyoid body and ascending to merge into the intrinsic musculature between the hyoglossus and genioglossus. A small slip occasionally springs from the cartilago triticea and enters the tongue with the posterior fibres of hyoglossus.

Action. Chondroglossus assists hyoglossus in depressing the tongue.

The styloglossus, shortest and smallest of the three styloid muscles, arises from the anterolateral aspect of the styloid process, near its apex, and from the styloid end of the stylomandibular ligament. Passing down and forwards, it divides at the side of the tongue into a longitudinal part, which enters the tongue dorsolaterally to blend with the inferior longitudinal muscle in front of the hyoglossus, and an oblique part, overlapping the hyoglossus and decussating with it.

Action. Styloglossus draws the tongue up and backwards.

Nerve supply. Excepting palatoglossus (p. 1290) all extrinsic lingual muscles are supplied by the hypoglossal nerve.

Intrinsic Muscles

These are the bilateral superior and inferior longitudinal, the transverse and the vertical.

The **superior longitudinal muscle** is a thin stratum of oblique and longitudinal fibres lying beneath the dorsal lingual mucosa, extending forwards from the submucous fibrous tissue near the epiglottis and from the median lingual septum to the lingual margins, some fibres being inserted into the mucous membrane. The **inferior longitudinal muscle** is a narrow band close to the inferior lingual surface between genioglossus and hyoglossus. It extends from the lingual root to the apex, some of its posterior fibres being connected to the body of the hyoid bone; anteriorly it blends with the styloglossus.

The transverse muscle passes laterally from the median fibrous septum to the submucous fibrous tissue at the lingual margin, blending with the palatopharyngeus (p. 1290).

The vertical muscle extends from the dorsal to the ventral aspects of the tongue in its anterolateral regions.

Nerve supply. All intrinsic lingual muscles are supplied by the hypoglossal nerve.

Actions. The intrinsic muscles alter the shape of the tongue; thus, the superior and inferior longitudinal muscles tend to shorten it; but the former also turns the apex and sides upwards to make the dorsum concave, while the latter pulls the apex down to make the dorsum convex. The transverse muscle narrows and elongates the tongue; the vertical muscle makes it flatter and wider. Acting alone or in pairs and in endless combination, they give the tongue precise and highly varied mobility, important not only in alimentary function but also in speech (p. 1257).

LINGUAL STRUCTURE

The tongue consists largely of skeletal muscular tissue, partly invested by mucous membrane. The *lingual mucosa* of the inferior surface is thin, smooth and like that in much of the rest of the oral cavity. The mucosa of the pharyngeal part of the dorsum contains many lymphoid follicles, each follicle forming a rounded eminence, central in which is the minute orifice of a funnel-shaped recess. Many round or oval lymphoid nodules, each encapsulated by submucous fibrous tissue, surround each recess, which receives the ducts of mucous glands in its floor. In the oral part the dorsal mucosa is somewhat thicker than ventrally and laterally; it is adherent to muscular tissue, and covered by numerous *papillae* (p. 79). It consists of connective tissue (*lamina propria*) and stratified squamous epithelium, which also covers each papilla. The *lamina propria* is a dense fibrous connective tissue, with numerous elastic fibres, united to similar tissue between the lingual muscle fasciculi. It contains the ramifications of numerous vessels and nerves from which the papillae are supplied, large lymph plexuses and lingual glands. The epithelium varies from parakeratinized stratified squamous epithelium posteriorly, to fully keratinized epithelium overlying the filiform papillae more anteriorly; these features appear to be related to the fact that the apex of the tongue is subject to greater dehydration than the posterior and ventral parts and is more abraded during mastication.

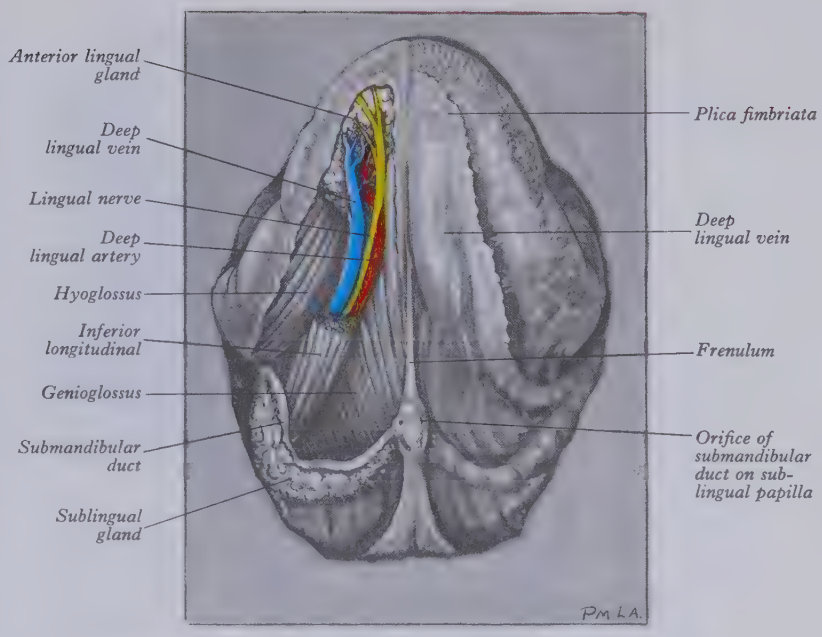
The *lingual glands* are mucous, serous and mixed. *Mucous glands* are like labial and buccal glands in structure; they are numerous in the postsulcal region but are also present at the apex and margins. *Anterior lingual salivary glands* lie at the ventral surface of the apex (**8**.95), one on each side of the frenulum, where they are covered by mucosa and a muscular fasciculus from the styloglossus and inferior longitudinal muscles. From 12 mm to 20 mm long and about 8 mm broad, each has mucous and serous alveoli and opens by three or four ducts on the inferior apical surface. The fine structure of the human *deep posterior lingual glands* has been described in detail by Testa Riva et al (1985). *Serous glands* (of von Ebner, **8**.91) occur near the taste buds, their ducts opening mostly into vallate sulci. They are racemose, the main duct dividing into several channels ending in acini. Their secretion is watery, probably assisting in gustation by spreading and then dispersing substances. The pyramidal shape and ultrastructure of the secretory cells of the acini are similar to those of serous cells elsewhere (Testa Riva et al 1985).

The *lingual septum*, a median fibrous partition of the whole organ, does not quite reach the dorsum. It is an attachment of the transverse lingual muscles and appears prominently in coronal sections. Posteriorly it widens to form the *hyoglossal membrane*, connecting the lingual root to the hyoid bone; the inferior fibres of the genioglossi are also attached to it.

Vessels and Nerves

The main *artery* is the lingual branch of the external carotid (p. 736) but the tonsillar and ascending palatine branches of the facial and ascending pharyngeal arteries also supply the lingual root. In the vallecula (p. 1252) epiglottic rami of the superior laryngeal artery anastomose with the inferior dorsal branches of the lingual artery. Lingual muscles are supplied from this rich anastomotic network and there is a very dense submucosal plexus (Combelles 1974). The *veins* are described on p. 797 and *lymph vessels* (**6**.203) on p. 845.

The *sensory nerves* are: (1) the lingual branch of the mandibular nerve for general sensation in the presulcal region; (2) the chorda tympani branch of the facial nerve (p. 1110), running in the sheath of the lingual nerve, for gustation in the presulcal region exclusive of the vallate papillae (p. 1170); this is partly derived from the nervus intermedius (p. 1107); (3) the lingual branch of the glossopharyngeal nerve (p. 1113), distributed to the postsulcal mucosa of the lingual base and sides and to the vallate papillae and mediating general and gustatory sensation; (4) the superior laryngeal nerve (vagus) (p. 1117), which sends fine rami to the root immediately in front of the epiglottis.

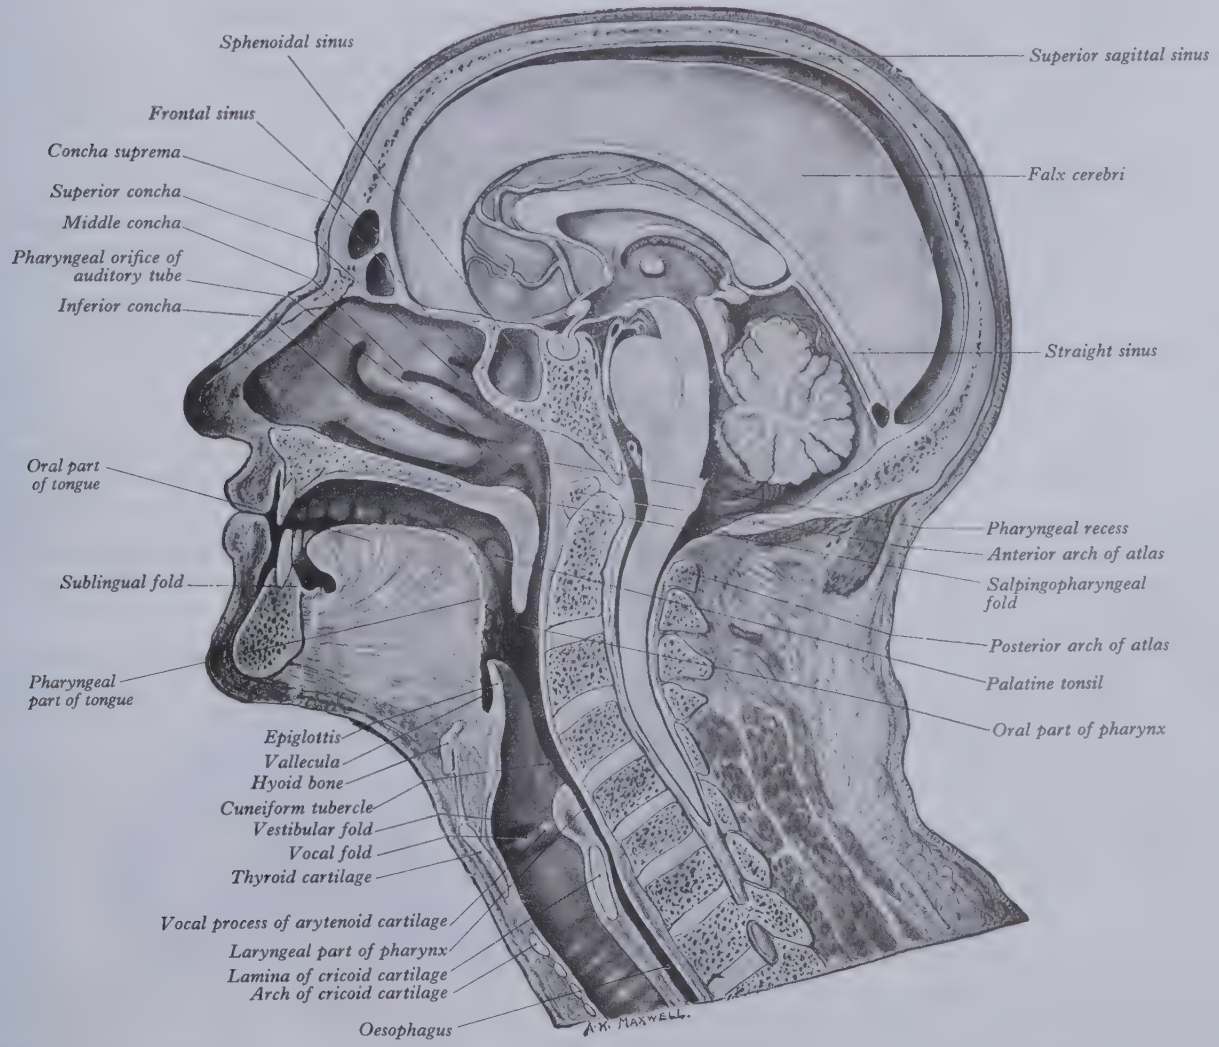


The problem of proprioception in the tongue has been reviewed by Fitzgerald & Sachithanadan (1979). Muscle spindles occur in monkeys (Bowman 1968) and in mankind (e.g. Nakayama 1944, Cooper 1953, Kubota et al 1975), as also confirmed in extensive simian material by the above reviewers. The peripheral route from these undoubted receptors is not clear, though it is perhaps in the lingual or hypoglossal nerves and by cervical spinal nerves communicating with the latter. In monkeys Fitzgerald & Sachithanadan presented strong evidence indicating the hypoglossal nerve as the main proprioceptor route for the intrinsic and extrinsic musculature, many fibres leaving it to enter the second and third cervical anterior primary rami.

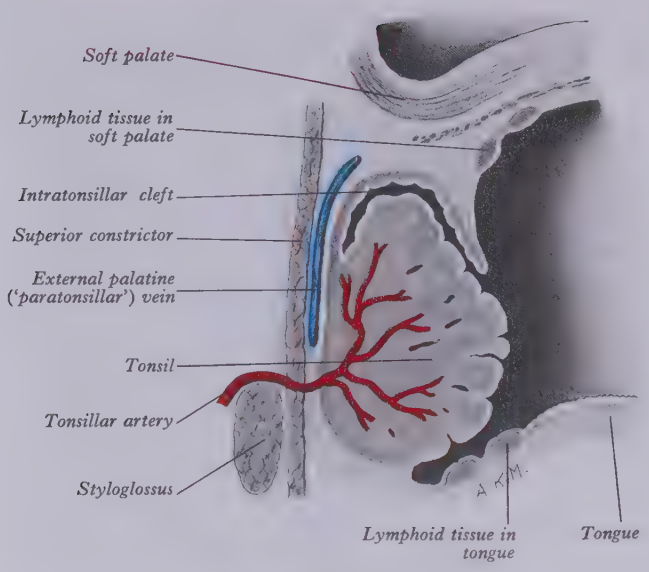
In the postsulcal region, isolated nerve cells have been observed, perhaps postganglionic parasympathetic neurons, *probably* innervating glandular tissue and non-striated vascular myocytes (Chu 1968).

Applied Anatomy. Congenital cysts and fistulae may develop from the persistent remains of the thyroglossal duct (p. 229). The attachment of the genioglossi to the genial tubercles behind the mandibular symphysis prevents the tongue from sinking back and obstructing respiration; therefore, anaesthetists pull forward the mandible to obtain the full benefit of this connection.

THE OROPHARYNGEAL ISTHMUS



The aperture of communication between the mouth and pharynx, the *oropharyngeal isthmus* (**8**.90) is between the soft palate and the lingual dorsum, joined at the sides by the palatoglossal arches. Each *palatoglossal arch* runs down, laterally and forwards from the soft palate to the side of the tongue; it is formed by the projecting palatoglossus (p. 1296) with its covering mucous membrane. Approximation of the arches, to shut off the mouth from the oropharynx, is essential to deglutition (p. 1328).



8.95 Dissection of the inferior lingual surface. On the right side (left side of figure) the mucous membrane has been removed and the inferior longitudinal muscle has been divided and partially resected.

The Pharynx

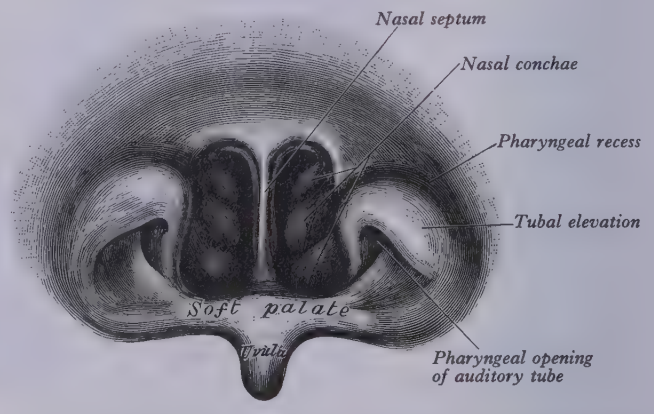
The pharynx (**8**.96–102), situated behind the nasal cavities, mouth and larynx, is a musculomembranous tube, 12–14 cm long, extending from the cranial base to the level of the sixth cervical

8.96 Sagittal section through the nose, mouth, pharynx and larynx. Where it divides the skull and the brain, the section passes slightly to the left of the median plane but, below the base of the skull, it passes slightly to the right of the median plane.

8.97 Coronal section through the palatine tonsil.

vertebra and the lower border of the cricoid cartilage. Its width is greatest superiorly, measuring 3.5 cm; at its junction with the oesophagus it is reduced to about 1.5 cm, this being the narrowest part of the alimentary canal (except for the vermiform appendix). It is limited *above* by the posterior part of the sphenoid body and the basilar part of the occipital bone; *below*, it is continuous with the oesophagus; *behind*, loose connective tissue separates it from the cervical part of the vertebral column and prevertebral fascia covering longus colli and capitis; *in front*, it opens into the nasal cavity, mouth and larynx, its anterior wall being therefore incomplete. It is attached, from above downwards on each side to: the medial pterygoid plate, pterygomandibular raphe, mandible, tongue, hyoid bone, thyroid and cricoid cartilages; *laterally*, it communicates with the tympanic cavities via the auditory tubes and is related to the styloid processes and their muscles, the common, internal and external carotid arteries, and some of the branches of the last named. The pharynx has three parts: nasal, oral and laryngeal (**8**.96).

NASAL PART OF THE PHARYNX



The nasal part (nasopharynx) is behind the nose and above the soft palate. Wood Jones (1940) suggested that the human nasopharynx is morphologically 'nasal', the soft palate really separating the pharynx from the nasal chambers, a view criticized by Leela et al (1974), who consider the transitional zone between nasal and pharyngeal territories to be just anterior to the orifices of the auditory tubes, although they confirm the concept of nasal and pharyngeal contributions to the region. Except for the soft palate its walls are static; its cavity is never obliterated, in which respect it differs from the oral and laryngeal parts and resembles the nasal cavities. It communicates with the nasal cavity (**8**.96) through the two posterior nasal apertures, which are each 25 mm vertically, 12.5 mm transversely, and are separated by the posterior edge of the nasal septum. Between the border of the soft palate and posterior pharyngeal wall the nasal and oral parts communicate through the *pharyngeal isthmus*, which is closed during swallowing by the elevation of the palate and contraction of the palatopharyngeal sphincter (p. 1290). Each *lateral wall* presents a *pharyngeal opening of the auditory tube*, 10–12.5 mm behind and a little below the posterior end of the inferior nasal concha. Somewhat triangular in shape, this opening is bounded above and behind by the *tubal elevation*, formed over the underlying pharyngeal end of the cartilage of the tube (p. 1226); its prominent posterior margin facilitates the introduction of catheters passed along the floor of the nasal cavity for auditory intubation. A vertical *salpingopharyngeal fold* of mucosa descends from the tubal elevation, covering the *salpingopharyngeus* in the wall of the pharynx. A smaller *salpingopalatine fold*, extends from the anterosuperior angle of the tubal elevation to the soft palate. The levator veli palatini, entering the soft palate, produces an elevation of the mucosa immediately below the tubal opening (**8**.100). Behind the tubal elevation the mucosa lines a variable *pharyngeal recess* (extensively surveyed by Khoo et al 1969). The nasopharyngeal *roof* and *posterior wall* form a continuous postero-inferior slope, supported mainly by the basilar occipital bone posteriorly, to a lesser extent by the posterior part of the body of the sphenoid anteriorly, and the anterior arch of the atlas below. A lymphoid mass, the *pharyngeal tonsil*, lies in the submucosa of the upper part of this surface and is best developed in childhood.

The pharyngeal tonsil is visible during the later fetal months, increases in size up to six or seven years and then usually begins to atrophy. In a child of 18 months it is a forward-directed pyramidal prominence, with its apex near the nasal septum and its base at the junction of the nasopharyngeal roof and posterior wall. It consists of folds radiating anterolaterally from a median recess, the *pharyngeal bursa*, which ascends backwards into its substance. The mucosal folds are mainly diffuse lymphoid tissue, but also contain deep mucous glands. The bursa, in the base of the tonsil, is a blind recess. In the embryo, the notochord lies for a short distance inferior to the cranial base, near the developing basilar part of the occipital bone (p. 164); it is attached here to the endoderm of the primitive pharyngeal roof. Subsequently, as this region grows, the notochordal attachment draws out an angled recess of endoderm (the *pouch of Luschka*) forming the pharyngeal bursa. (For discussion see Cave 1965, Slipka 1972). The lateral prolongation of the pharyngeal tonsil behind the opening of the auditory tube produces a *tubal tonsil*, consisting of unencapsulated lymphoid tissue.

THE ORAL PART OF THE PHARYNX

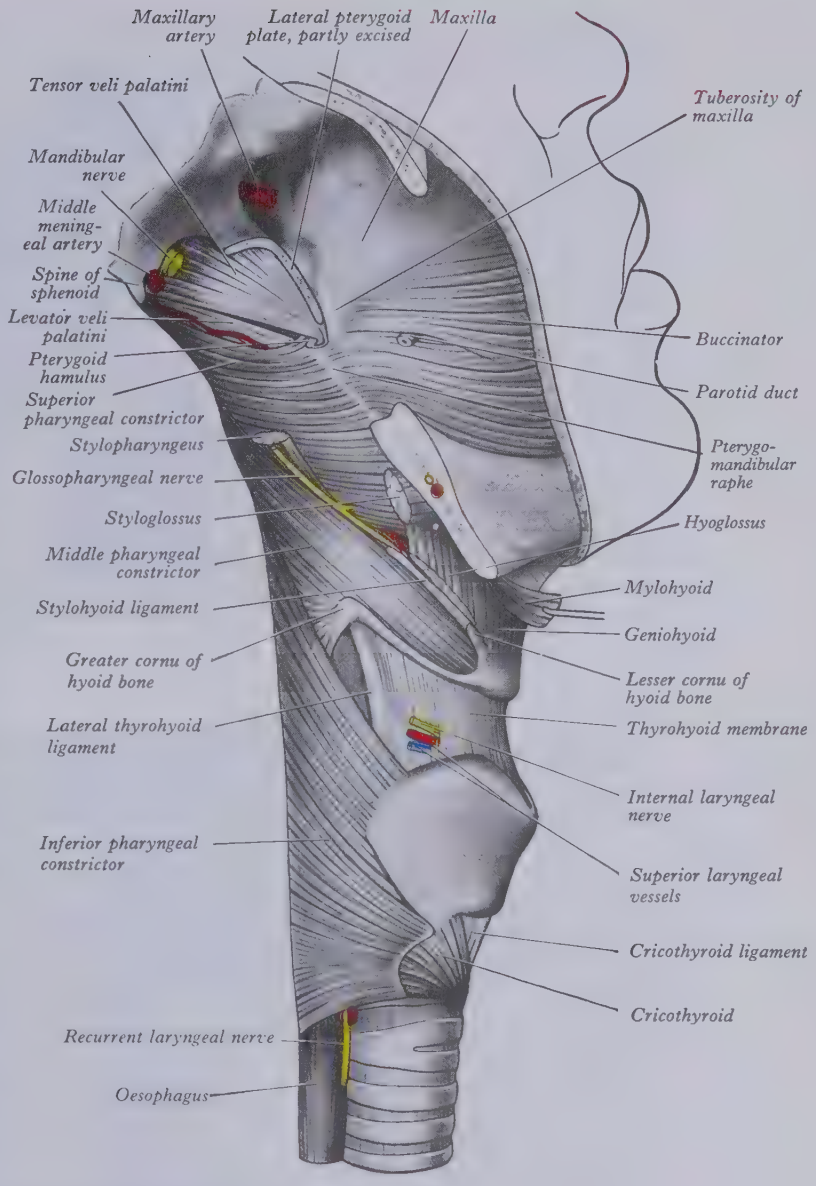
The oropharynx reaches from the soft palate to the upper border of the epiglottis. Through the oropharyngeal isthmus it opens into the mouth, facing the pharyngeal aspect of the tongue. Its lateral wall consists of the palatopharyngeal arch and palatine tonsil. Posteriorly, it is level with the second cervical vertebral body and upper part of the third. The *palatopharyngeal arch* lies behind and projects medially more than the palatoglossal; it descends posterolaterally from the uvula to the side of the pharynx, as a fold of mucosa over the palatopharyngeus (p. 1290). On each side the palatopharyngeal and palatoglossal arches flank the triangular *tonsillar sinus* containing the palatine tonsil.

The palatine tonsils (**8**.90,97), two masses of lymphoid tissue in the lateral walls of the oropharynx, are each in a triangular *tonsillar sinus* between the diverging palatoglossal and palatopharyngeal arches. Its medial surface projects conspicuously into the pharynx during childhood, but the extent of this projection is not a true indication of tonsillar size. The deep, lateral aspect extends upwards, downwards and forwards beyond the medial surface and is embedded below the mucous membrane. Inferiorly, it invades the dorsum of the tongue and, superiorly, the soft palate; anteriorly, it may extend for some distance under the

8.98 Ventral boundary of the nasal part of the pharynx, as seen in posterior rhinoscopy.

palatoglossal arch. The tonsil is variable in size and is frequently infected, leading to inflammatory changes and hypertrophy. It is hence difficult to define a normal appearance. In late fetal life a mucous fold, the *plica triangularis*, extends back from the palatoglossal arch, covering the antero-inferior aspect of the tonsil. In childhood this fold is usually invaded by lymphoid tissue and fuses with the tonsil; it rarely persists in adults.

The upper part of the tonsil contains a deep *intratonsillar cleft*, often erroneously termed the *supratonsillar fossa*. It is not above the tonsil but in its substance; its upper wall contains lymphoid tissue (8.97) extending into the soft palate. The mouth of the cleft is semilunar and lies parallel to the dorsal curve of the tongue. After puberty the deep part of the tonsil diminishes considerably and the medial surface flattens.



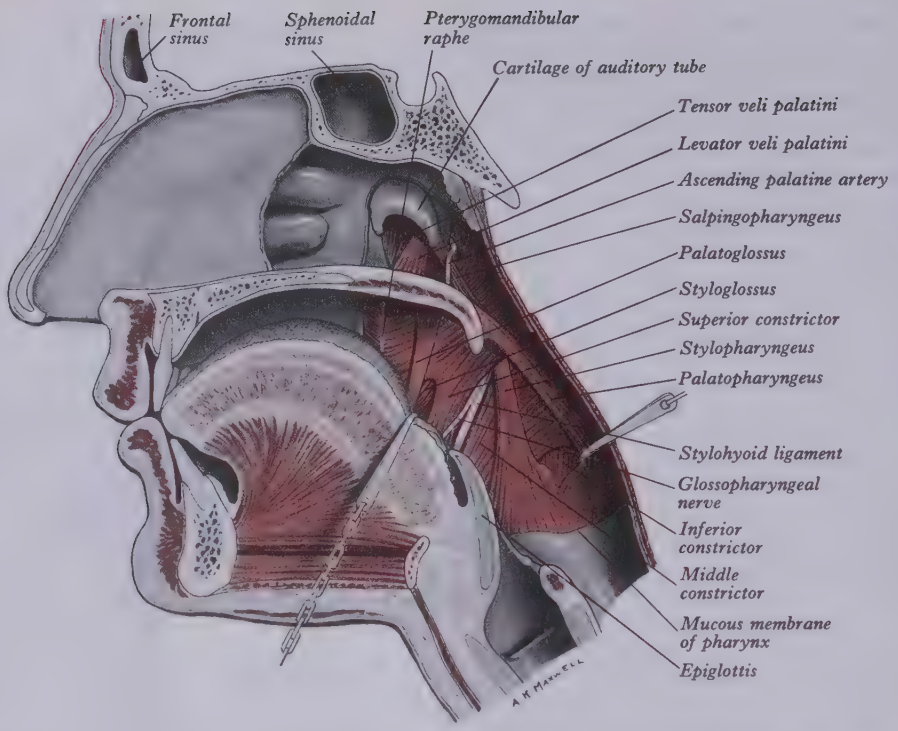
On the *medial surface* of the tonsil are 12–15 orifices of deep, narrow *tonsillar crypts*, penetrating almost through the whole thickness of the tonsil and from which numerous follicles branch. The *lateral* or *deep aspect* is covered by a fibrous *capsule*. The tonsil and its capsule are separable with ease for most of their extent from the muscular wall of the pharynx, formed here by the superior constrictor with the styloglossus laterally (8.82,97,100). Antero-inferiorly the capsule is adherent to the side of the tongue and behind this point it receives the insertion of some muscular fibres of palatoglossus and palatopharyngeus. Here the tonsillar artery, a branch of the facial, pierces the superior constrictor to enter the tonsil with two venae comitantes. An important and sometimes large vein (the *external palatine* or 'paratonsillar vein') descends from the soft palate lateral to the tonsillar capsule before piercing the pharyngeal wall (8.97); from this vessel severe venous haemorrhage from the upper angle of the tonsillar sinus may complicate tonsillectomy (Browne 1928). The muscular wall of the tonsillar sinus separates the tonsil from the ascending palatine artery and occasionally from the facial artery itself (p. 736), which, if very tortuous, may be extremely near the pharyngeal wall at the lower tonsillar level. The internal carotid artery is 25 mm posterolateral to the tonsil.

The tonsils are part of a protective annulus of lymphoid tissue (*Waldeyer's ring*). Its antero-inferior part is formed by the lingual tonsil; lateral are the palatine and tubal tonsils, and posterosuperior the pharyngeal tonsil (p. 1324). Minor lymphoid masses exist between these major groups.

Surface Anatomy. The palatine tonsil lies behind the third lower molar tooth and is represented by an oval area over the lower part of the masseter, a little anterosuperior to the mandibular angle.

Structure. The tonsillar crypts are lined by stratified squamous epithelium, continuous with that of the pharyngeal mucosa and invaded by numerous lymphocytes, some of which less enter the mouth and form salivary corpuscles. The tonsillar lymphoid tissue is arranged in nodules or follicles, in the centres of which less close-packed lymphocytes form *germinal centres* (p. 822) of proliferation. The crypts may contain caseous plugs of lymphocytes, bacteria and desquamated epithelium which are gradually eliminated or may become calcified; the bacteria may cause local or general infection. Unlike lymph nodes, there are no lymph sinuses (p. 824) and the tonsil has no *afferent* vessels; but a dense plexus of vessels surrounds each follicle and from it *efferent* vessels pass to the upper deep cervical lymph nodes, especially the jugulodigastric group (p. 843). This and the other lymphoid masses of Waldeyer's ring belong to the category of *mucosa-associated lymphoid tissue* (see p. 832) which provides humoral and cellular defence against infections of the oral and nasal cavities and pharynx and related areas of the alimentary and respiratory tracts.

Vessels and nerves. The main *artery* is the tonsillar branch of the facial. It may also receive rami from dorsal lingual branches of the lingual artery, the ascending palatine branch of the facial, the ascending pharyngeal artery and the greater palatine branch of the maxillary. One or more *veins* leave the inferior deep aspect of the tonsil, traversing the superior constrictor to join the external palatine ('paratonsillar'), pharyngeal or facial veins. Its *nerves* are from the pterygopalatine ganglion via the lesser palatine and from the glossopharyngeal nerve which, by its tympanic branch, also supplies the mucosa of the tympanic cavity; hence tonsillitis may cause pain referred to the ear.



8.99 The buccinator and the muscles of the pharynx.

THE LARYNGEAL PART OF THE PHARYNX

The laryngeal part of the pharynx (laryngopharynx) extends from the cranial border of the epiglottis to the inferior border of the cricoid cartilage, where it becomes continuous with the oesophagus. In its incomplete anterior wall is the laryngeal inlet (p. 1253) and below this the posterior surfaces of the arytenoid and cricoid cartilages. A small *piriform fossa* on each side of the inlet is bounded medially by the aryepiglottic fold and laterally by the thyroid cartilage and thyrohyoid membrane. Beneath its mucous membrane are the branches of the internal laryngeal nerve which have pierced the thyrohyoid membrane. Foreign bodies may lodge in the fossa and, if the mucous membrane is pierced during their removal, the nerve may be damaged, with consequent anaesthesia of the region. Posteriorly the laryngopharynx extends from the lower part of the third cervical vertebral body to the upper part of the sixth.

STRUCTURE OF THE PHARYNX

The pharynx is described as having, from within outwards, mucous, fibrous and muscular laminae and finally a thin buccopharyngeal fascia external to the constrictor muscles and passing forwards over the pterygomandibular raphe on to the buccinator.

8.100 Median sagittal section of the head, showing a dissection of the interior of the pharynx, after the removal of the mucous membrane. The bodies of the cervical vertebrae have been removed and the cut posterior wall of the pharynx then retracted dorsolaterally. The palatopharyngeus is drawn dorsally to show the cranial fibres of the inferior constrictor; the dorsum of the tongue is drawn ventrally to display a part of the styloglossus in the angular interval between the mandibular and the lingual fibres of origin of the superior constrictor.

The *mucous membrane* is continued into the auditory tubes, nasal cavity, mouth and larynx. Its nasopharyngeal epithelium is ciliated, pseudostratified 'respiratory' epithelium containing goblet cells and receiving submucous glands; in the oro- and laryngopharynx it is non-keratinized stratified squamous. Between the two regions is a narrow transitional zone of cuboidal epithelium, the cilia being imperfect or absent. Superiorly, this zone adjoins the nasal septum; laterally it passes over the auditory tube orifices and turns posteriorly at the union of the soft palate and the lateral wall (pp. 1289, 1327, 1328). Mucous glands are numerous around the auditory tube orifices.

The intermediate *fibrous* layer is thick above (*pharyngobasilar fascia*), where muscular fibres are absent, and is firmly connected to the basilar occipital and petrous temporal bones medial to the carotid canal, curving under the auditory tube and forwards to the posterior border of the medial pterygoid plate and pterygomandibular raphe. As it descends it diminishes in thickness but is strengthened posteriorly by a fibrous band, attached to the occipital's pharyngeal tubercle and descending as the median *pharyngeal raphe* of the constrictors. The pharyngeal muscles are described as external to this fibrous lamina, but really it is the thick, deep epimysial covering of the muscles, the thinner external epimysium being the *buccopharyngeal fascia*. The *muscular coat* is described below.

Pharyngeal Musculature

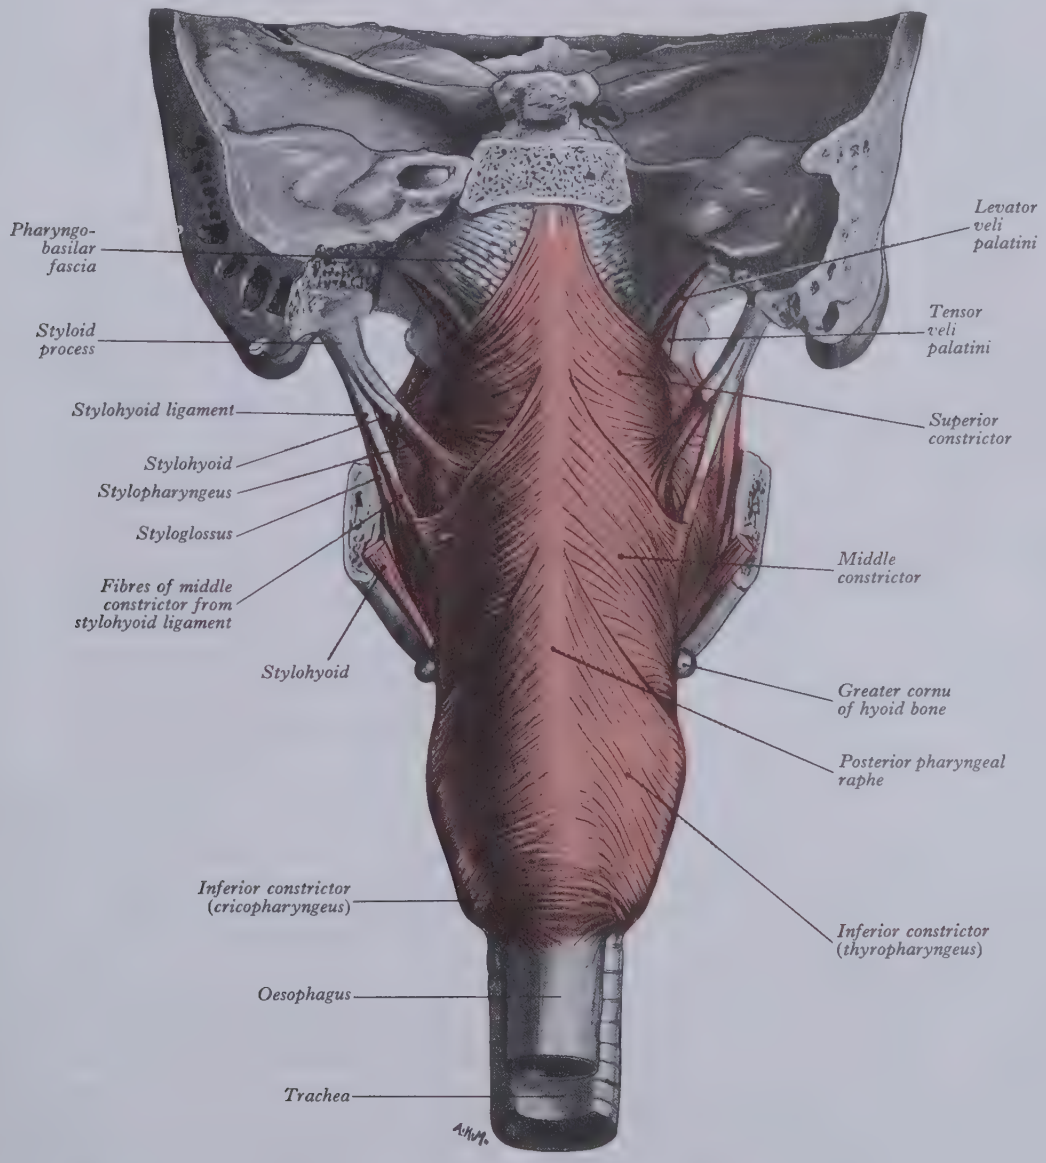
This consists of: three *constrictor* muscles, superior, middle and inferior, and a trio of muscles descending from the styloid process, the cartilaginous torus of the auditory tube, and the soft palate, respectively the *stylo-*, *salpingo-* and *palatopharyngei*, passing obliquely into the muscular wall. Palatopharyngeus is described on p. 1290.

The inferior pharyngeal constrictor, the thickest of the constrictors, has two parts, the cricopharyngeus and the thyropharyngeus. It is attached to (**8.99**) the side of the cricoid cartilage between the attachment of cricothyroid and, posteriorly, the articular facet for the inferior thyroid cornu (*cricopharyngeus*). It also arises: from the oblique line of the thyroid lamina, from a strip of the lamina behind this, from a fine tendinous band crossing cricothyroid from the inferior thyroid tubercle to the cricoid cartilage and, by a small slip, from the inferior cornu (*thyropharyngeus*). Both parts spread posteromedially to join the opposite muscle in the median pharyngeal raphe. The inferior fibres, which are horizontal, blend with the circular oesophageal fibres round the narrowest part of the pharynx; the rest ascend obliquely and overlap the middle constrictor. During swallowing the cricopharyngeus is 'sphincteric' (Fuller et al 1959) and the thyropharyngeus 'propulsive'; failure of relaxation of the cricopharyngeus may cause posterior mucosal herniation between the two parts of the muscle (Killian's dehiscence).

Relations. Buccopharyngeal fascia is external to the inferior constrictor. *Posterior* are the prevertebral fascia and muscles, *lateral* the thyroid gland, common carotid artery and the sternothyroid, *internal* are the middle constrictor, stylopharyngeus, palatopharyngeus and the fibrous lamina. The internal laryngeal nerve and laryngeal branch of the superior thyroid artery reach the thyrohyoid membrane between the inferior and middle constrictors. The external laryngeal nerve descends on the superficial surface of the muscle, just behind its thyroid attachment and piercing its lower part. The recurrent laryngeal nerve and the laryngeal branch of the inferior thyroid artery ascend internal to its lower border to enter the larynx.

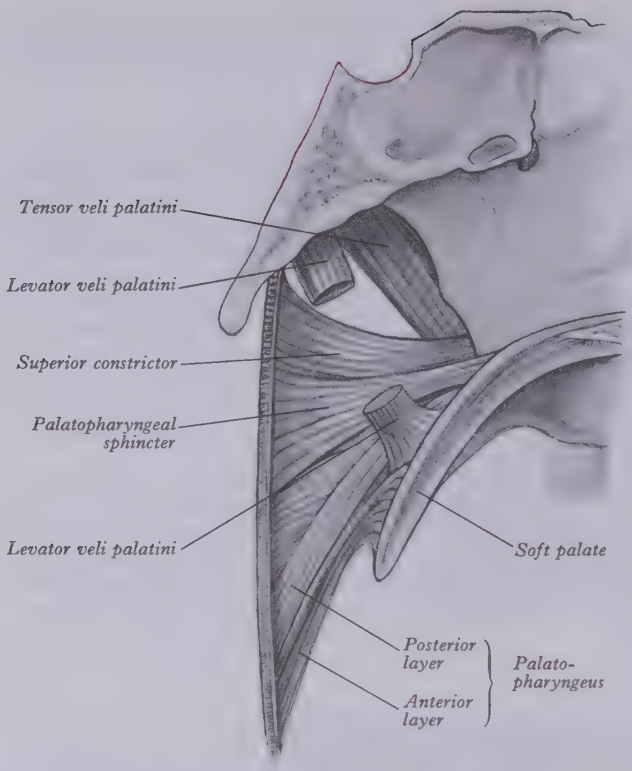
The middle constrictor is a fan-shaped sheet attached anteriorly to the lesser hyoid cornu and the lower part of the stylohyoid ligament (the *chondropharyngeal* part of the muscle) and to the whole upper border of the greater cornu of the hyoid (the *ceratopharyngeal* part). Inferior fibres descend internal to the inferior constrictor to the lower end of the pharynx, middle fibres pass transversely and superior fibres ascend and overlap the superior constrictor. It is inserted posteriorly into the median pharyngeal raphe with its opposite fellow.

Relations. Between the middle and superior constrictors pass the glossopharyngeal nerve and the stylopharyngeus muscle and between the middle and inferior constrictors pass the internal laryngeal nerve and laryngeal branch of the superior thyroid artery. *Posterior* are the prevertebral fascia, longus colli and longus capitis; *lateral* are the carotid vessels, pharyngeal plexus of nerves and some lymph nodes. Near its hyoid attachment the constrictor is deep to the hyoglossus, the lingual artery lying between them.



Internal are the superior constrictor, stylopharyngeus, palatopharyngeus and the fibrous lamina.

The superior constrictor is a quadrilateral sheet, thinner and paler than the others. It is attached anteriorly to the pterygoid hamulus (and sometimes to the adjoining posterior margin of the medial pterygoid plate), the pterygomandibular raphe, the posterior end of the mylohyoid line of the mandible and by a few fibres to the side of the tongue (**8**.100). These attachments differentiate *pterygopharyngeal, buccopharyngeal, mylopharyngeal* and *glossopharyngeal* parts of the superior constrictor. Its fibres curve back into the median pharyngeal raphe; some are also prolonged by an aponeurosis to the pharyngeal tubercle on the basilar part of the occipital bone, the superior fibres curving under levator veli palatini and the auditory tube and leaving an interval below the cranial base for passage of the auditory tube. This interval is limited anteriorly by the medial pterygoid plate and closed by the pharyngobasilar fascia (p. 1326).



A constant band of muscle sweeps backwards from the anterolateral part of the upper surface of the palatine aponeurosis, lateral to levator veli palatini, to blend internally with the superior constrictor near its superior border (**8**.102); this band is the *palatopharyngeal sphincter* and it ridges the pharyngeal wall (*ridge of Passavant*) visibly when the soft palate is elevated (Whillis 1930). It is hypertrophied in cases of complete cleft palate. The change from columnar, ciliated, 'respiratory' epithelium to stratified, squamous epithelium on the superior palatal aspect occurs at the attachment of the palatopharyngeal sphincter to the palate.

Relations. *External* to the superior constrictor are the prevertebral fascia and muscles, the ascending pharyngeal artery and the pharyngeal venous plexus, glossopharyngeal and lingual nerves, styloglossus, middle constrictor, medial pterygoid, stylohyoid ligament and stylopharyngeus; the internal carotid artery, sympathetic trunk, hypoglossal nerve, interal jugular vein and styloid process are more distant relations. *Internal* are the palatopharyngeus, the tonsillar capsule and pharyngobasilar fascia. *Superiorly* it is separated from the cranial base by a crescentic interval containing the levator veli palatini, tensor veli palatini and the auditory tube. *Inferiorly* its border is separated from the middle constrictor by stylopharyngeus and the glossopharyngeal nerve. *Anteriorly* it is separated from buccinator by the pterygomandibular raphe.

Nerve supply. The constrictors are supplied by the *pharyngeal plexus* (p. 1117), the inferior also by rami of the external and recurrent laryngeal nerves. The pharynx is largely a branchial derivative (p.227), hence its motor and sensory supply is through the trigeminal, glossopharyngeal and vagus nerves. Additionally, glandular tissue in pharyngeal mucosa and vascular non-striated

muscle receive an autonomic supply through the pharyngeal plexus. Postganglionic sympathetic fibres reach this plexus from the superior cervical ganglion via specific rami; the preganglionic parasympathetic issue from the medulla oblongata, chiefly in the glossopharyngeal nerve, which also contains afferents from the oral and laryngeal mucosae, the nasal mucosa being trigeminal territory. The vagus nerve carries branchial efferent fibres for pharyngeal striated musculature but most of these fibres probably emerge from the brain stem in the bulbar part of the accessory nerve.

Pharyngeal rami of the glossopharyngeal and vagus nerves and of the superior cervical ganglion form a plexus in the connective tissue external to the constrictors, particularly the intermediate muscle (Hovelacque 1927). From the plexus, in which autonomic (sympathetic and parasympathetic) and branchial (efferent and afferent) fibres intermingle, mixed rami ascend and descend exterior to the superior and inferior constrictors, branching into the muscular layer and mucosa. This pattern is common to most primates (Sprague 1944), including mankind; but in some lower primates the plexus is absent or simplified and may lack glossopharyngeal or vagal components. In other mammals arrangements vary; in many there is no plexus, but precise information on the main supply rami and their exact brain-stem sources is lacking. The marked development of the plexus in man and some other primates has been ascribed to phonation; perhaps this is too facile a view, considering the lack of factual evidence.

Actions. The constrictors exercise a general sphincteric and peristaltic action in swallowing. For details, vide infra.

The stylopharyngeus (**8**.94,100), is a long slender muscle, cylindrical above and flat below. It arises from the medial side of the base of the styloid process, descending along the side of the pharynx and passing between the superior and middle constrictors to spread out beneath the mucous membrane. Some fibres merge into the constrictors and the lateral glosso-epiglottic fold, others are attached with palatopharyngeus to the posterior border of the thyroid cartilage. The glossopharyngeal nerve curves round the posterior border and the lateral side of stylopharyngeus, passing between the superior and middle constrictors to the tongue.

Nerve supply: a branch of the glossopharyngeal nerve.

Action: elevation of the pharynx in swallowing and speech (vide infra).

The salpingopharyngeus (**8**.100) arises from the inferior part of the cartilage of the auditory tube near the tube's pharyngeal opening to pass downwards and blend with palatopharyngeus.

Nerve supply: the pharyngeal plexus.

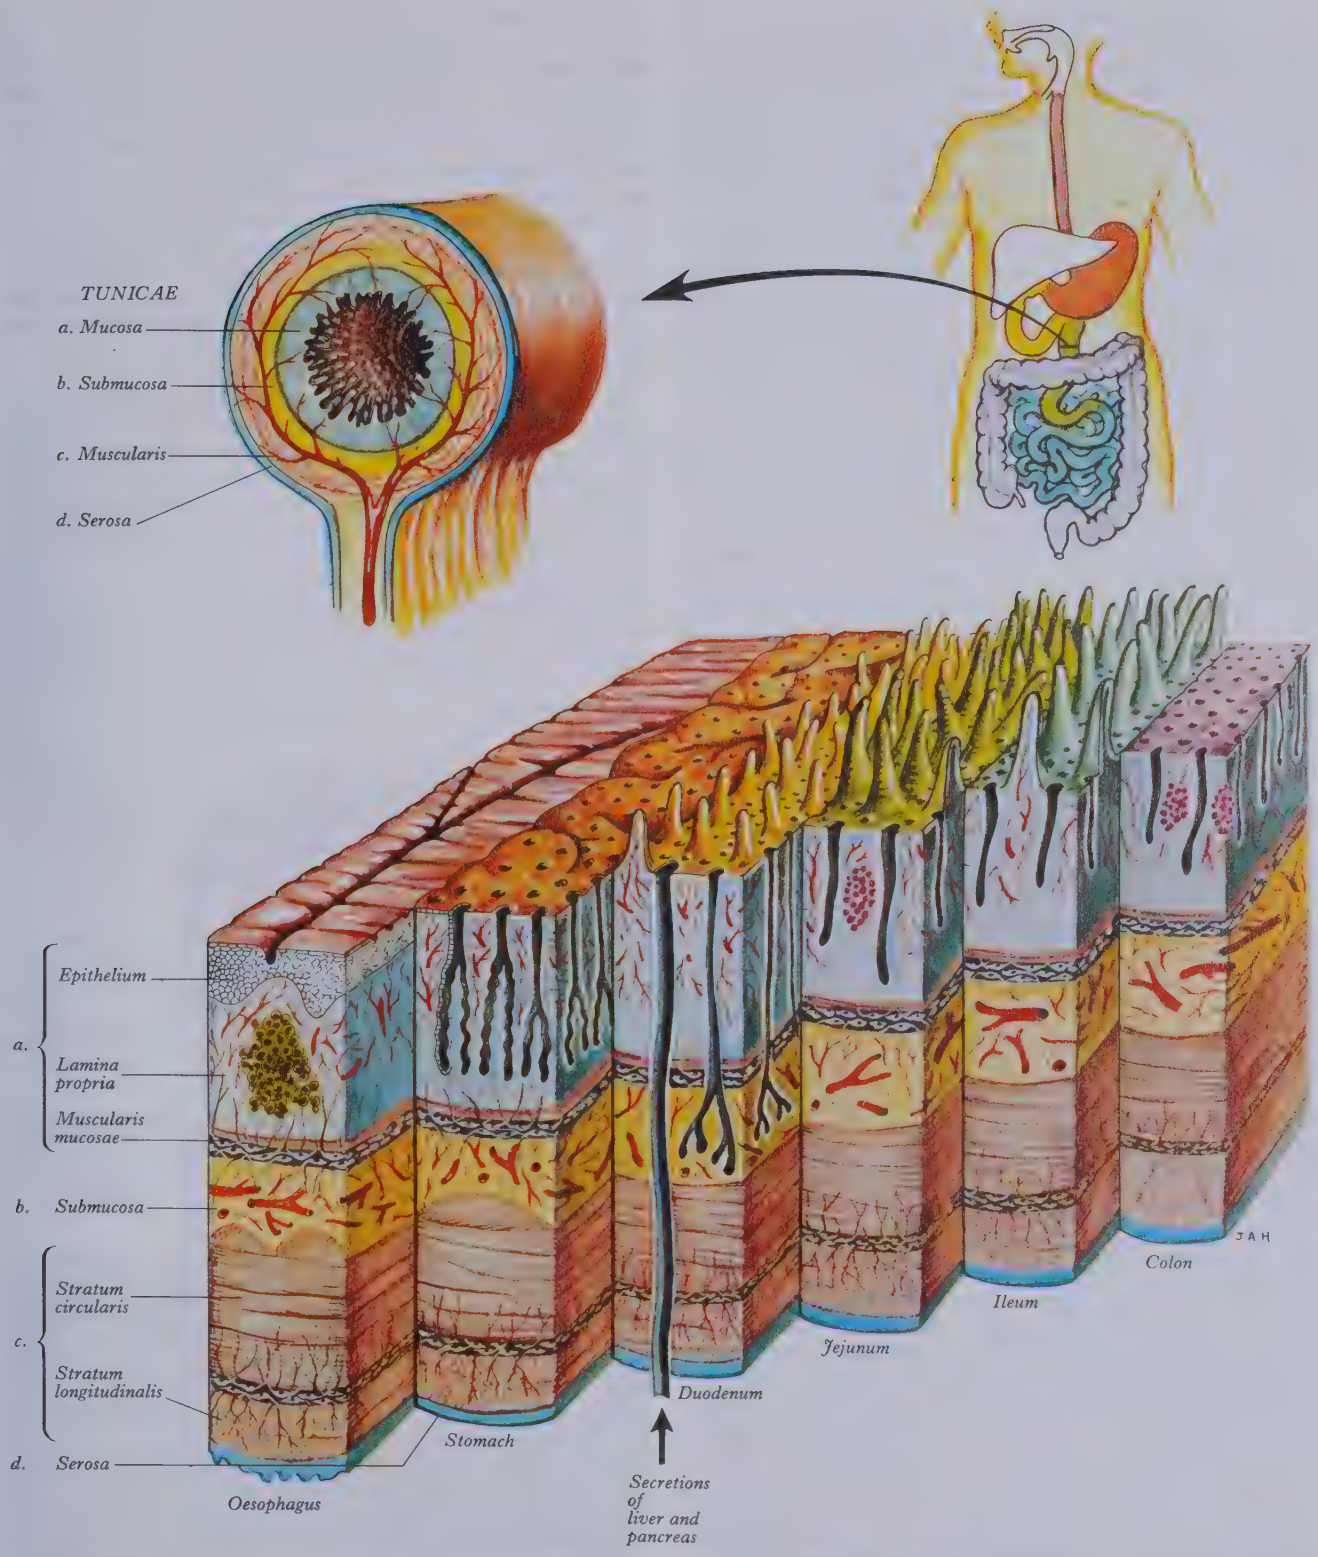
Action: elevation of the upper lateral pharyngeal wall, i.e. the part above the attachment of stylopharyngeus. For its role in swallowing, see below.

Vessels and Nerves

The *pharyngeal arterial supply* is from the ascending pharyngeal, ascending palatine and tonsillar rami of the facial artery, rami of the maxillary artery (greater palatine, pharyngeal and artery of the pterygoid canal) and dorsal lingual rami of the lingual artery. The *veins* form a plexus connected above with the pterygoid plexus and draining below into the internal jugular and facial veins.

The *lymph vessels* are described on pp. 844, 855.

The *nerve supply* is mainly from the pharyngeal plexus (p. 1117). The principal *motor* element is the cranial part of the accessory nerve, which, through vagal branches, supplies all pharyngeal and palatal muscles except stylopharyngeus (glossopharyngeal nerve) and tensor veli palatini (mandibular nerve). The main *sensory* nerves are the glossopharyngeal and vagal; much nasopharyngeal mucosa is supplied by the maxillary nerve (via the pterygopalatine ganglion); mucosa of the soft palate and tonsil is supplied by the lesser palatine and glossopharyngeal nerves. Proprioceptor endings have not been convincingly identified in the pharynx (Bossy & Vidić 1967).



PALATINE MOVEMENTS

Movements of the palate are essential to swallowing, blowing and speech; all require variable degrees of closure of the pharyngeal isthmus (p. 1323). Closure is maximal in oral blowing to prevent the escape of air through the nose. In deglutition closure prevents regurgitation into the nasopharynx. In speech closure is maximal in the production of explosive consonants (e.g. *b,p*). Closure of the isthmus is effected as follows: the levatores veli palatini pull the soft palate up and back towards the posterior pharyngeal wall, while simultaneously the palatopharyngeal sphincter raises the wall to meet the palatine nasopharyngeal surface over a wide area. (It is at the upper limit of this contact area that the epithelium on the upper surface of the soft palate changes from respiratory to stratified squamous.)

The palatal tensors are active in deglutition rather than speech; by producing a localized anterior depression in the soft palate (p. 1329) they squeeze the bolus against the tongue, aiding its descent in the oropharynx.

MECHANISM OF DEGLUTITION

The *first stage* of swallowing is *voluntary*: the anterior part of the tongue is raised and pressed against the hard palate, the movement commencing at the lingual apex and spreading rapidly back. A bolus, formed behind the apex, is thus pushed posteriorly. At the end of this stage the soft palate descends on to the lingual dorsum, helping to grip the bolus. Lingual movements are effected by the intrinsic muscles, especially the superior longitudinal and transverse. Simultaneously the hyoid bone is moved up and forwards by the geniohyoid, mylohyoid, digastric and stylohyoid. The postsulcal part of the tongue is drawn up and back by the styloglossi and the palatoglossal arches are approximated by the palatoglossi, pushing the bolus through the oropharyngeal isthmus into the oropharynx, where the second, *involuntary*, stage begins. In swallowing fluids, the intrinsic lingual muscles squirt liquid backwards in the mouth, after which mylohyoid contraction bulges the lingual base into the oropharynx. In swallowing solids only the mylohyoid action is needed, except in cleansing the mouth of saliva and debris after a bolus is swallowed (Whillis

8.103 The general arrangement of the alimentary canal, its mural tunicae and (below) the general histology at the levels indicated (highly diagrammatic). The transverse colon (above right) has been displaced downwards to reveal the duodenum.

1946). Hiiemae et al (1978) analysed lingual and hyoid activity in swallowing, using the cat and the opossum as models. By cineradiography and electromyography they described the cyclic activities of hyoid muscles (p. 541), delineating 'envelopes' of movement. They regard lingual movements as largely transportive, the precise combination of lingual and hyoid movements depending on the nature of the ingested material. The extension of these studies to primates is awaited with interest.

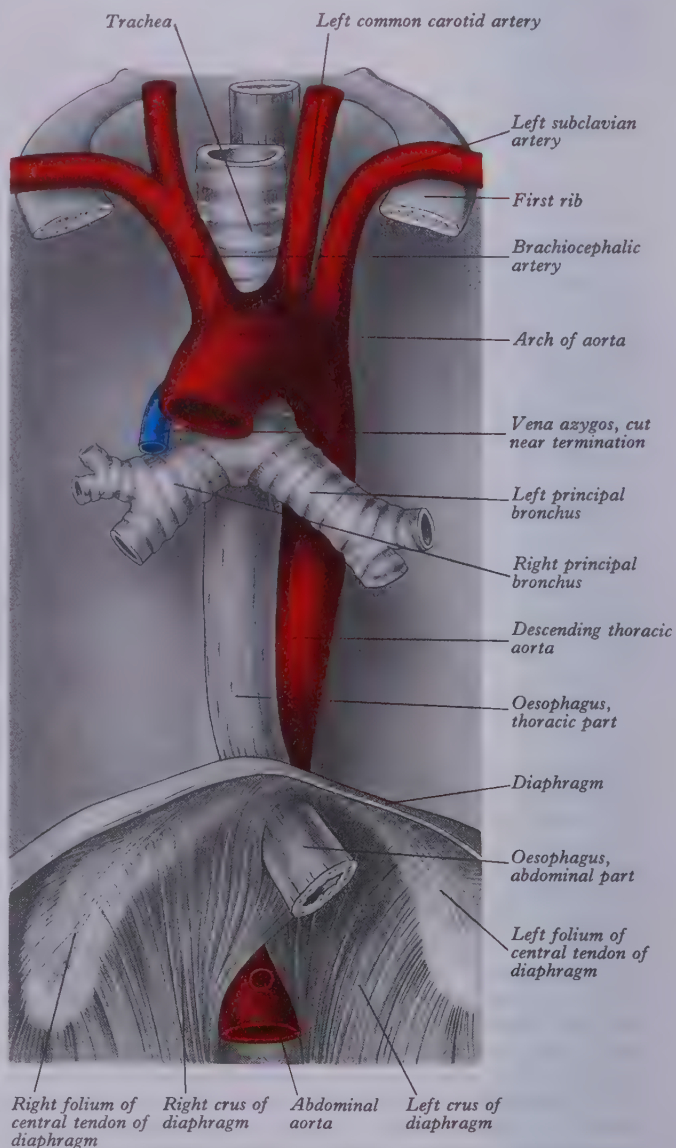
In the *second stage*, the soft palate is elevated (by levator muscles), tightened (tensor muscles) and firmly approximated to the posterior pharyngeal wall by the palatopharyngeal sphincter (p. 1290) and the upper part of the superior constrictor. The pharyngeal isthmus closes tightly to prevent food from ascending into the nasopharynx. Meanwhile the larynx and the pharynx are drawn up, behind the hyoid bone, by the stylopharyngeus, salpingopharyngeus, thyrohyoid and palatopharyngeus muscles. Simultaneously the aryepiglottic folds are approximated and the arytenoid cartilages drawn up and forwards by the aryepiglottic, oblique arytenoid and thyro-arytenoid muscles, excluding the bolus from the larynx. Partly by gravity and partly by successive

contractions of superior and middle constrictors, the bolus slips over the epiglottis (now bent back on to the laryngeal aditus), the closed laryngeal inlet and posterior arytenoid surfaces into the lowest part of the pharynx. Its passage is facilitated by the palatopharyngei, which shorten the pharynx by elevating it; on contraction, they make the posterior pharyngeal wall into an inclined plane directed postero-inferior and under this the bolus descends. The aryepiglottic folds provide lateral channels leading from the sides of the epiglottis through the piriform fossae into the oesophagus. They are kept tense and vertical by the backward pull of the posterior crico-arytenoids on the arytenoid cartilages and by the muscles (aryepiglottic and thyro-epiglottic) within them, assisted by the cuneiform cartilages which act as passive props. In paralysis of these muscles (which are supplied by the recurrent laryngeal nerves) the laryngeal inlet is not closed in swallowing, the folds sink medially and fluids tend to enter the larynx.

The *last stage* in swallowing is the expulsion, by the inferior constrictors, of the now compressed bolus into the oesophagus (p. 1326). The pump-like action of the pharyngeal muscles in this activity has been described by Buthitaya et al (1987).

These stages follow on each other, but it is easy to ascertain by palpation of the hyoid bone and laryngeal prominence that, during swallowing, elevation and forward movement of the hyoid precede laryngeal elevation. Note that the thyroid cartilage, and hence the whole larynx, ascends also *relative* to the hyoid, shortening the larynx and causing structures between the hyoid bone and thyroid cartilage to bulge posteriorly into the larynx above the vestibular folds. This also increases the curvature of the epiglottis, especially in its lower part, aiding stenosis of the laryngeal aditus during swallowing (see Fink & Martin 1977).

The evidence for the foregoing analysis is not mere hypothecation from muscular geometry but has been adduced from radiological studies, the effects of known paralyses, electromyography, ultrasound analysis (Shawker 1984) and cineradiography. Swallowing is, however, a highly complex neuromuscular integration and disagreement over details persists. For full critiques of the literature consult Bosma (1957), Doty (1968), Hiiemae (1978), Buthitaya et al (1987).



Applied Anatomy. In young children lymphoid hypertrophy in the nose and nasopharynx (adenoids), with or without enlargement of the palatine tonsils, may obstruct nasal respiration. The mouth has to be kept open to breathe: the hard palate and alveolar arch are then habitually out of contact with the lingual dorsum and, lacking this pressure, they develop an abnormally high arch and forward projection. The hard palate becomes transversely narrow and projecting alveolar processes afford little room for permanent teeth, which are crowded and irregular and overhang the lower teeth. The facial maxillary surfaces appear pinched together, with narrowing of the nasal cavities and maxillary air sinuses. The upper lip is drawn up, exposing the projecting upper incisors. The face is lengthened by dropping of the lower jaw. The child's expression ('adenoid facies') is characteristic, suggesting vacuity and inattention, the latter being partly due to deafness often associated with nasal obstruction and due to blockage of the pharyngeal openings of the auditory tubes.

General Alimentary Organization

Despite structural variations along the alimentary tract, there is a common basic plan which is best appreciated by reference to development (p. 100). Much of the alimentary canal develops initially as a tube of endoderm enveloped in the splanchnopleuric mesoderm, its external surface facing the intra-embryonic coelom. The endodermal lining forms the epithelium of the tract and also the secretory and ductual cells of various glands secreting into the lumen, including the pancreas and liver. The surrounding splanchnopleuric mesoderm forms the connective tissue, muscle layers, blood vessels and lymphatics of the wall, its external surface becoming visceral mesothelium; this is of course absent throughout the neck and thorax and where the hindgut traverses the pelvic floor. The disposition and development of the dorsal and ventral mesenteries of the subdiaphragmatic foregut and of the dorsal mesentery of the midgut and hindgut have been described (p. 232). Associated neural elements invade the gut from neighbouring neural crest tissue (p. 199). Cranially, the skeletal muscle of branchial arch origin and caudally of less certain origin, contribute to the musculature of the gut's extremities.

The mature gut wall (**8**.103) is a series of layers; arranged from inside outwards as follows: (1) *epithelium*, (2) *lamina propria*, (3) *muscularis mucosae*, which with (1) and (2) constitutes the *mucosa*, (4) *submucosa*, (5) *muscularis externa*, the main muscle coat, and (6) *serosa*, or *visceral peritoneum*. In the pharynx and most of the oesophagus, the serosa is replaced by a dense connective tissue *adventitia*, blending with the fascial planes of adjacent structures (**8**.103). Mesenteries carry blood vessels, autonomic nerves and lymphatic channels to and from the gut and accompany the ducts of outlying glands.

The epithelium is the region of interaction between the body and ingested food. Its cytology varies with its regional functions: in the pharynx, oesophagus and distal anal canal it is a non-keratinizing, stratified, squamous epithelium which protects the underlying tissue and facilitates passage of material by lubricant secretions. Elsewhere the epithelium is simple, composed largely of secretory cells, providing mucus, enzymes and various ions, and of columnar absorptive cells, with striated or brush borders. The total amount of secretion and absorption depends partly on the epithelial surface area, which is increased by the presence of large folds, villi, crypts and glands. Some glands lie in the lamina

8.104A Dissection to expose the oesophagus in the posterior mediastinum and in the abdomen.

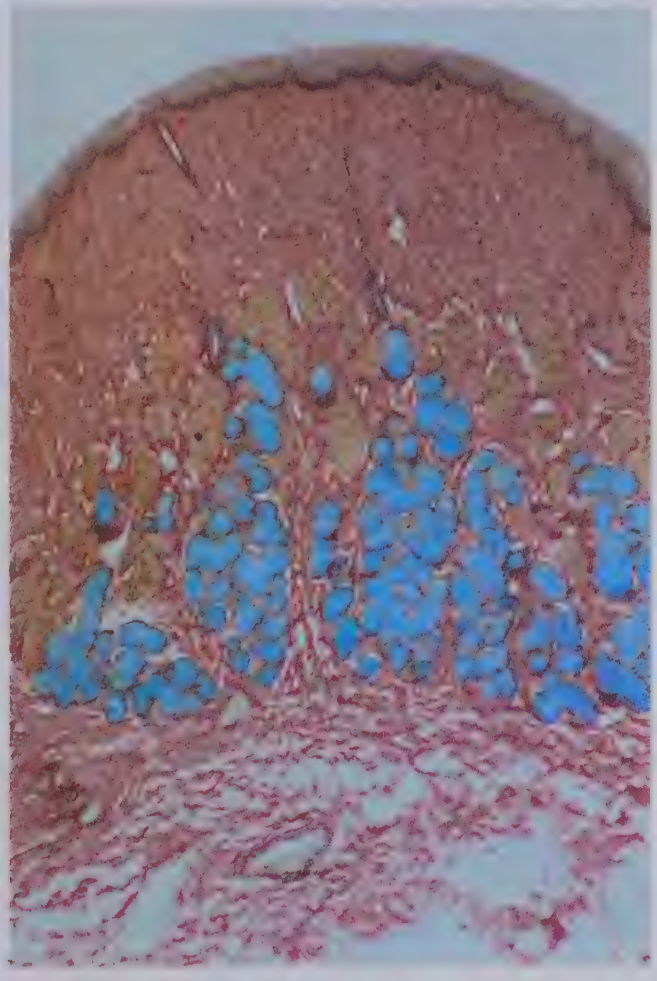
propria, some in the submucosa and some completely outside the tract, e.g. the liver and pancreas. Their secretions also maintain the correct environment for optimal activity of digestive enzymes; they are usually under neural or hormonal control.

The lamina propria is made of compact connective tissue, often rich in elastin fibres, which supports the epithelium; on its external aspect is the **muscularis mucosae**, a plexus of non-striated muscle fibres which can alter the local conformation of the mucosa by contraction of its inner circular and outer longitudinal layers.

The submucosa is rich in blood vessels, lymphatics and nerves; variations in thickness create macroscopic folds on the inner aspect of the gut, particularly in the small intestine.

The muscularis externa usually consists of distinct inner circular and outer longitudinal layers, the antagonistic activities of which create waves of peristalsis responsible for movement of ingested material through the lumen of the gut. In the stomach, where movements are more complex, there is a partial oblique layer, internal to the other two layers. The muscularis externa is chiefly non-striated muscle, except where striated muscle of the upper oesophagus and anal canal blend with it. Its layers are separated by connective tissue containing vascular and nervous plexuses. Some controversy has existed over the direction of fibres in the layers of the muscularis externa, one suggestion being that the inner circular muscle is a tight helix and the longitudinal one an open spiral (Carey 1921). Other observations (Elsen & Arey 1966) on various mammals, including man, indicated that, despite some deviations from precisely circular and longitudinal directions, fibres do not follow spiral pathways. In the human small intestine adjacent 'rings' of circular muscle are often connected by oblique slips, with some interchange between muscle groups (Schofield 1968).

The neural element consists of three plexuses: between the circular and longitudinal layers of the external muscle (*myenteric* or Auerbach's plexus), between the submucosa and external muscle (*submucosal* or *Meissner's plexus*) and a third associated with the muscularis mucosae (*mucosal plexus*). All three are interconnected. The first two contain scattered autonomic ganglion cells, whereas the mucosal plexus appears to be derived from the submucosal plexus. The epithelium is also innervated from the mucosal plexus; several types of sensory cells have been described (see **8**.142 and pp. 1373, 1467).



The Oesophagus

The oesophagus (**8**.101, 104, 105), a muscular tube about 25 cm (10 in.) long, connects the pharynx to the stomach. It begins in the neck, level with the lower cricoid border and the sixth cervical vertebra; descending largely anterior to the vertebral column through the superior and posterior mediastina, it traverses the diaphragm, level with the tenth thoracic vertebra, and ends at the gastric cardiac orifice level with the eleventh thoracic vertebra. Generally vertical, it has two shallow curves. At its beginning it is median but inclines to the left as far as the root of the neck, gradually returns to the median plane near the fifth thoracic vertebra, and at the seventh deviates left again, finally turning anterior to traverse the diaphragm at the tenth. The tube also bends in an anteroposterior plane to follow the cervical and thoracic curvatures of the vertebral column. It is the narrowest part of the alimentary tract, except for the vermiform appendix, and is constricted (1) at its commencement, 15 cm (6 in.) from the incisor teeth, (2) where crossed by the aortic arch, 22.5 cm (9 in.) from the incisor teeth, (3) where crossed by the left principal bronchus, 27.5 cm (11 in.) from the incisors, and (4) as it traverses the diaphragm, 40 cm (16 in.) from the incisors. These data are important clinically with regard to the passage of instruments along the oesophagus.

The cervical part is *anterior* to the trachea and attached to it by areolar tissue; the recurrent laryngeal nerves ascend on each side in or near the groove between the trachea and the oesophagus; *posterior* are the vertebral column, longus colli and prevertebral layer of deep cervical fascia; *lateral* on each side are the common carotid artery and posterior part of the thyroid gland. In the lower neck, where the oesophagus deviates left, it is closer

8.104B A low-power micrograph of a vertical section through the wall of a human oesophagus taken in the upper thorax. Visible in this section are: the epithelium (blue-grey on the right), the lamina propria, muscularis mucosae, submucosa with a group of mucous glands, the external muscle with the circular fibres more deeply placed and the longitudinal fibres placed externally. See text for further description. Mallory's triple stain. Magnification × 6. Prepared by W Owen, Department of Anatomy, Guy's Hospital Medical School, London.

8.104C Low magnification light micrograph of a section of the oesophagus showing the stratified squamous non-keratinized epithelium lining it and mucous glands (stained turquoise) of the submucosa. Weigert and Van Gieson, with alcian blue. Prepared by David Ristow; photographed by Marina Morris, Department of Anatomy, Guy's Hospital Medical School, London.

8.105 An oblique radiograph of the thorax during the oesophageal transit of part of a 'meal' of barium sulphate paste. At (A) the translucency of the air-containing right principal bronchus is visible. The concave ventral aspect of the oesophagus (B) is topographically related to the pericardium covering the left atrium of the heart. Longitudinal mucosal folds are visible (C) immediately proximal to the soft tissue shadow of the diaphragm (D). Some barium sulphate is already admixed with the gastric contents (E). The oesophagus in the lower thorax curves ventrally away from the vertebral column to reach the oesophageal orifice in the diaphragm.

to the left carotid sheath and thyroid gland than it is on the right. The thoracic duct ascends for a short distance along its left side.

The thoracic part (**8**.18, 19, 29, 30, 104A), at first a little to the left in the *superior mediastinum* between the trachea and the vertebral column, passes behind and to the right of the aortic arch to descend in the posterior mediastinum along the right side of the descending thoracic aorta. Below, as it inclines left, it crosses anterior to the aorta to enter the abdomen through the diaphragm at the level of the tenth thoracic vertebra. *Anterior* (from above downwards) are: the trachea, right pulmonary artery, left principal bronchus, pericardium (separating it from the left atrium) and the diaphragm; *posterior* are the vertebral column, longus colli muscles, right posterior (aortic) intercostal arteries, thoracic duct, azygos vein and the terminal parts of the hemiazygos and accessory hemiazygos veins and, near the diaphragm, the aorta. In the posterior mediastinum there is a long recess of the right pleural sac between the oesophagus in front and the vena azygos and vertebral column behind. *Left lateral*, in the superior mediastinum, are the end of the aortic arch, the left subclavian artery, thoracic duct, the left pleura and the left recurrent laryngeal nerve which ascends in or near the groove between the oesophagus and trachea. In the *posterior mediastinum* it is related to the descending thoracic aorta and left pleura. *Right lateral* are the right pleura, the azygos vein intervening as it arches forwards above the right principal bronchus to join the superior vena cava. Below the pulmonary roots the vagus nerves descend in contact with it, the right chiefly behind and the left in front, uniting to form an oesophageal plexus around it (pp.1118, 1125). Low in the *posterior mediastinum* the thoracic duct is behind and to the right; higher, it is posterior, crossing to the left at about the level of the fifth thoracic vertebra and then ascending on the left. On the right of the oesophagus, just above the diaphragm, a small serous *infracardiac bursa* may occur, representing the detached apex of the right pneumato-enteric recess (p. 233).

The abdominal part, emerging from the right diaphragmatic crus (p. 592), slightly left of the midline and level with the tenth thoracic vertebra, grooves the posterior surface of the left lobe of the liver. It forms a truncated cone, 1.25 cm long, curving sharply left (**8**.104A), its base continuous with the gastric cardiac orifice; its right side continues smoothly into the lesser curvature, while the left is separated from the gastric fundus by the cardiac notch (**8**.120). Covered by peritoneum on its front and left side, it is contained in the upper left part of the lesser omentum; the peritoneum reflected from its posterior surface to the diaphragm is part of the gastrophrenic ligament (p. 1340), through which oesophageal branches of the left gastric vessels reach it. Posterior are the left crus and left inferior phrenic artery. The vagus nerves vary in relation as the oesophagus traverses the diaphragm (Doubilet et al 1948). Sometimes one trunk (mainly of left vagal fibres) is anterior and another (mainly right vagal fibres) is posterior; but each vagus may consist of two or three trunks at this level.

Structure (**8**.104A,B). Oesophageal structure follows the general pattern of the adventitious (serosal below the level of the diaphragm), muscular, submucous and mucous layers, the last adjoining the lumen. The *fibrous adventitia* is irregular, dense connective tissue with many elastin fibres. Its fibres also penetrate and surround the fasciculi of muscle in the deeper layers.

The *muscular layer* (muscularis externa) has the usual outer longitudinal and inner circular strata, here particularly thick. The *longitudinal fibres* surround almost the whole length of the oesophagus with a continuous coat; but posterosuperiorly, 3–4 cm below the cricoid cartilage, they diverge as two fasciculi ascending obliquely to the front of the tube, where they pass deep to the lower border of the inferior constrictor to end in a tendon attached to the upper part of the ridge on the back of the cricoid lamina (**8**.14). The V-shaped interval between these fasciculi is filled by circular fibres of the oesophagus, thinly covered below by some decussating longitudinal fibres and above by the overlapping inferior constrictor. The longitudinal layer is generally thicker than the circular. *Accessory slips* of non-striated muscle sometimes pass between the oesophagus and left pleura or the root of the left principal bronchus, trachea, pericardium or aorta. These are sometimes considered to fix the oesophagus to these

structures. Superiorly the *circular fibres* are continuous behind with the inferior constrictor; in front, the uppermost are attached to the lateral margins of the tendon of the two longitudinal fasciculi. Inferiorly, they are continuous with the oblique gastric fibres. Skeletal muscle is limited to the upper two-thirds of the muscularis externa in the human oesophagus; the lower third contains only non-striated. In the upper quarter both layers are skeletal; in the second non-striated muscle appears, at first internally and below this it gradually replaces the skeletal muscle.

Whitmore (1982), using primate (including human) material, has identified 'fast' and 'slow' twitch fibres in oesophageal muscle; he also observed that the striated musculature gave way to non-striated more gradually and proximally in primates than in rodents.

Radiological studies show that swallowed food stops momentarily in the gastric end of the oesophagus, before entering the stomach (**8**.105). A sphincteric mechanism, capable of contraction and relaxation, must be present at the oesophagogastric junction. Vaithilingham et al (1984) have emphatically described a sphincter muscle with a rich innervation in macaque monkeys. However, failure to identify aggregations of muscle for the control of entry into the stomach or regurgitation in man, has lead to the vague phrase, 'a physiological cardiac sphincter'. The frequency of pathological disturbances of this sphincteric control has exacerbated the controversy (see Bombeck et al 1944, Botha 1962, DiDio & Anderson 1968, Code 1968). Various factors have been invoked to explain the undoubted sphincteric effect. Circular muscle fibres in both diaphragm and oesophagus near their junction are reinforced by the splitting of the right crus round the oesophagus (p. 593), though this has been denied (Atkinson et al 1957). The phrenico-oesophageal ligament, a layer of connective tissue extending from the inferior diaphragmatic surface across the oesophageal orifice to blend with the interfascicular septa and submucosa of the terminal oesophagus, has also been invoked. The obliquity of this junction, the effects of spiral and longitudinal muscle (Stelzner & Lierse 1967) and various mucosal folds (Creamer 1955), have all been mooted as valvular mechanisms. Hence some *structures* may, alone or collectively, exert '*physiological*' sphincteric control at this site of controversy; however, the actual mechanism is still uncertain (p. 1349).

The *submucosa* loosely connects mucous and muscular layers and contains larger blood vessels, nerves and mucous glands.

The *mucosa*, thick and pink above, pale below, shows longitudinal folds which disappear in distension. It consists of: (1) lining non-keratinizing stratified squamous epithelium, (2) connective tissue, papillae from which project into the epithelium, and (3) non-striated muscularis mucosae. Where the oesophagus begins the muscularis mucosae is absent or represented merely by sparse scattered bundles; below this it is a considerable stratum. At intermediate levels its fascicles are mainly longitudinal but become more plexiform towards the gastro-oesophageal junction, where the stratified squamous epithelium is abruptly succeeded by gastric simple columnar epithelium. The junction is visible as a crenated line, the greyish-pink, smooth, oesophageal mucosa contrasting with the red, mamillated, gastric mucosa.

There are small *oesophageal glands* of compound racemose mucous type in the submucosa external to the muscularis mucosae, each with a long duct traversing it and the other layers of the mucosa. Glands of the abdominal oesophagus resemble gastric cardiac glands and lie between the muscularis mucosae and the lumen (Johns 1952).

Vessels and Nerves

Oesophageal *arteries* come from the inferior thyroid branch of the thyrocervical trunk, descending thoracic aorta, bronchial arteries, left gastric branch of the coeliac artery and left inferior phrenic. Their direction of supply is generally longitudinal. *Veins* from the cervical part drain to the inferior thyroid veins, from the thoracic part into azygos, hemiazygos and accessory hemiazygos veins, and from the abdominal part to the azygos and left gastric vein. The latter is a tributary of the portal vein, this being one of the anastomoses between portal and systemic veins (p. 820). In portal obstruction (e.g. in hepatic cirrhosis), these anastomatic veins may become varicose and burst into the lower oesophagus, leading to haematemesis and even fatal haemorrhage. *Lymph vessels* are described on pp. 821, 850.

The *nerve supply* is parasympathetic (vagal) and sympathetic. The cervical part receives rami from the recurrent laryngeal nerves and from cervical sympathetic trunks (via the plexus around the inferior thyroid artery). The thoracic part is innervated by branches from the vagal trunks and oesophageal plexus, the sympathetic trunks and greater splanchnic nerves. The abdominal part (Mitchell 1938) is supplied by the vagal trunks (anterior and posterior gastric nerves), the thoracic sympathetic trunks, greater (and sometimes lesser) splanchnic nerves and the plexuses around the left gastric and inferior phrenic arteries. These rami form a plexus containing groups of ganglion cells between the two layers of the muscular coat, and a second, submucous, plexus (Semenova 1962). In addition to these, free-ending nerve fibres have been observed in the oesophageal epithelium (Robles-Chillida 1981). Rodrigo et al (1975) have surveyed these plexuses, describing also intraganglionic nerve endings, possibly afferent.

Radiology

In oblique lateral views (**8**.105) the thoracic part of the oesophagus is shown by a barium swallow to be mainly in the 'retrocardiac space'; the entire thoracic part is seen to be near the vertebral column, its lower end inclining forwards. Its anterior wall is indented by the aortic arch, left bronchus and left atrium. A thin layer of the barium contrast medium may outline longitudinal mucosal grooves, producing a striated shadow.

THE ABDOMEN

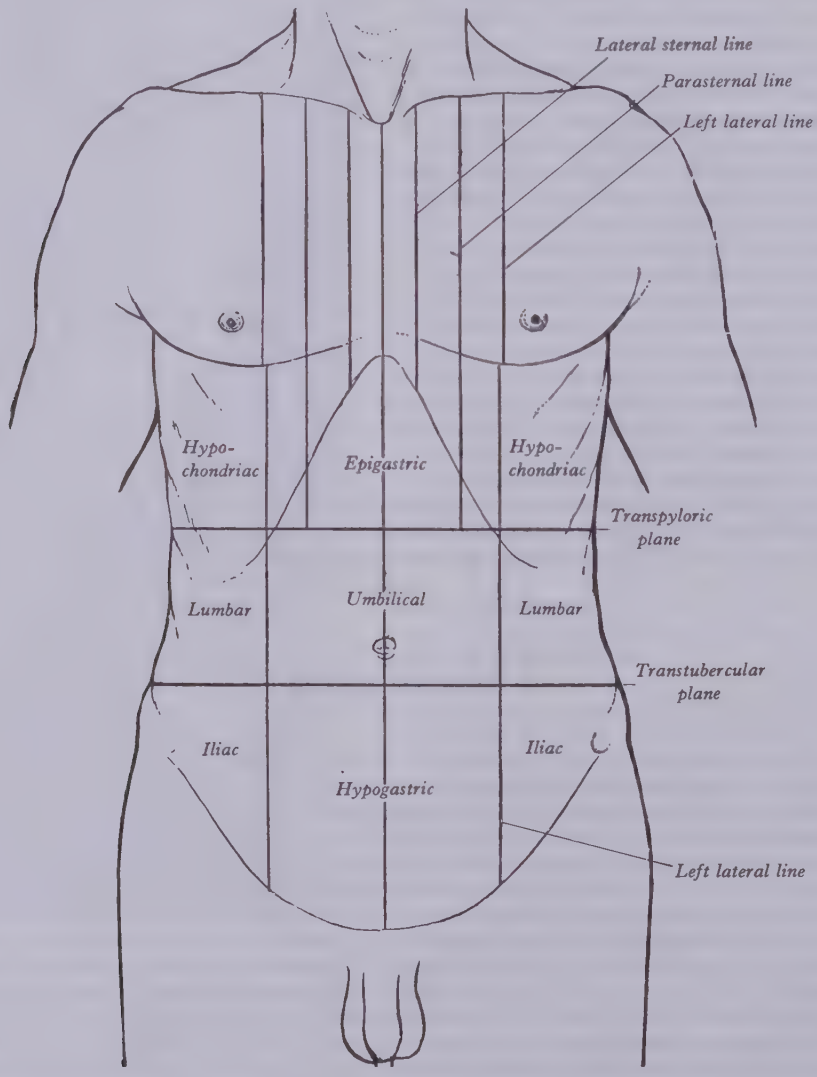
The abdomen extends from the diaphragm to the base of the pelvis (**8**.107), comprising the *abdomen proper* and the *lesser pelvis*, continuous at the plane of the inlet into the lesser pelvis, which is bounded by the sacral promontory, arcuate lines of the innominate bones, pubic crests and the upper border of the symphysis pubis. The abdomen is largely enclosed by muscles, its shape and size varying with degrees of distension of the contained hollow organs and the phases of respiration. Muscular tone is a large factor in maintaining the positions of the abdominal and pelvic viscera (pp. 602, 606).

The *abdomen proper* is bounded: *in front* by the rectus abdominis muscles, the pyramidales and the aponeurotic parts of the obliqui externus, internus and transversus abdominis; *laterally* by the fleshy parts of these flat muscles, the iliacus muscles and iliac bones, *behind* by the lumbar vertebral column, diaphragmatic crura, paired psoas and quadratus lumborum muscles and the posterior parts of the iliac bones; *above* by the diaphragm, while *below* it is continuous with the lesser pelvis through its superior aperture (p. 429). Since the diaphragm, the domed roof of the abdominal cavity, is convex upwards, part of the cavity is within the osseous framework of the thorax (pp. 594–595). The abdomen proper contains most of the digestive tube, liver, pancreas, spleen, kidneys, ureters (in part), suprarenal glands and numerous blood and lymph vessels, lymph nodes and nerves.

The *lesser pelvis* is approximately funnel-shaped, like an inverted, truncated cone; it extends postero-inferiorly from the abdominal cavity proper (**8**.110, **3**.116) and is bounded: *anterolaterally* by the innominate (hip) bones below their pubic crests and arcuate lines, and by the obturatores interni, *posterosuperiorly* by the sacrum, coccyx, piriformes and coccygei; *inferiorly* by the levatores ani which, with their covering fasciae, form the pelvic diaphragm (pp. 604–606), and by the transversi perinei profundi

and sphincter urethrae which, with *their* fascial coverings, constitute the urogenital diaphragm. The lesser pelvis contains: the urinary bladder, terminal parts of the ureters, the sigmoid colon, rectum, some ileal coils, internal genitalia, blood and lymph vessels, lymph nodes and nerves.

The abdominal and pelvic muscles are ensheathed in fascia, which receives regional names from adjacent structures, e.g. on the internal surface of transversus abdominis is the *transversalis fascia* (p. 603), inferior to the diaphragm is the *diaphragmatic fascia*, covering the psoas and iliacus is the *iliac fascia* (p. 604); anterior to the quadratus lumborum is the *anterior layer of the thoracolumbar fascia* (p. 604) and over the muscles in the pelvis is the *pelvic fascia* (p. 604). Most abdominal and pelvic organs are largely covered by a serous membrane, the *visceral peritoneum* (pp. 1336–1343).



ABDOMINAL REGIONS

For the location of viscera in clinical practice, the abdomen is divided into nine regions by imaginary planes, two horizontal and two parasagittal, their edges indicated by lines projected to the surface of the body (**8**.106). The upper, horizontal, *transpyloric plane* (of Addison) is indicated by a line encircling the body midway between the suprasternal notch and the symphysis pubis (or midway between the umbilicus and inferior end of the sternal *body* or a hand's breadth below the xiphisternal joint); it intersects the first lumbar vertebral body near its lower border and meets the costal margins at the tips of the ninth costal cartilages. The lower horizontal, *transtubercular plane* corresponds to a line round the trunk level with the iliac tubercles (**8**.106, pp. 430–431); it cuts the front of the fifth lumbar vertebral body near its upper border. The abdomen is thus divided into three arbitrary zones; each is further subdivided into three by the *right* and *left lateral planes*, indicated on the surface by vertical lines through points midway between the anterior superior iliac spines and the symphysis pubis (these lines are also called 'midclavicular' or 'mammary' lines).

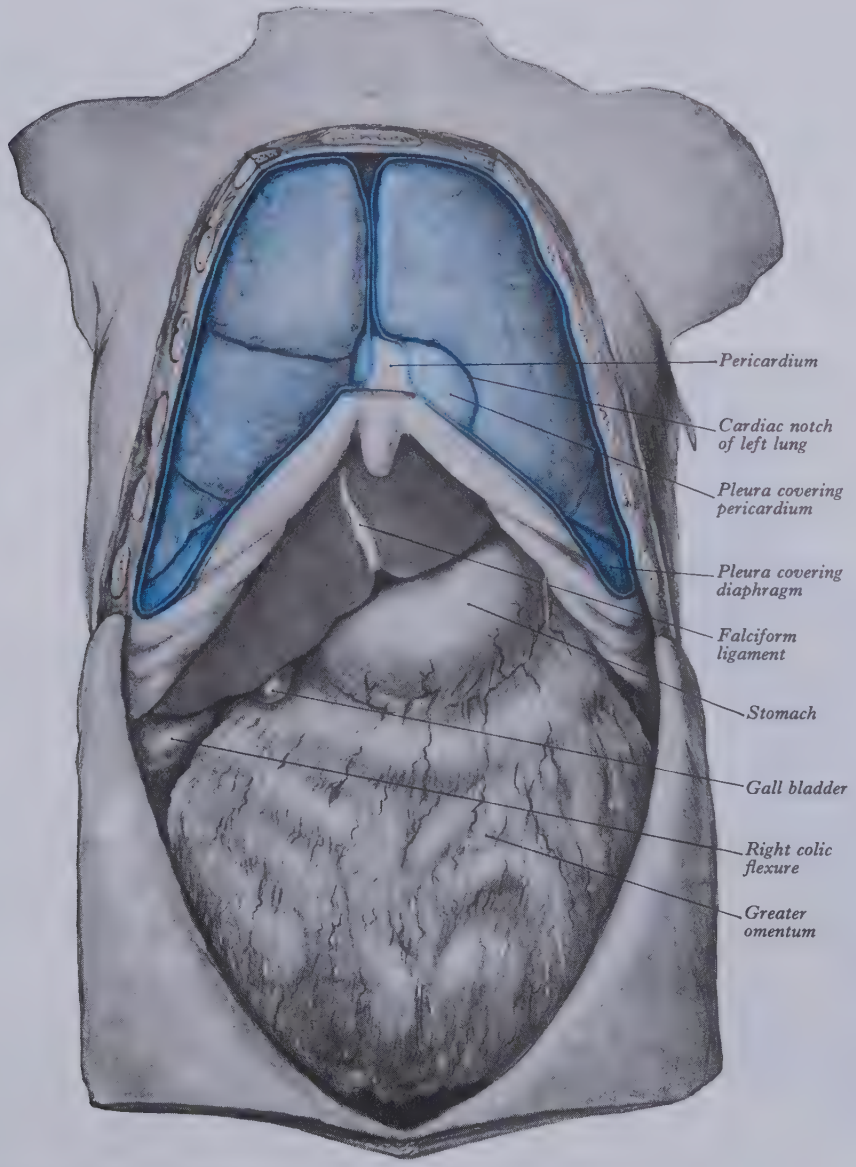
The median upper *epigastric* is flanked by *right* and *left hypochondriac* regions; the median region of the middle zone is the *umbilical* region, flanked by *right* and *left lumbar* or *lateral* regions. The lower median *hypogastric* or *pubic* region is between the *right* and *left iliac* or *inguinal* regions (**8**.106) (see Addison 1899–1901). A third horizontal plane, often used in abdominal topography, the *subcostal plane*, corresponds to a line level with the lowest limits of the tenth costal cartilages. It cuts the front of the third lumbar vertebral body near its upper border. It often replaces the transpyloric plane in descriptions of abdominal regions.

The *umbilicus* is variable in position, being usually level with the disc between the third and fourth lumbar vertebrae in young adults but, as age advances and in conditions of deficient abdominal tone, it sinks lower. It is also lower in children because of the under-developed condition of the pelvic region.

On the body's posterior surface a transverse line between the highest points on the iliac crests and level with the fourth lumbar vertebral spinous process delineates a *supracristal plane*. The fourth spine is a useful landmark in identifying other vertebral spinous processes.

8.106 Reference lines on the anterior aspect of the thorax and abdomen for use in delineating surface projections.

LOCATION OF ABDOMINAL VISCERA



After removal of the anterior abdominal wall (**8**.107), the viscera are partly displayed as follows: above and right is the liver, largely in the shelter of the lower right ribs and cartilages, extending across the midline, where it descends to the transpyloric plane. The stomach is partly exposed in the angle between the left costal margin and the lower hepatic border; from its lower border an apron-like peritoneal fold, the *greater omentum*, descends for a varying distance anterior to the other viscera. Below this, however, some coils of the small intestine are usually visible. In the right iliac region the caecum and, in the left iliac region, the lower part of the descending colon are partly exposed (p. 1368). The urinary bladder, in the anterior part of the pelvis, ascends above the symphysis pubis into the hypogastric region when distended; the rectum is in the sacral concavity, usually hidden by coils of the small intestine. The sigmoid colon may appear between the rectum and the bladder.

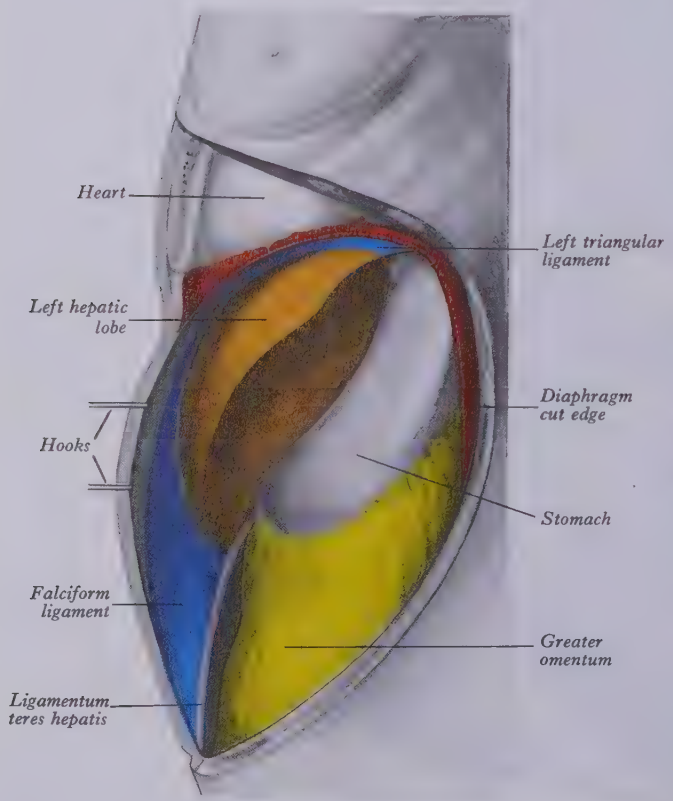
Followed to the right, the stomach is continuous with the *duodenum*, their junction being marked by a thick, palpable *pyloric sphincter*. The duodenum reaches the liver and curves down under its cover. If, however, the greater omentum and the transverse colon behind it are turned up over the chest, the horizontal part of the duodenum can be seen crossing the vertebral column from right to left. The duodenum then ascends to the second lumbar vertebra to become continuous with the coils of the *jejunum* and *ileum*, which are about six metres long (p. 1355) and form the rest of the small intestine. Followed inferiorly, the ileum ends in the right iliac region, opening into the colon at the junction of the *caecum* and *ascending colon*. From the caecum the colon ascends on the right, then loops to the left across the median plane below the liver and stomach and turns downwards; thus it is composed of *ascending*, *transverse* and *descending* parts. In the pelvis it forms a loop, the *sigmoid colon*, ending in the rectum. The *spleen* is posterolateral to the stomach in the left hypochondriac region and is partly exposed by displacing the stomach to the right.

The sheen on the surfaces of the abdominal wall and exposed viscera is due to their covering of *peritoneum*, a serous membrane.

The relations of the organs described here obtain in the recumbent position, but visceral relations depend on posture, respiratory movements and the degree of distension of the the hollow organs. The shapes of chest, abdomen and pelvis also vary, as do organs in the same individual and at different times, depending on physiological activity and mobility. Therefore the surface outlines of viscera, particularly the hollow organs described here, must be regarded as highly variable within wide limits.

In physique, individuals have been classified into two extremes: *hypersthenic* (pyknic) and *asthenic* (leptosomatic) with intermediate grades, *sthenic* and *hyposthenic* (Mills 1917, 1922). In the

8.107 Anterior aspect of the thoracic and abdominal viscera.



hypersthenic, with massive physique, the thorax is wide and short and the subcostal angle very obtuse, so that the heart and lungs are wide transversely; the abdomen is widest superiorly and the stomach less elongated vertically, with the pylorus relatively high; while the transverse colon is more truly transverse. In the asthenic type, with a light and slender physique, the thorax is long and narrow and the subcostal angle acute, so that the heart and lungs are long and narrow; the abdomen is widest inferiorly, the stomach being long with a relatively low pylorus and the colon long with a V-shaped transverse colon descending to the pelvis. Varieties of physique (somatotypes) have also been classified as endomorphic (massive), mesomorphic (intermediate) and ectomorphic (slender) with intermediate grades, each reputed to have predominant psychological characteristics (Sheldon et al 1940, Sheldon & Stevens 1942; see current physical anthropology monographs for details).

THE PERITONEUM

The peritoneum (Brizon et al 1956), the largest and most complexly arranged of the serous membranes, is an empty and intricately folded sac, lining the abdomen and reflected over the viscera. In males it is a closed sac; in females the lateral ends of the uterine tubes open into the sac's potential cavity. Where it lines the abdominal wall (parieties) it is named the *parietal* peritoneum and is reflected over the viscera as the *visceral* peritoneum. Its free surface is covered by a layer of *mesothelium*, kept moist and smooth by a film of serous fluid. Hence mobile viscera glide freely on the abdominal wall and each other within limits dictated by their attachments. Sessile organs are covered by peritoneum wherever they are in contact with mobile viscera.

The peritoneal cavity is a *coelom*—a discontinuity in the mesoderm lined by an epithelium (mesothelium) which maintains the surface. Loss of this mesothelium leads to the adherence of underlying tissues and interference with visceral function, which may be serious and even lethal (p. 1346), providing convincing evidence of an essential function of the serosa, separating of the viscera sufficiently for unimpeded activity. This basic biological arrangement is used to classify all animals as either *Coelomata* or *Acoelomata*.

Many functions are served by coelomic spaces in invertebrates and vertebrates (Jones 1913, Romer 1970). Excretory organs such as nephridia drain fluid and excretory products from a general coelom and vertebrate nephric systems are partly derived from it. As animals evolved to greater size, a coiled gut became essential. Such coiling could not evolve and develop without the emergence of a coelom. In early chordates such as *Amphioxus*, gametes are extruded from the gonads into a coelom and in some early vertebrates this also occurs in both sexes, persisting in the females of later forms, including mankind. Special ducts have evolved to connect the kidneys and testes to the cloaca (and its derivatives) and are in part formed from coelomic epithelium, which is also involved in formation of the gonads themselves (p. 248).

8.108 Dissection to expose the left side of the falciform fold or ligament of the liver.

GENERAL STRUCTURE

A considerable amount of *extraperitoneal connective tissue* separates the parietal peritoneum from the abdominal walls, blending with their fascial lining. Its thickness and content of fat varies in different regions. While parietal peritoneum is generally loosely attached to the abdominal and pelvic walls and so is easily stripped from them, the tissue is denser on the inferior surface of the diaphragm and behind the linea alba, the parietal peritoneum being here more firmly adherent. Its attachment is especially loose in some places to allow alteration in the size of certain organs; e.g. in the pelvis and the adjoining anterior abdominal wall it allows the urinary bladder to distend upwards behind the wall, from which it temporarily strips the peritoneum as it ascends. There is usually much perinephric extraperitoneal fat on the posterior abdominal wall. The visceral peritoneum, in contrast, is firmly united to the underlying tissues and cannot be easily detached; its connective tissue layer (*tela subserosa*) is continuous with the fibrous visceral stroma; and the visceral peritoneum must therefore be considered as part of its viscus, a concept of significance in pathology.

THE PERITONEAL CAVITY

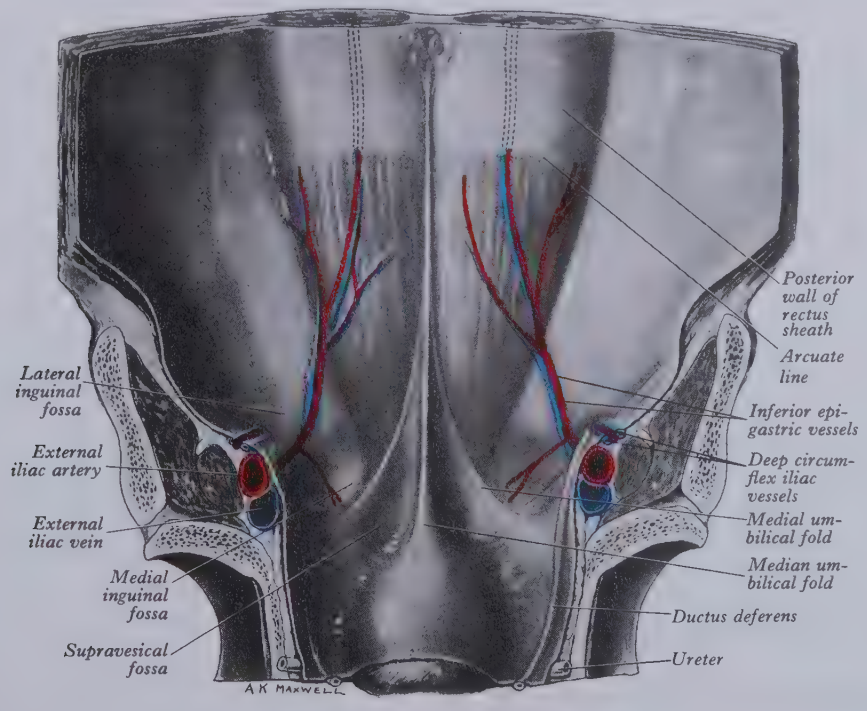
The parietal and visceral layers of peritoneum are in contact, the potential space between them being the *peritoneal cavity*. This consists of: (1) a main region, the *greater sac*, and (2) a diverticulum, the *omental bursa* or *lesser sac* behind the stomach and adjoining structures; the two communicate via the *epiploic foramen* (*aditus to the lesser sac*).

The complex arrangement of the peritoneum can best be rationalized by the study of alimentary development (pp. 232–236) and by examination in cadavers before they are made unnaturally rigid by preservative fluids. To trace it from one viscus to another and from viscera to parieties, it is useful to follow its continuity in vertical and horizontal directions and simpler to describe the greater and lesser sacs separately.

VERTICAL DISPOSITION OF THE PERITONEUM

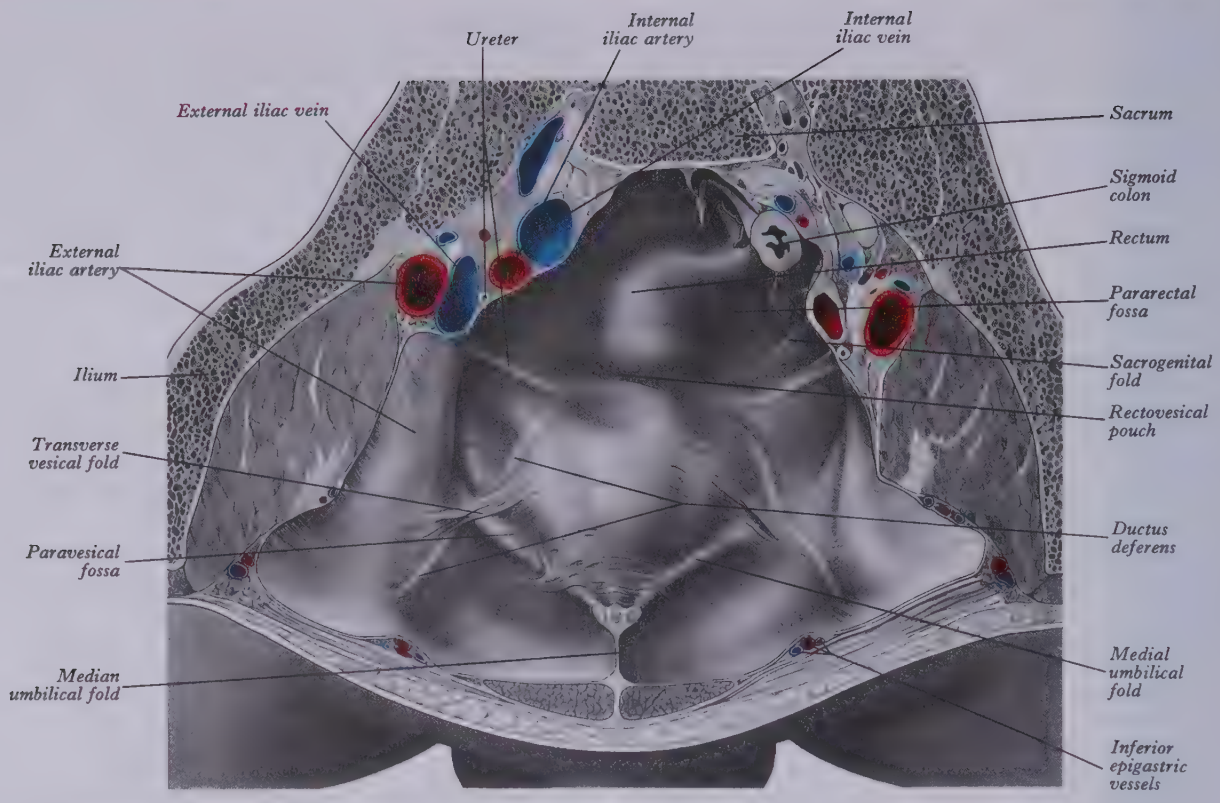
The ensuing descriptions will be more clearly comprehended if frequent reference is made to the development of the alimentary tract (pp. 232–236) and to illustrations, models and dissections.

It is convenient to commence tracing the arrangement of the greater sac in the vertical plane (**8.112**) from the anterior abdominal wall at the umbilical level. A fibrous *ligamentum teres* (*obliterated left umbilical vein*, p. 724) ascends from this to the



inferior surface of the liver, inclining slightly right and receding from the abdominal wall as it ascends, raising a triangular *falciform hepatic ligament* (p. 1388 and **8**.108) of parietal peritoneum from the wall and inferior diaphragmatic surface. The falciform ligament has right and left peritoneal layers with intervening connective tissue (**8**.114A,B). Its juxta-umbilical region has a posterior free border from the umbilicus to the inferior hepatic surface, containing the *ligamentum teres*. Superiorly the falciform ligament extends from the diaphragm to become continuous with the visceral peritoneum on the hepatic anterosuperior surface (**8**.108). At the site of reflexion from the diaphragm to the liver, the two layers diverge (**8**.154), the right passing transversely to the right as the *superior layer of the hepatic coronary ligament* (from the diaphragm to the upper surface of the right hepatic lobe), the left layer passing left as the *anterior layer of the left hepatic triangular ligament* (from the diaphragm to the upper surface of the left hepatic lobe).

The visceral peritoneum on the anterosuperior hepatic surface continues round the sharp inferior hepatic border to the inferior (visceral) surface, where it is arranged as follows: right of the gallbladder it covers the inferior surface of the right lobe of the liver and is reflected posteriorly to the right suprarenal gland and the upper pole of the right kidney, forming the *inferior layer of the coronary ligament*; it often passes direct from the liver to the kidney as the *hepatorenal ligament*. From the right kidney it descends to the front of the first part of the duodenum and right colic flexure; it also passes medially in front of a short segment of the inferior vena cava (between the duodenum and liver), continuing on to the posterior wall of the omental bursa (**8**.113). Between the two layers of the coronary ligament is a large, triangular, posterior area on the right hepatic lobe devoid of peritoneal covering, the *bare area of the liver*, where the liver is attached to the diaphragm by areolar tissue.



Near the right hepatic margin layers of the coronary ligament converge fusing to form the *right triangular ligament* which connects the right hepatic lobe to the diaphragm (**8**.154) and forms the apex of the bare area, the base being the *groove for the inferior vena cava*.

Visceral peritoneum covers the inferior aspect and sides of the gallbladder, the inferior surfaces of the quadrate lobe of the liver as far back as the anterior margin of the porta hepatis and of the left lobe, from whose posterior surface it reaches the diaphragm as the *posterior layer of the left triangular ligament*. Along the anterior margin of the porta hepatis the peritoneum is continuous at its right end with the peritoneum of the omental bursa, the latter being reflected from the posterior portal margin (**8**.154). The visceral peritoneum plunges into the fissure for the ligamentum venosum (**8**.154), between the caudate and left hepatic lobes, in two layers, anterior and posterior. The anterior layer merges with peritoneum reflected from the anterior portal margin (**8**.154). From this L-shaped line, formed by the left margin of the fissure for the ligamentum venosum and the anterior margin of the porta hepatis, peritoneum is reflected to the gastric lesser curvature and approximately the first 2 cm of the duodenum, as the anterior layer of the *lesser omentum*.

The region of lesser omentum connecting liver to stomach is the *hepatogastric ligament*, the part passing from the liver to the duodenum being the *hepatoduodenal ligament*. The anterior layer, traced to the right, passes anterior to the hepatic artery, bile duct and portal vein, turning round their right side to continue behind them into the posterior omental layer, which here forms the anterior surface of the bursa. Thus the lesser omentum has a free right border, in which lie the hepatic artery, bile duct and portal vein; behind this border is the *epiploic foramen* (foramen of Winslow) (**8**.114A). The anterior layer of the lesser omentum is continuous below with the visceral peritoneum of the anterior gastric surface and the first 2 cm of the duodenum. This layer then descends from the greater curvature and neighbouring duodenum to become the most anterior layer of the *greater omentum*. Reaching the lower edge of this large fold, it ascends as its most *posterior* layer, running to the anterosuperior aspect of the transverse colon (at the *taenia omentalis*). It then turns back, adherent to but separable from the *upper* layer of the transverse mesocolon, to the anterior aspect of the head and the anterior border of the body of the pancreas; it leaves the latter as the upper layer of the transverse mesocolon (**8**.112), passing to the posterior surface of the transverse colon (at the *taenia mesocolica*) and covering all but its posterior aspect, returning thence to the pancreatic head and body as the *inferior* layer of the transverse mesocolon. It then descends over the pancreas to the front of the horizontal and ascending parts of the duodenum, from there turning downwards on the posterior abdominal wall. It is also carried forward on the superior mesenteric vessels to the jejenum and ileum as the *right layer of the mesentery*. It invests them and reaches the posterior

8.109 The infra-umbilical part of the anterior abdominal wall of a male subject: posterior surface, with the peritoneum in situ.

8.110 The peritoneum of the male pelvis: anterosuperior view. The median umbilical fold contains both the unpaired median and the paired medial umbilical ligaments in the plane of section in this subject.

abdominal wall as the *left layer of the mesentery*, descending over the abdominal aorta, inferior vena cava, ureters and psoas major muscles into the lesser pelvis. Reflected from the posterior pelvic wall as the *anterior layer of the sigmoid mesocolon*, it encloses the sigmoid colon and returns to the pelvic wall as the *posterior layer* of that mesocolon, descending then to cover the front and sides of the rectum's upper third and the front of its middle third.

In males, the peritoneum leaves the junction of the middle and lower thirds of the rectum, passing forwards to the upper poles of the seminal vesicles and superior aspect of the bladder. Between the rectum and bladder it forms the *rectovesical pouch*, descending slightly below the upper seminal poles to a level about 7.5 cm from the anal orifice. From the apex of the bladder it returns along the median and medial umbilical ligaments (**8**.109) to the anterior abdominal wall and umbilicus. When the bladder distends, the peritoneum is lifted from the lower anterior abdominal wall so that part of the bladder's anterior surface is in *direct* contact with the wall (p. 1416). Instruments can then be passed through the wall into the bladder without traversing the peritoneum.

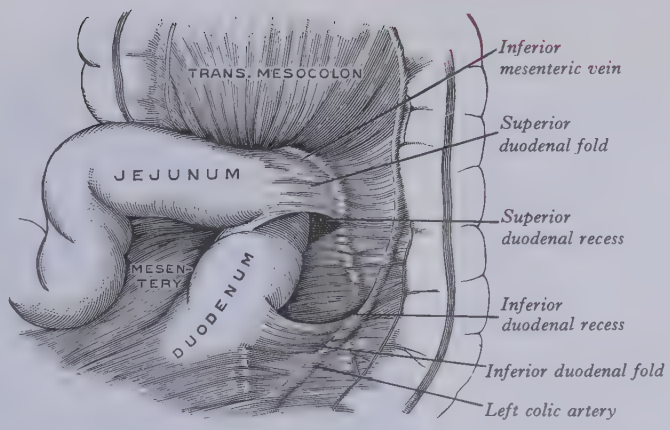
In females, the peritoneum passes from the rectum to the posterior vaginal fornix and then to the back of the uterine cervix and body, as the *recto-uterine fold*, which descends to form the *recto-uterine pouch* (of Douglas), the base of which is only 5.5 cm from the anal orifice. The peritoneum spreads over the uterine fundus to its anterior (vesical) surface as far as the junction of the body and cervix, from which it is reflected forwards to the upper surface of the bladder, forming a shallow *vesico-uterine pouch*. Peritoneum on the anterior and posterior uterine surfaces leaves the organ to reach the lateral pelvic walls as the *broad ligaments of the uterus*, each consisting of antero-inferior and posterosuperior layers continuous at the upper border of the ligament; between them at this border is the uterine tube. Peritoneum is reflected from the bladder to the anterior abdominal wall as in males.

HORIZONTAL DISPOSITION OF THE PERITONEUM

Below the transverse colon the arrangement is simple, but differs at pelvic, lower abdominal and upper abdominal levels.

(1) **In the lesser pelvis**, the peritoneum follows the surfaces of the pelvic viscera and walls, with differences in the sexes. **In males** (**8**.110) it almost encircles the sigmoid colon, passing to the posterior pelvic wall as the *sigmoid mesocolon*. It leaves the sides and finally the front of the rectum, continuing over the upper poles of the seminal vesicles to the bladder; lateral to the rectum it forms right and left *pararectal fossae*, varying with rectal distension, and anteriorly a *rectovesical pouch*, limited laterally by peritoneal folds from the sides of the bladder posteriorly to the anterior aspect of the sacrum, the *sacrogenital folds*, each lateral to its pararectal fossa. Anteriorly it covers the superior surface of the bladder, forming on each side a *paravesical fossa*, limited laterally by a ridge containing the ductus deferens. The size of these fossae depends on the state of the bladder; when it is empty, a variable *transverse vesical* fold bisects each fossa and the anterior ends of the sacrogenital folds may sometimes be joined by a ridge separating a *middle fossa* from the main rectovesical pouch (**8**.110). Between the paravesical and pararectal fossae the only elevations are due to the ureters and internal iliac vessels. **In females**, pararectal and paravesical fossae also appear, the lateral limit of the latter being the peritoneum investing the round ligament of the uterus. The rectovesical pouch is, of course, divided by the uterus and vagina into a small, anterior, vesico-uterine and a deep, posterior, recto-uterine pouch (**8**.209). Marginal recto-uterine folds of the latter (p. 1339) correspond to the sacrogenital folds in males and pass back to the sacrum from the sides of the cervix lateral to the rectum. The *broad ligaments* extend from the sides of the uterus to the lateral pelvic walls, with the uterine tubes contained in their free superior margins and the ovaries attached to their posterior layers. Below, they are continuous with the lateral pelvic parietal peritoneum. Between the elevations over the obliterated umbilical artery and the ureter on the lateral pelvic wall is a shallow *ovarian fossa* containing the ovary in nulliparous females. It lies behind the lateral attachment of the broad ligament.

(2) **In the lower abdomen**, the peritoneum of the lower anterior abdominal wall is raised into five ridges converging upwards (**8**.109). A *median umbilical fold* extends from the apex of the bladder to the umbilicus. It contains the urachus (p. 1417). On



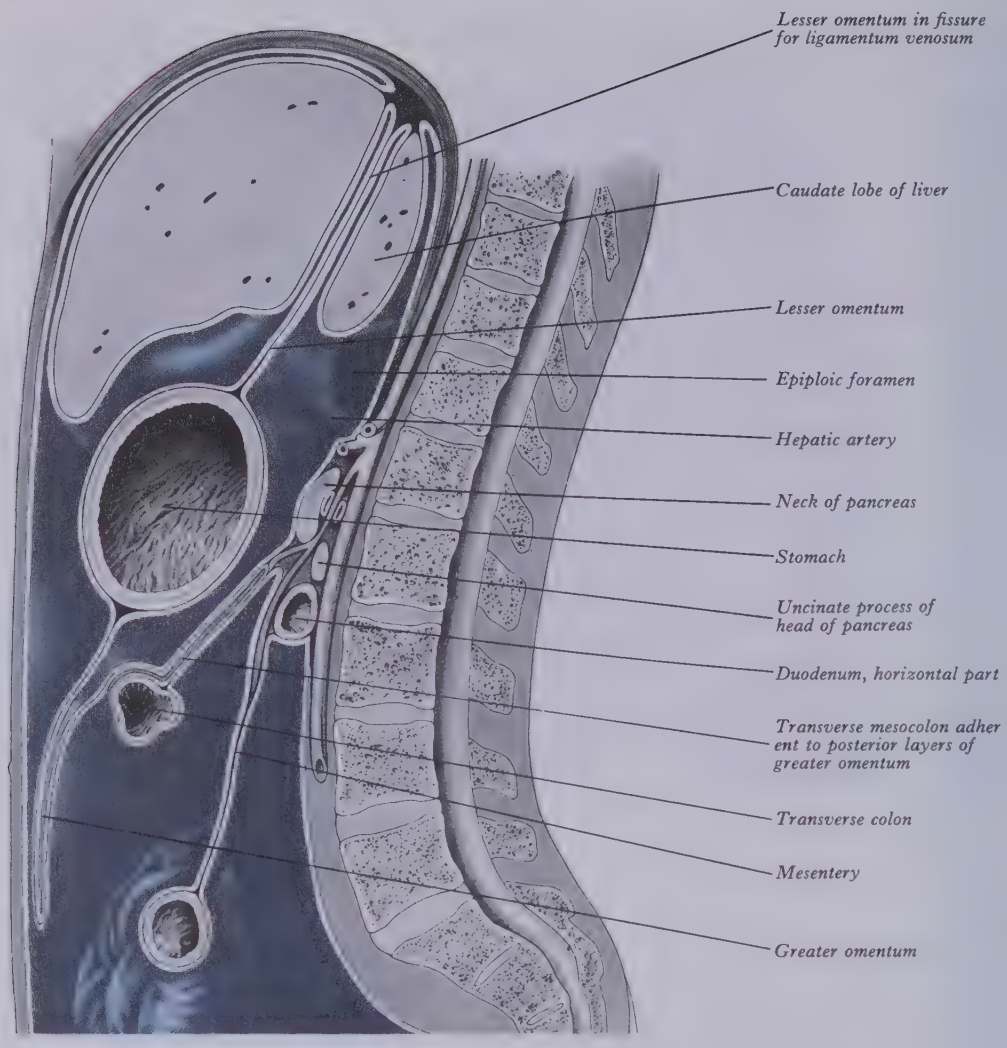
each side of it the obliterated umbilical artery raises a *medial umbilical fold*, ascending from pelvis to umbilicus. Between these three folds are the two *supravesical fossae*. Further laterally each inferior epigastric artery raises a *lateral umbilical fold*, below its entry into the rectus sheath. *Medial inguinal fossae* exist between the lateral and medial umbilical folds. A *lateral inguinal fossa* over the deep inguinal ring is lateral to the lateral umbilical fold and indicates the site of descent of the processus vaginalis and testis into the anterior abdominal wall. A *femoral fossa*, inferomedial to the lateral inguinal and separated from it by the medial end of the inguinal ligament, overlies the femoral ring (p. 781).

From the linea alba, caudal to the level of the transverse colon, the peritoneum, followed horizontally to the right, lines the abdominal wall almost to the lateral border of quadratus lumborum; it is reflected over the sides and front of the ascending colon, enclosing the caecum and vermiform appendix and passing medially over the duodenum, psoas major and inferior vena cava towards the median plane, whence it passes along the superior mesenteric vessels to invest the small intestine and back again to the large vessels anterior to the vertebral column, forming the *mesentery* (**8**.112, 113). This encloses: the jejunum, the ileum, superior mesenteric blood vessels, nerves, lacteals and lymph nodes. The peritoneum then continues left across the abdominal aorta and left psoas major, covering the sides and front of the descending colon, and then returns round the abdominal wall to the midline.

(3) **In the upper abdomen** (**8**.105, 114A), above the transverse colon, the arrangement of the peritoneum in the greater sac is more complex. From the front of the inferior vena cava, just above the first part of the duodenum, it passes *left* behind the epiploic foramen to form the posterior wall of the omental bursa (**8**.114A); it passes *right* over the front of the right suprarenal gland and the upper pole of the right kidney to the anterolateral abdominal wall. From the anterior median line a double fold, the *falciform ligament*, passes back to the right around the liver. To the left the peritoneum lines the anterolateral abdominal wall, covers the lateral part of the left kidney and passes to the splenic hilum as the posterior (lateral) layer of the *splenicorenal* (lienorenal) or *phrenicolienal ligament* (**8**.114A). It then invests the spleen, returning to the front of its hilum and thence to the cardiac end of the greater curvature as the left layer of the *gastrosplenic ligament*. Covering the anterosuperior gastric surface and adjacent duodenum, it ascends from the lesser curvature to the liver as the anterior layer of the lesser omentum, whose right free border has been described (p.1337); this anterior layer of the lesser omentum (peritoneum of the greater sac) continues as the posterior layer of the omental bursa (peritoneum of the omental bursa).

THE OMENTAL BURSA (LESSER SAC)

The omental bursa or lesser sac is a large, irregular, potential recess behind the stomach and beyond its limits. Its name is related to the concept that it forms a bursa (p.563) facilitating movements of the posterior aspect of the stomach. However, it is not closed; its connection with the greater sac is narrowed by embryological rather than functional factors. The stomach expands or contracts just as freely in vertebrates with no special narrow-necked diverticulum. (In any case movements of the *anterior aspect* of the stomach also occur.) The extensive anterior and posterior walls of the 'bursa' are limited by variable borders (right, left, inferior and superior). It is separated from the greater sac except at its upper *right border* where they communicate by a vertical slit, the *epiploic foramen*. Its upper posterior wall is a single peritoneal layer closely applied to the posterior abdominal wall (**8**.112) but below the pancreas its potential cavity projects into the greater omentum, whose posterior wall is formed by two layers which, above the transverse colon, blend with the transverse mesocolon (**8**.112). The greater omentum is traditionally described as having *four* peritoneal layers; but it must be understood that mesothelial peritoneum is lost, except where a true surface persists. Where two separate 'folds' of peritoneum adhere and blend, opposed mesothelia disappear but recognizable layers of subepithelial connective tissue often remain.

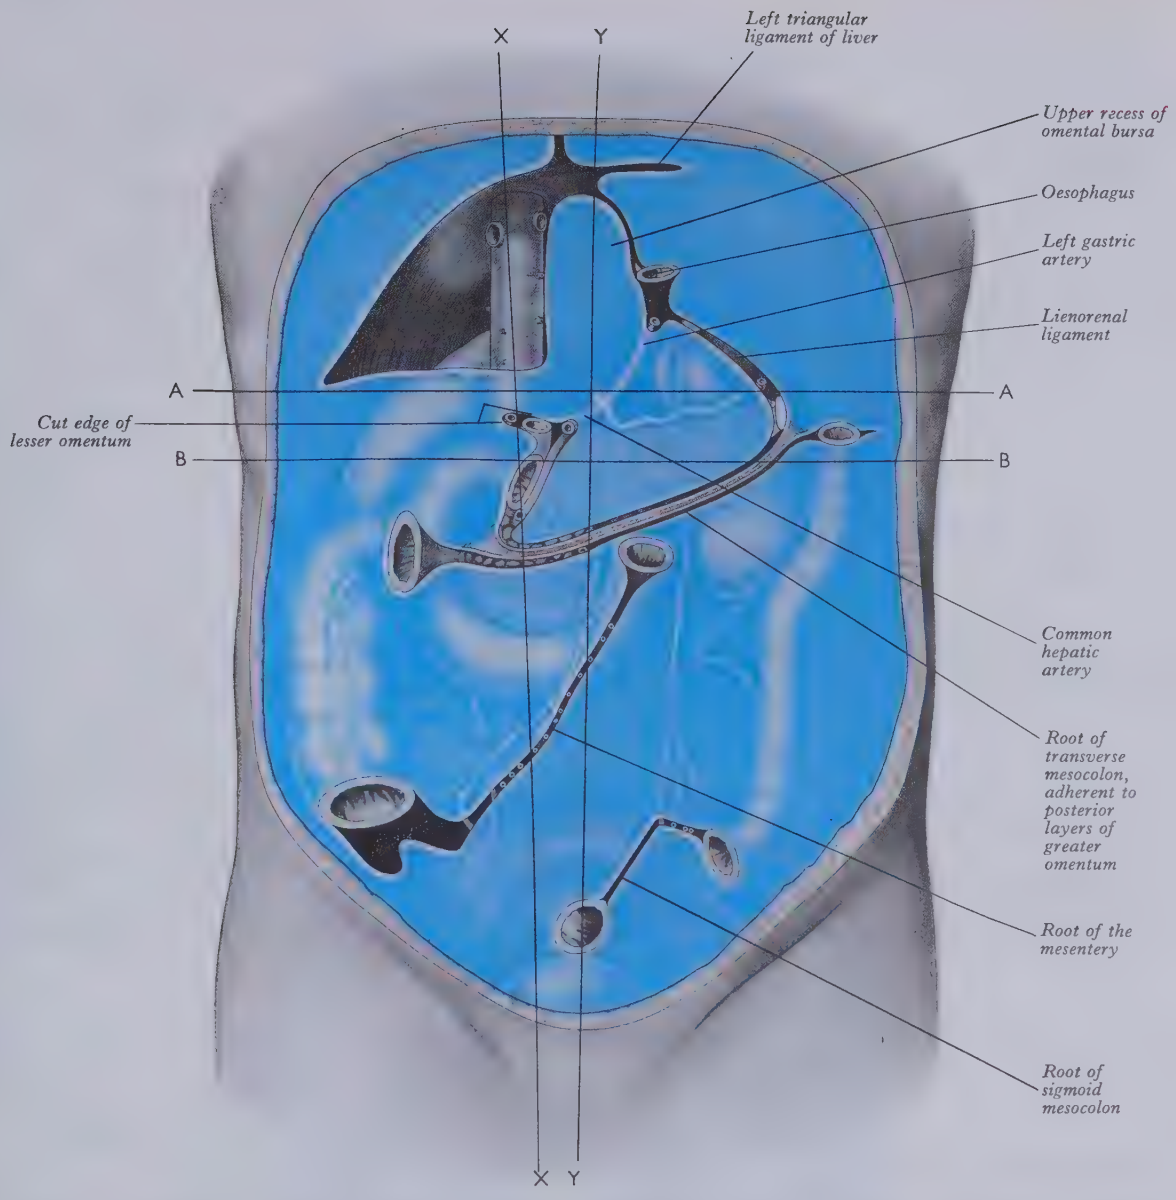


8.111 The superior and inferior duodenal recesses. The transverse colon and jejunum have been displaced (after Jonnesco, from Poirier & Charpy *Traité d'Anatomie humaine*. Masson et Cie).

The epiploic foramen (aditus to the lesser sac), a short, vertical slit of about 3 cm, leads from the upper part of the right border of the lesser into the greater sac, this border forming the foramen's *anterior margin* and containing between its layers the bile duct (on the right), portal vein (posterior) and hepatic artery (left) (**8**.114A). Superiorly the two layers separate, the posterior covering the caudate process of the liver in the *roof* of the foramen (**8**.115) and descending anterior to the inferior vena cava as the foramen's *posterior margin*. At the upper border of the first duodenal segment this layer passes forwards from the inferior vena cava, above the head of the pancreas, into the posterior layer of the lesser omentum, forming the foramen's *floor* which is medially continued down into the right border of the sac (**8**.105). Passing forwards below the medial end of this floor the hepatic artery passes between the two layers of the lesser omentum (**8**.114A). A narrow passage, the *vestibule* of the omental bursa, is left of the foramen between the caudate process and the first part of the duodenum. To the right the rim of the foramen is continuous with the peritoneum of the greater sac: the roof is continuous with the peritoneum on the inferior surface of the right hepatic lobe (**8**.154), the posterior wall with the peritoneum on the right suprarenal gland (**8**.105), its anterior wall with the anterior layer of the lesser omentum round the portal vein and bile duct (**8**.114A), the floor with the peritoneum on the lower part of the right suprarenal gland and on adjacent parts of the duodenum and right kidney (**8**.113). Anterior and posterior walls of the foramen are normally apposed.

The omental bursa has an *anterior wall* formed (1) by peritoneum over the postero-inferior aspect of the stomach and about the first 2 cm of the duodenum, which *descends* to become the posterior of the anterior two layers of (2), the greater omentum, and *ascends* to the right to leave the lesser gastric curvature and duodenum at its upper border, becoming the posterior layer of (3), the lesser omentum. The bursa is often described as ascending *behind* the caudate lobe, but this projects into the bursa from its right border and is covered by peritoneum on both anterior and posterior surfaces (**8**.112,154).

The *posterior wall* is formed by the anterior of two posterior layers of the greater omentum. Above, the posterior of these is fused, but not inseparably, with the upper peritoneum of the transverse colon and mesocolon. Surgical separation of the greater omentum from these provides posterior access to the stomach through the posterior wall of the greater omentum. Dissection where the omentum and transverse colon meet opens up an embryological 'bloodless plane' between vessels of the greater omentum (from the gastro-epiploic) and the middle colic vessels in the transverse mesocolon (Freder 1905, Lardennois & Okinczyc 1913, Grégoire 1922, Ogilvie 1935). There are no anastomoses across this plane. Above the anterior pancreatic border the posterior bursal peritoneum covers the posterior abdominal wall, a small part of the head and the whole neck and body of the pancreas, part of the anterior aspect of the left kidney, most of the left



8.112 Sagittal section through the abdomen, approximately in the median plane. Compare with **8**.113. The section cuts the posterior abdominal wall along the line YY in **8**.113. The peritoneum is shown in blue except along its cut edges, which are left white.

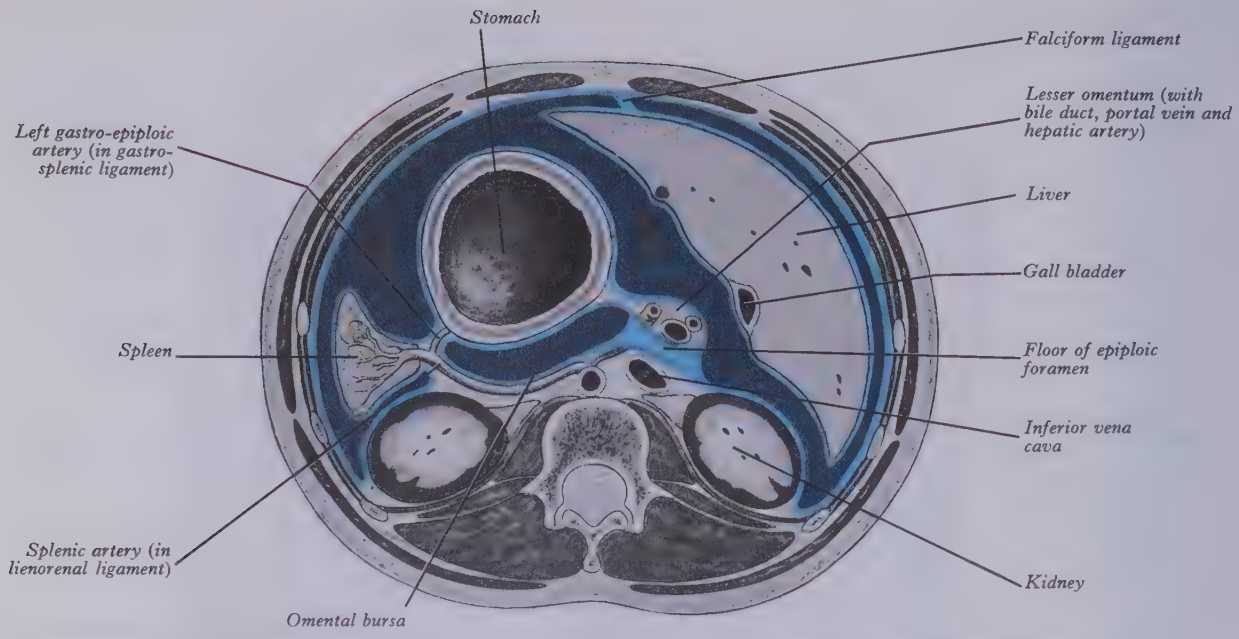
suprarenal gland, the commencement of the abdominal aorta and coeliac artery and part of the diaphragm. The inferior phrenic, splenic, left gastric and hepatic arteries lie partly behind the bursa (**8**.113, 114A).

The *limits of the bursa* are the lines where its posterior peritoneal wall is reflected to be continuous with its anterior; their positions vary somewhat. The *inferior border* is, developmentally (p. 235), the lower limit of the greater omentum; but partial fusion of the latter's layers usually occurs after birth, so that the bursa's *cavity* in adults does not usually extend very far below the transverse colon. The internally apposed peritoneal surfaces lose their mesothelium. The narrow *upper border* is between the right side of the oesophagus and the upper end of the fissure for the ligamentum venosum (**8**.154). Here peritoneum of the posterior omental wall is reflected anteriorly from the diaphragm to join the posterior layer of the lesser omentum.

The *right border* corresponds, below, to that of the greater omentum; above, its upper part is formed by reflexion of the peritoneum from the pancreatic neck and head on to the inferior aspect of the beginning of the duodenum (**8**.114B); the line of this reflexion ascends to the left, along the medial side of the gastroduodenal artery. Near the upper duodenal margin the right border joins the floor of the epiploic foramen round the hepatic artery proper (**8**.113). Above this interruption the border is formed by the reflexion of peritoneum from the diaphragm to the right margin of the liver's caudate lobe and along the left side of the inferior vena cava (**8**.113).

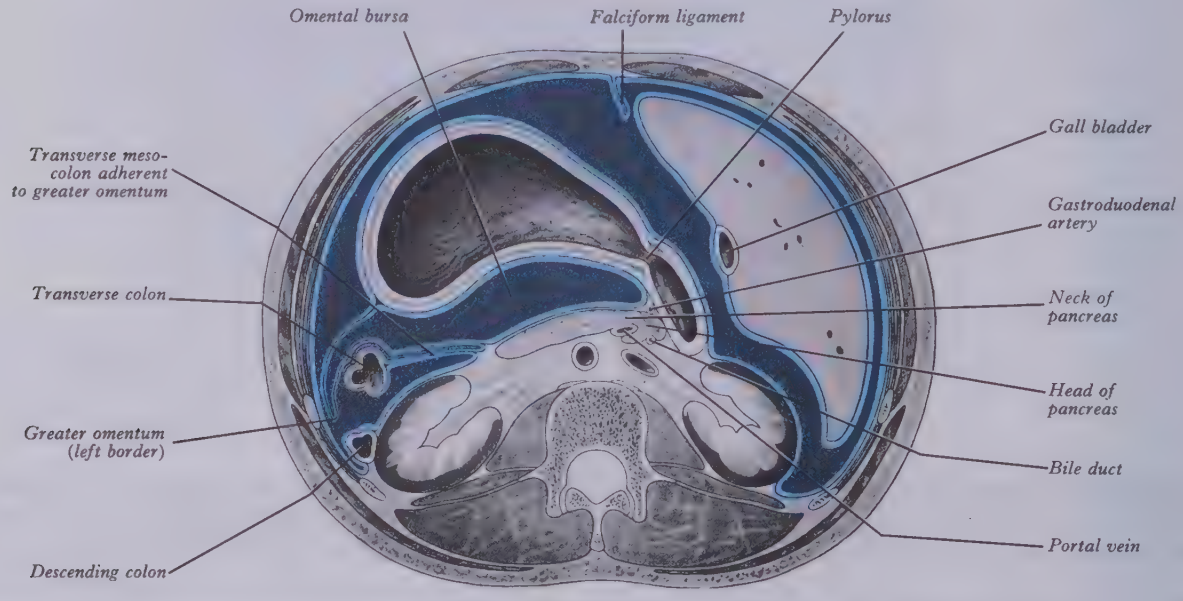
The *left border* again corresponds, below, to that of the greater omentum. Above the root of the transverse mesocolon (**8**.113) the border broadens and is formed by the *splenico-* (lieno-) *renal* and *gastrosplenic ligaments* (**8**.114A), both formed from a part of the original dorsal mesogastrium (p. 232). The splenicorenal ligament extends from the front of the left kidney to the splenic hilum as a bilaminar fold, enclosing the splenic vessels and pancreatic tail (**8**.113, 114A). From the hilum these two layers proceed to the greater curvature of the stomach as the gastrosplenic ligament. The inner (right) layer of the splenicorenal ligament joins the corresponding layer of the gastrosplenic; but its outer (left) layer joins the peritoneum covering the spleen at the back of the hilum. The latter is reflected from the front of the hilum, as the outer (left) layer of the gastrosplenic ligament. The spleen thus projects left into the greater sac (**8**.114A). The part of the bursa projecting towards it, between the splenic ligaments, is the *splenic recess*. Superiorly the two ligaments merge into a short *gastrophrenic ligament*, passing forwards from the diaphragm to the posterior aspect of the fundus of the stomach. Its two layers diverge near the oesophagus, leaving part of the posterior gastric surface devoid of peritoneum. The upper end of the left border is continuous with the left end of the roof; the left gastric artery turns forwards here into the lesser omentum. (Many peritoneal *folds* are misleadingly termed 'ligaments'. With little in common in structure or function with skeletal ligaments, they are more often neurovascular pedicles of organs which *must* be covered by peritoneum. Some may have a supportive function, but the evidence for this usually is tenuous.)

8.113 The posterior abdominal wall, showing the lines of peritoneal reflexion, after removal of the liver, spleen, stomach, jejunum, ileum, caecum, transverse colon and sigmoid colon. The various sessile (retroperitoneal) organs are seen shining through the posterior parietal peritoneum. Note: the ascending and descending colon, duodenum, kidneys, suprarenals, pancreas and inferior vena cava. Line YY represents the plane of **8.112**. Line AA represents the plane of **8.114A**. Line XX represents the plane of **8.115**. Line BB represents the plane of **8.114B**.



The omental bursa is narrowed by two crescentic peritoneal folds drawn into the sac by the hepatic and left gastric arteries. The *left gastropancreatic fold* transmits the left gastric artery from the posterior abdominal wall to the lesser curvature of the stomach; the *right gastropancreatic fold*, at a lower level, transmits the hepatic artery from the posterior abdominal wall to the lesser omentum (**8.113**). The folds vary, but when well marked they constrict the lesser sac to form a *foramen bursae omenti majoris*. The *superior recess* of the omental bursa is above this, joined through it to the *inferior recess* (representing the embryonic pancreatico-enteric recess, p. 235). The superior recess lies posterior to the lesser omentum and liver, the inferior behind the stomach and in the greater omentum.

During much of fetal life the transverse colon is attached to the posterior abdominal wall by its own mesentery, the posterior two layers of the greater omentum passing in front of the colon (**8.154**), a condition which may persist; usually, however, the mesentery of the transverse colon and posterior omental layer adhere; even so, these layers are separable in adults, especially in the living (pp. 1343, 1344), though their mesothelial elements disappear where the layers have fused. In its final form the omental bursa separates the stomach from structures which form the 'stomach bed' (p. 1349) and therefore facilitates movements of the stomach over these structures.



Peritoneal folds between various organs, or connecting them to the abdominal and pelvic walls, enclose the vessels and nerves proceeding to the viscera; though clearly not designed to sustain much weight, they may help to retain certain viscera in contact with each other. They are named ligaments, omenta and mesenteries. (The inappropriate nature of the term 'ligament' has been alluded to above.) An 'omentum' is a cover; the word may have been used to denote an apron and is thus suitable for the greater omentum, but is less suitably extended to other gastric peritoneal folds. The peritoneal 'ligaments' will be described with their respective organs.

THE OMENTA

The lesser omentum is the fold of peritoneum that extends to the liver from the lesser gastric curvature and the commencement of the duodenum. It is continuous with the two layers covering the anterosuperior and postero-inferior gastric surfaces and about

8.114A Transverse section through the abdomen, at the level of line AA in 8.113, viewed from above. The peritoneal cavity is shown in dark blue; the peritoneum and its cut edges in lighter blue.

the first 2 cm of the duodenum. From the lower part of the lesser curvature and upper border of the duodenum these two layers ascend as a double fold to the porta hepatis; from the upper part of the lesser curvature they pass to the bed of the fissure for the ligamentum venosum. This hepatic attachment is J-shaped, with a hook-like limb corresponding to the margins of the porta hepatis and a vertical ascending along the roof of the fissure (**8**.112, 154), at the superior limit of which the lesser omentum reaches the diaphragm where its two layers separate around the abdominal part of the oesophagus. At the right omental border the two layers are continuous and this free margin is anterior to the epiploic foramen. (The omentum may be described as consisting of *hepatogastric* and *hepatoduodenal ligaments*, but these form a single entity.) Close to its right free margin the two omental layers enclose the hepatic artery, portal vein and bile duct, a few lymph nodes and lymph vessels and the hepatic plexus of nerves, all enclosed in a *perivascular fibrous capsule* (**8**.114A). The right and left gastric vessels, rami of gastric (vagus) nerves (p. 1118), and some of the left gastric lymph nodes and their lymph vessels are all contained between the two layers near their gastric attachment. The lesser omentum is thinner on the left and may be fenestrated. This variation in thickness is dependent upon the amount of connective tissue, especially fat.

The greater omentum, the largest of the peritoneal folds (**8**.107,108,112,115), is a double sheet, folded on itself to make four layers. The anterior double-layered fold descends from the

8.115 Section through the upper part of the abdominal cavity, along the line XX in **8**.113. The boundaries of the epiploic foramen are shown and a small recess of the omental bursa is displayed in front of the head of the pancreas. Note that the transverse colon and its mesocolon are adherent to the posterior two layers of the greater omentum.

stomach and first part of the duodenum in front of the succeeding part of the small intestine for a variable distance and ascends behind itself as far as the transverse colon (opposite the taenia omentalis). It adheres to, though it is separable from the peritoneum on the superior surface of the transverse colon and mesocolon (pp. 1341, 1344). The left border is continuous above with the gastrosplenic ligament; the right border extends to the commencement of the duodenum. (It must be emphasized that the greater omentum and gastrosplenic ligament are not merely continuous but the same structure, separated only by descriptive convenience and terminology. Their continuity has been further obscured by *changes* in terminology; the gastrosplenic *ligament* was formerly an *omentum* but is now officially the gastro-*lienal* ligament (an inadvisable use of the stem 'lien', the spleen, in a region where all else is 'splenic'!). The greater omentum is usually thin and cribriform but it always contains some adipose tissue, which in the obese may be massive in amount. Between the two layers of its anterior fold, close to the greater curvature of the stomach, the right and left gastro-epiploic vessels form a wide anastomotic arc. Variations in distribution and anastomoses of arteries in the omentum were recorded by Jiang Dian-fu (1978).

Apart from storing fat, the greater omentum may limit peritoneal infection. When the abdomen is opened without disturbance it is frequently found wrapped about organs in the upper abdomen; it is rarely evenly dependent anterior to the intestines. It is less absorptive than the general peritoneum. It may be congenitally absent and may be removed without apparent ill effect and is hence not physiologically vital. It contains numerous fixed macrophages which are easily mobilized. These may accumulate into dense, oval or round visible '*milky-spots*'. Similar spots may occur on other serous membranes (pleura p. 1267), pericardium and sometimes the leptomeninges.

THE MESENTERIES

Peritoneal folds, designated *mesenteries*, include the mesentery of the small intestine (the mesentery proper), mesoappendix, transverse mesocolon, sigmoid mesocolon, (sometimes) an ascending or descending mesocolon and occasionally a mesentery for the gallbladder.

The mesentery (of the small intestine), a broad, fan-shaped fold, connects the coils of the jejunum and ileum to the posterior abdominal wall. The attached, parietal border is the *root of the mesentery*, (**8**.113) about 15 cm (6 in.) long and directed obliquely down from the duodenojejunal flexure (left of the second lumbar vertebra) to the upper part of the right sacro-iliac joint. (Schmidt 1974 measured the mesenteric 'root' in 44 cadavers, finding a mean length of 13.9 cm, with extremes of 7.4 and 19.3 cm.) It passes successively in front of the horizontal part of the duodenum (where the superior mesenteric vessels enter it), the abdominal aorta, inferior vena cava, right ureter and right psoas major. The intestinal border is about 6 m (20 ft) long and compactly plicated. (For variations in length, see p. 1355.) The plication diminishes towards the posterior abdominal wall where the attachment is almost along a straight line. The central part is longest (measured from its root to the intestinal border), attaining a maximum of about 20 cm (8 in.); it shortens towards each end. The mesentery consists of two layers of peritoneum, a right and a left, enclosing the jejunal and ileal branches of the superior mesenteric vessels, with their accompanying neural plexuses, lymph vessels (here called *lacteals*), mesenteric lymph nodes, connective and adipose tissue. Fat is most abundant in its caudal part and here extends from the root to the intestinal border; the upper mesentery contains less fat, with a tendency to accumulate near the root, leaving rounded, translucent, fat-free areas adjoining the upper jejunum. At the intestinal border, the layers separate to enclose the gut, as its visceral peritoneum. At the mesenteric root the right layer is reflected in its lower part to the posterior abdominal wall and ascending colon and in its upper part to become continuous with the inferior layer of the transverse mesocolon; the left layer passes to the posterior abdominal wall and descending colon. (This arrangement helps to distinguish between proximal and distal coils of small intestine when in situ.)

The mesoappendix (**8**.117) is a triangular fold of peritoneum around the vermiform appendix, attached to the back of the lower end of the mesentery close to the ileocaecal junction. It usually reaches the tip of the appendix but sometimes fails to reach the distal third, being then represented by a low peritoneal ridge containing fat. It encloses the blood vessels, nerves and lymph vessels of the vermiform appendix, together with a lymph node (p. 853).

The transverse mesocolon is a broad fold connecting the transverse colon to the posterior abdominal wall. Its two layers pass from the anterior aspect of the head and anterior border of the body of the pancreas to the posterior aspect of the transverse colon (opposite the *taenia mesocolica*), where they separate to surround it. The upper layer is adherent to, but separable from, the greater omentum (pp. 1340, 1341 and **8**.112). Posteriorly, the inferior layer covers the inferior aspect of the pancreas and passes in front of the horizontal and ascending parts of the duodenum. Between its layers are the blood vessels, nerves and lymphatics of the transverse colon. The middle colic artery descends to the right, leaving a large avascular area to its left and a smaller one to its right.

The sigmoid mesocolon is a peritoneal fold attaching the sigmoid colon to the pelvic wall, the attachment being an inverted V, with an apex near the division of the left common iliac artery (**8**.113); the left limb descends medial to the left psoas major and the right passes into the pelvis to end in the midline at the level of the third sacral vertebra. Sigmoid and superior rectal vessels run between its layers and the left ureter descends into the pelvis behind its apex.

Peritoneum usually covers only the front and sides of the ascending and descending parts of the colon, but sometimes these are virtually surrounded by peritoneum and attached to the posterior abdominal wall by an ascending and descending mesocolon respectively (p. 1367). The *phrenicocolic ligament* is a peritoneal fold extending from the left colic flexure to the diaphragm level with the tenth and eleventh ribs; it has an anterior edge and passes inferolateral to the lateral end of the spleen, sometimes being misleadingly named the *sustentaculum lienis* or 'splenic shelf', implying a hypothetical supportive role.

Appendices epiploicae are small peritoneal appendages filled with adipose connective tissue and situated along the colon; they are most conspicuous on the transverse (**8**.116) and sigmoid parts, absent from the rectum and rudimentary on the caecum and appendix. Many contain a small arteriole from the wall of the gut. In the colon they are most numerous along the line of the *taenia libera* (p. 1374).

PERITONEAL RECESSES

Peritoneal folds may create fossae or recesses of the peritoneal cavity. These are of clinical interest because a segment of intestine may enter one and be constricted by the fold at the entrance to the recess and may be a site of a kind of 'internal' hernia. Since the entrance to a recess may need to be cut to relieve strangulation and to withdraw the gut, the degree of vascularization of the fold becomes important. Surgically the omental bursa belongs to this category, with its opening at the epiploic foramen. Much smaller recesses sometimes occur, sometimes related to the duodenum, caecum and sigmoid mesocolon. For a discussion of the developmental origins of these recesses, see p. 242.

1. Duodenal Recesses

(*a*) The *superior duodenal recess* (**8**.111), present in about 50% of people, may exist alone but usually occurs with an inferior duodenal recess. It is to the left of the distal end of the duodenum, opposite the second lumbar vertebra, behind a crescentic *superior duodenal fold* (*duodenojejunal fold*), which has a semilunar free lower edge, merging on the left with peritoneum anterior to the left kidney. The inferior mesenteric vein is behind the junction of the left end of this fold and the posterior parietal peritoneum. The recess is about 2 cm deep, admitting a fingertip; it opens downwards, its orifice being in the angle formed by the left renal vein as it crosses the abdominal aorta.

(*b*) The *inferior duodenal recess* (**8**.111) is present in about 75% of subjects, usually associated with a superior recess with which it

may share an orifice; it lies left of the distal end of the duodenum, opposite the third lumbar vertebra, behind a non-vascular, triangular *inferior duodenal fold* (*duodenomesocolic fold*), which has a sharp upper edge. It is about 3 cm deep, admits one or two fingers and opens upwards towards the superior duodenal recess. It sometimes extends behind the ascending part of the duodenum and to the left, in front of the ascending branch of the left colic artery and inferior mesenteric vein. This large fossa is liable to become the site of an internal hernia.

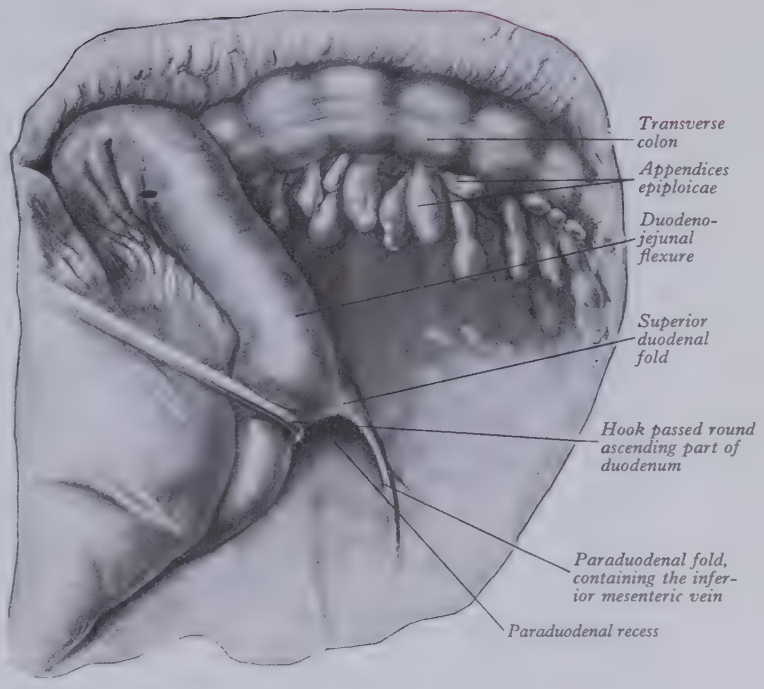
(*c*) The *paraduodenal recess* (**8**.116) may occur with the superior and inferior duodenal recesses. It is more frequent in the fetus and newborn than in adults, in whom it occurs in about 2%. It is a little to the left of the ascending part of the duodenum, behind a falciform *paraduodenal fold*, the free right edge of which contains the inferior mesenteric vein and ascending branch of the left colic artery, the fold being their mesentery. Its free edge lies in front of the wide orifice of the recess, which faces right.

(*d*) The *retroduodenal recess* is rarely present. The largest of the duodenal recesses, it lies behind the horizontal and ascending parts of the duodenum in front of the abdominal aorta. It ascends nearly to the duodenojejunal junction, being about 8–10 cm deep and bounded on both sides by *duodenoparietal folds*; its orifice faces down to the left.

(*e*) *The duodenojejunal* or *mesocolic recess*, present in about 20% and rarely or never accompanied by any other duodenal recess, is about 3 cm deep and lies on the left side of the abdominal aorta, between the duodenojejunal junction and the root of the transverse mesocolon. Bounded above by the pancreas, on the left by the kidney, and below by the left renal vein, it has a circular opening between two peritoneal folds, which faces down to the right.

(*f*) The *mesentericoparietal recess* (of Waldeyer) is more frequent in the fetus and newborn, occurring in only about 1% of adults. It lies just below the horizontal part of the duodenum, invaginating the upper part of the mesentery towards the right. Its orifice is large and faces left behind a fold of mesentery raised by the superior mesenteric artery.

2. Caecal Recesses



The *superior ileocaecal recess* (**8**.117), usually present and best developed in children, is often reduced and absent in the aged, especially the obese. It is formed by the *vascular fold of the caecum*, which arches over the anterior caecal artery, supplying the anterior part of the ileocaecal junction, and its accompanying vein. It is a narrow slit bounded in front by the vascular fold, behind by the ileal mesentery, below by the terminal ileum and on the right by the ileocaecal junction. Its orifice opens downwards to the left.

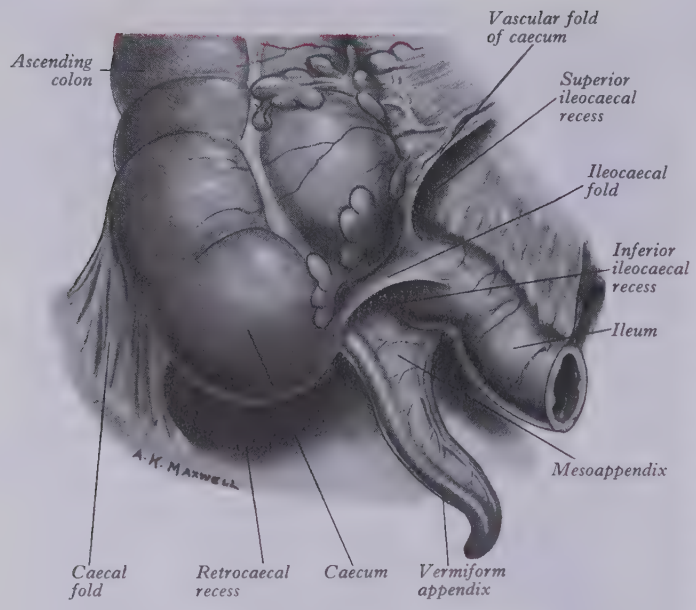
The *inferior ileocaecal recess* (**8**.117) is well marked in youth but frequently obliterated by fat in later years. It is produced by the *ileocaecal fold*, extending from the antero-inferior aspect of the terminal ileum to the front of the mesoappendix (or to the appendix or caecum). It is also known as the '*bloodless fold of Treves*', although it sometimes contains blood vessels; if inflamed, especially when the appendix and its mesentery are retrocaecal, it may be mistaken for the mesoappendix. (For the source of vessels in this fold, see Cabanie & Javelle 1966.) The recess is bounded in front by the ileocaecal fold, above by the posterior ileal surface and its mesentery, to the right by the caecum, and behind by the upper mesoappendix. Its orifice opens downwards to the left.

The *retrocaecal recess* (**8**.117), behind the caecum, varies in size and extent and ascends behind the ascending colon, being large enough to admit an entire finger. It is bounded in front by the caecum (and sometimes the lower ascending colon), behind by the parietal peritoneum and on each side by *caecal folds* (parietocolic folds) passing from the caecum to the posterior abdominal wall. The vermiform appendix frequently occupies this recess (pp. 1365, 1366).

3. The Intersigmoid Recess

This recess is constant in fetal life and infancy, but may later disappear. It lies behind the apex of the V-shaped parietal attachment of the sigmoid mesocolon, is funnel-shaped and directed upwards and opens downwards. It varies in size from a dimple to a fossa admitting the fifth finger. Its posterior wall of posterior parietal peritoneum covers the left ureter as this crosses the bifurcation of the left common iliac artery. Occasionally the recess is within the layers of the sigmoid mesocolon nearer gut than root. Its presence is due to an imperfect blending of the mesocolon with the posterior parietal peritoneum.

8.116 The paraduodenal recess.



ANOMALOUS PERITONEAL FOLDS

Certain other folds, bands or ligaments sometimes occur in the abdomen. Some are considered to cause obstruction by pulling on or kinking sections of intestine; others may limit the spread of peritoneal effusions. Their exact modes of origin are doubtful; they have been attributed to errors in development, previous inflammation (peritonitis), mechanical traction by the gut and even (and improbably) linked with the evolution of upright posture. These anomalous folds must be distinguished from pathological adhesions definitely due to peritonitis; also, when coils of intestine are pulled out of normal position during examination they may be artificially kinked, with resultant simulation of bands. Anomalous folds are only clinically important if proved to interfere with normal function; their presence should not halt a search for other possible causes of the symptoms. The commonest anomalous folds encountered are as follows:

(*a*) Occasionally the lesser omentum is prolonged to the right of the usual site of the epiploic foramen by a peritoneal fold extending from the gallbladder to the superior part of the duodenum (*cystoduodenal ligament*), or in front of the superior part of the duodenum to the greater omentum or right colic flexure, or from the inferior surface of the right hepatic lobe to the right colic flexure (*hepatocolic ligament*).

(*b*) The duodenojejunal junction is sometimes joined to the transverse mesocolon by a peritoneal band.

(*c*) The greater omentum may be attached to the front of the ascending colon or extend over it to the lateral abdominal wall. A thin sheet of peritoneum (*Jackson's membrane*), containing small blood vessels, may spread from the front of the ascending colon and caecum to the posterolateral abdominal wall and may merge on the left with the greater omentum. Occasionally a band passes from the right side of the ascending colon to the lateral abdominal wall near the level of the iliac crest. Sometimes termed a 'sustentaculum hepatis', it is closely related to the liver only in fetal and early postnatal life, when the liver is relatively larger. Other folds between the ascending colon and posterolateral abdominal wall may divide the right lateral paracolic gutter (between the

8.117 The peritoneal folds and recesses in the caecal region.

ascending colon and posterior abdominal wall) into several small recesses.

(d) The ascending and less frequently the descending colon may have a mesentery.

(e) Proximal and distal ends of the sigmoid colon may be tied together by a fibrous band.

(f) Frequently a fan-shaped *presplenic fold* extends from the front of the gastrosplenic ligament (near the greater gastric curvature), below the inferolateral pole of the spleen, to blend with the phrenicocolic ligament; it may adhere to the spleen or diaphragm and contains rami of the splenic or the left gastro-epiploic artery; the omental bursa may enter it. It is more obvious in the fetus, often appearing as just part of the phrenicocolic ligament in adults. It may limit peritoneal effusions in the left supracolic space (vide infra), and, if adherent to the spleen or diaphragm, it may form a vascular obstruction in splenectomy.

(g) A fibrous band, described as passing from the terminal ileum to the posterior abdominal wall, and a similar one, from the proximal sigmoid colon to the same wall, were once thought to be causes of partial obstruction by kinking of these parts of the gut, but this view is no longer popular.

SPECIAL PERITONEAL REGIONS

Regarding the spread of pathological collections of fluid, certain potential peritoneal spaces or recesses, normally in communication with each other, must be mentioned because they may be sealed off by pathological adhesions. These are as follows:

(1) The *supracolic space (subphrenic region)* between the diaphragm and the transverse colon and mesocolon is subdivided into: *(a)* the *right subphrenic space*, between the diaphragm and the anterior, superior and right lateral surfaces of the right lobe of the liver, bounded on the left side by the falciform ligament and behind by the coronary ligament's upper layer; *(b)* the *left subphrenic space* between the diaphragm, the anterior and superior surfaces of the left hepatic lobe, the anterosuperior surface of the stomach and the diaphragmatic surface of the spleen; it is limited to the right by the falciform ligament and behind by the left triangular ligament's anterior layer; *(c)* the *right subhepatic space* (*hepatorenal recess*, or *Morison's pouch*), bounded above and in front by the inferior surface of the right hepatic lobe and gallbladder, below and behind by the right suprarenal gland, the upper part of the right kidney, the descending part of the duodenum, right colic flexure, transverse mesocolon and part of the head of the pancreas; above and behind, it extends between the right kidney and the liver as far as the inferior layer of the coronary ligament and right triangular ligament; *(d)* the *left subhepatic space*, i.e. the omental bursa.

(2) The *right infracolic space* lies postero-inferior to the transverse colon and mesocolon and to the right of the mesentery, whose obliquity narrows the lower part of the space. The vermiform appendix is often in the lower part of this space.

(3) The *left infracolic space* is below and behind the transverse colon and mesocolon and left of the mesentery; it is widest below, continuing into the pelvis.

(4) The *pelvic cavity* (p. 604).

(5) The *paracolic gutters* are alongside the ascending and descending colon (which are normally sessile), where the peritoneum turns dorsally on the medial and lateral aspects of the gut. *Medial* and *lateral paracolic gutters* flank both left and right parts of the colon. Of commonest clinical interest is the *right lateral paracolic gutter*, which skirts the superolateral aspect of the hepatic flexure of the colon and continues into the hepatorenal pouch (of Morison) and, through the epiploic foramen, into the omental bursa and its superior recess. Inferiorly, around the caecum it curves over the pelvic brim into the *rectovesical* (male) or *recto-uterine* (female) *pouch* (of Douglas). Related to this gutter, and its superior extension, are the vermiform appendix, right kidney, gallbladder, lesser gastric curvature and the first and second parts of the duodenum; all are common sites of acute abdominal disease. Seepage of infected fluid along this channel, from place to place, may cause puzzling symptoms and signs and errors in diagnosis. In supine patients infected fluid in the right lateral gutter may *ascend* to, enter and accumulate in the superior recess of the omental bursa, with grave consequences, because of its inaccessibility and nearness to the pleural and pericardial cavities. In patients nursed in a sitting posture, fluid *descends* to the relatively accessible rectovesical pouch or to the recto-uterine pouch, approachable surgically through the rectum or vagina.

(6) Two extraperitoneal subphrenic regions may become infected; *(a)* the *right extraperitoneal space*, between the two layers of the coronary ligament i.e. the 'bare area' of the liver and the diaphragm; and *(b)* the *left extraperitoneal space*, which contains extraperitoneal connective tissue around the left suprarenal gland and upper pole of left kidney.

PERITONEAL ABSORPTION

Substances in *solution* are probably absorbed into the capillaries, whereas suspended matter probably passes into the lymph vessels, aided by phagocytes. After abdominal or pelvic operations, it has been customary to prop up patients to encourage intraperitoneal effusions to gravitate into the pelvis. One reason for this was the belief that the subphrenic peritoneum was more absorptive than elsewhere and hence inflammatory products would enter the circulation more rapidly here. It was supposed that gaps or (peritoneal stomata) between the mesothelial cells of the subphrenic peritoneum and similar gaps (endothelial stigmata) between the endothelial cells of lymph vessels greatly facilitated absorption. Such gaps have been often considered to be histological artefacts, but scanning electron microscopy supports the existence of slit-like orifices. However absorption is believed to be much the same in all parts of the peritoneum. Greater absorption in the upper abdomen may be due to the larger subphrenic peritoneal area and to respiratory movements.

PERITONEAL STRUCTURE

The peritoneum is composed of a single layer of flat mesothelial cells lying on a layer of loose connective tissue. Mesothelium usually forms a continuous surface, adjacent cells being joined by junctional complexes but probably allowing the passage of macrophages, just as leucocytes pass between endothelial cell junctions. In some areas, e.g. the greater omentum, the peritoneum may be discontinuous, having fenestrations which are sometimes visible to the unaided eye; but mesothelium continues over the trabeculae of connective tissue interlacing around such fenestrae.

Submesothelial connective tissue contains cells typical of loose connective tissue (p. 58) but macrophages, lymphocytes and in some regions adipocytes are particularly numerous. Macrophages

and lymphocytes may aggregate as submesothelial 'milky spots'. Mesothelial cells may also transform into fibroblasts; the fusion between layers of fibroblasts of mesothelial origin may cause macroscopic adhesions between the peritoneal surfaces, interfering with intestinal motility or even leading to complete obstruction of the gut.

The mesothelium resembles vascular endothelium in being a dialysing membrane which fluids and small molecules may traverse. Numerous endocytic vesicles occur near the cell surfaces, the remaining cytoplasm being poor in organelles, indicating low metabolic activity (Tesi & Forssmann 1970). Normally the volumes of fluid transmitted by peritoneal surfaces are small, but large volumes may be administered via the intraperitoneal route; conversely, substances such as urea can be dialysed from blood into fluid circulated through the peritoneal cavity.

PERITONEAL FLUID

The fluid covering the peritoneal surfaces contains water, electrolytes and other solutes derived from interstitial fluid in the adjacent tissues and from the plasma of local vessels. It also contains proteins and cells (Carr 1967), the latter varying in number, structure and type in different diseases; hence it is of diagnostic importance. Normally they are mesothelial desquamated elements, nomadic peritoneal macrophages, mast cells, fibroblasts, lymphocytes and some other leucocytes. Some, particularly macrophages, migrate freely between the peritoneal cavity and the surrounding connective tissue; intraperitoneally injected particles are ingested by them and transported to various tissue sites. Lymphocytes provide both cellular and humoral immunological defence mechanisms.

PERITONEAL VESSELS AND NERVES

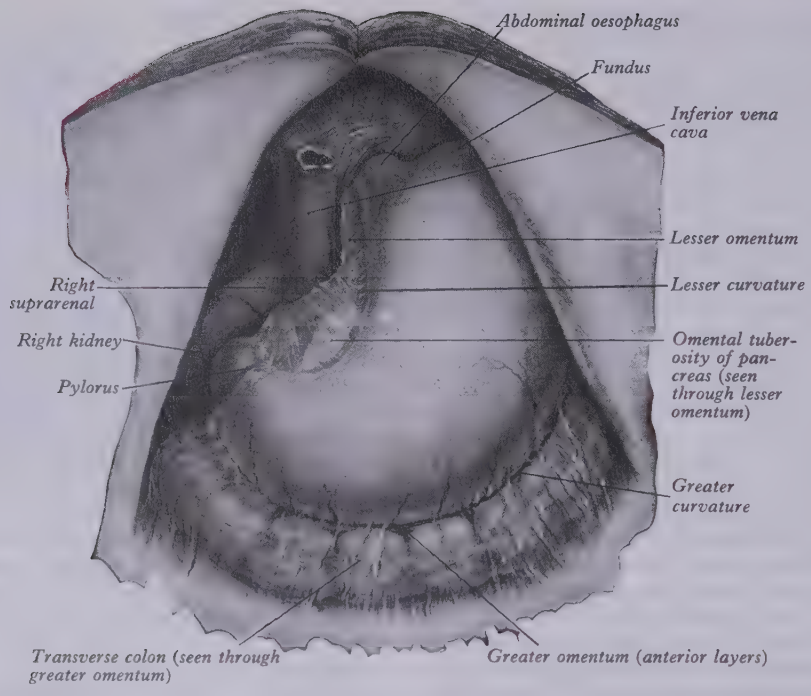
Parietal and visceral peritoneum are developed from, respectively, somatopleural and splanchnopleural layers of lateral plate mesoderm (p. 138). Parietal peritoneum is therefore supplied by somatic blood vessels of the abdominal and pelvic walls; its lymphatics join those in the body wall and drain to parietal lymph nodes; its nerve supply is derived from nerves supplying the muscles and skin of the parietes. Visceral peritoneum, however, as an integral part of the viscera, derives its blood vessels from those supplying viscera. Its lymphatics join the visceral vessels and its nerve supply is autonomic. Differences in the sensibility of the two layers correlate with their innervations. Whereas pain is elicited by mechanical, thermal or chemical stimulation of the parietal peritoneum, the visceral peritoneum and viscera are not affected; e.g. the liver, stomach or intestine can be injured without evoking pain, insensibility extending from the mid-oesophagus to the junction of endoderm and ectoderm in the anal canal. However, tension *does* evoke pain when applied to viscera or visceral peritoneum by over-distension or traction on mesenteries, stretching various neural elements in the visceral walls or mesenteries. Also effective are spasms of visceral muscle and ischaemia. Somatic nerves of the parietal peritoneum also supply the corresponding segmental areas of skin and muscles and, when the parietal peritoneum is irritated, muscles are reflexly contracted, causing rigidity of the abdominal wall. The parietal peritoneum on the underside of the diaphragm is supplied centrally by the phrenic nerves and peripherally by the lower six intercostal and subcostal nerves. Hence peripheral irritation may result in pain, tenderness and muscular rigidity in the distribution of the lower thoracic spinal nerves, while central irritation may result in pain in the cutaneous distribution of the third to fifth cervical spinal nerves, i.e. the shoulder region.

ABDOMINAL VISCERA

The Stomach

The stomach (ventriculus or preferably *gaster*) is the most dilated part of the alimentary canal and is situated between the oesophagus and the small intestine; it lies in the epigastric, umbilical and left hypochondriac areas of the abdomen, occupying a recess bounded by the upper abdominal viscera and completed above and anterolaterally by the anterior abdominal wall and diaphragm. Its shape and position are modified by intrinsic changes and by changes in the surrounding viscera. Its mean capacity varies from about 30 ml at birth, increasing to 1000 ml at puberty and about 1500 ml in adults. It has two openings and is described as if it had two borders or curvatures and two surfaces. In reality its external surface is a continuum and not divided by perceptible 'borders'. However, since its peritoneal surface is interrupted by the attachments of the greater and lesser omenta along profiles which define the gastric radiographic shadow, these curvatures may be conveniently regarded as 'borders' separating the surfaces. (Similar arbitrary borders are assigned to the heart, p. 700.)

THE GASTRIC ORIFICES



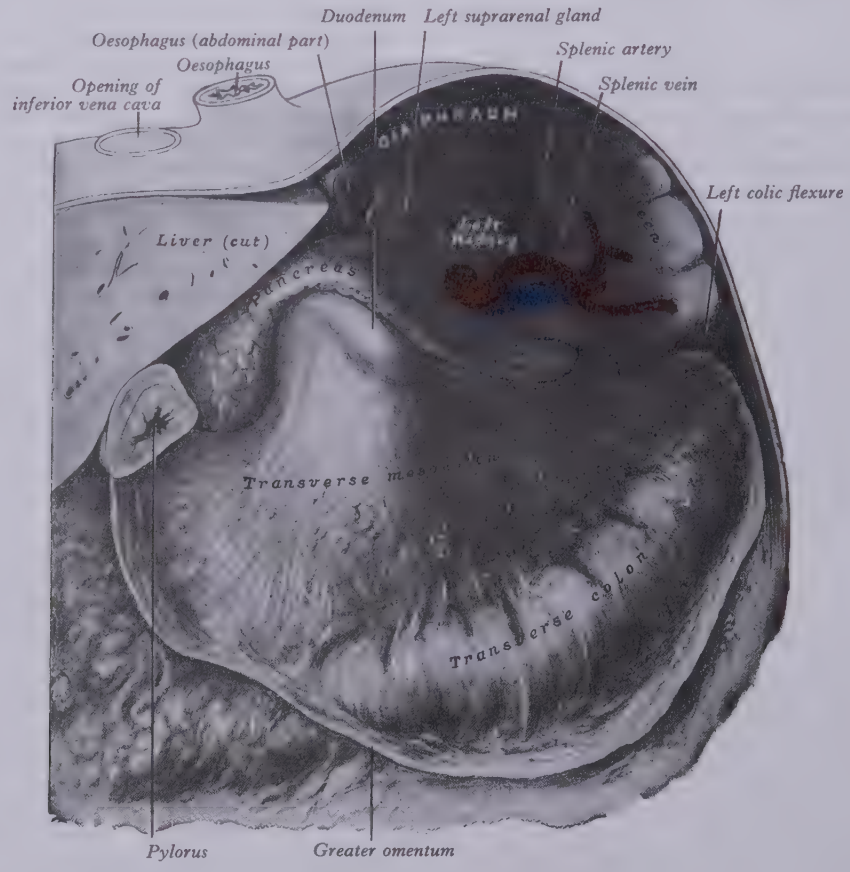
The opening from the oesophagus into the stomach is the *cardiac orifice*, situated to the left of the midline behind the seventh costal cartilage, 2.5 cm (1 in.) from its sternal junction at the level of the eleventh thoracic vertebra. It is about 10 cm (4 in.) from the anterior abdominal wall and 40 cm (16 in.) from the incisor teeth. The short abdominal part of the oesophagus, shaped like a truncated cone, curves sharply left, the base of the cone being continuous with the cardiac orifice. The right side of the oesophagus is continued as the *lesser curvature*, while its left side joins the *greater curvature* at an acute angle, the *cardiac notch* or *incisure*. The part of the stomach above the level of the cardiac orifice is the *fundus*, an inappropriate term, but it is the *bottom* of the stomach, when entered surgically from below.

The *pyloric orifice*, the opening into the duodenum, is usually indicated (**8**.118) by a circular *pyloric constriction* on the surface of the organ, indicating the pyloric sphincter; it can be identified by the prepyloric vein crossing its anterior surface vertically. The pyloric orifice is about 1.2 cm (0.5 in.) right of the midline in the transpyloric plane (level of the lower border of the first lumbar vertebra), with the body supine and the stomach empty.

THE GASTRIC CURVATURES

The lesser curvature, extending between the cardiac and pyloric orifices, is the right (posterosuperior) border of the stomach. It descends from the right side of the oesophagus in front of the decussating fibres of the right crus, curving to the right below the omental tuberosity of the pancreas to end at the pylorus (**8**.118, 120). In the most dependent part may be the *angular incisure*, varying in position with gastric distension; it is sometimes used to define the right and left parts of the stomach. The lesser omentum is attached to the lesser curvature and contains the right and left gastric vessels near the curvature.

The greater curvature is directed antero-inferiorly and is four or five times as long as the lesser; it starts from the cardiac incisure and arches upwards posterolaterally and to the left; its highest convexity, the *fundus*, is level with the left fifth intercostal space just below the left nipple in males, though varying with respiration (pp. 594–595). From this level it sweeps down and forwards, slightly convex to the left, almost as far as the tenth costal cartilage in the supine body; it finally turns right to end at the pylorus. Opposite the angular incisure of the lesser curvature the greater curvature presents a bulge, taken as the left limit of the *pyloric part* of the stomach, its right limit being a slight groove (*sulcus intermedius*) indicating subdivision into the *pyloric antrum* and *canal*, the latter only 2–3 cm in length and terminating at the pyloric constriction. The start of the greater curvature is covered by peritoneum continuous with that anterior



8.118 The stomach in situ, after removal of the liver.

to the stomach. Left of the fundus and the adjoining gastric body the greater curvature gives attachment to the gastrosplenic ligament and beyond this to the greater omentum, its two layers being separated by the gastro-epiploic vessels. The gastrosplenic ligament and the greater omentum (with the gastrophrenic and splenicorenal ligaments see p. 1339, 8.114A) are continuous parts of the original dorsal mesogastrium (p. 232). The names merely indicate regions of the same fold.

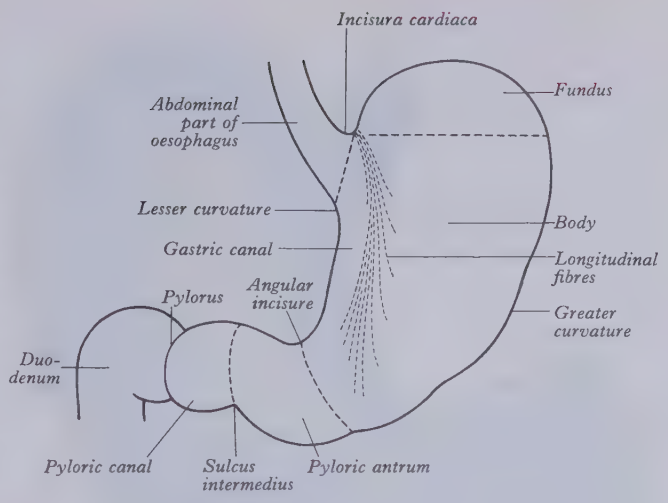
THE GASTRIC SURFACES

When the stomach is empty and contracted its surfaces are almost superior and inferior; but in distension they become anterior and

8.119 The stomach bed: a dissection in which the stomach has been removed to show its posterior relations.

posterior and are therefore described here as anterosuperior and postero-inferior.

Anterosuperior surface. The left part of this surface is posterior to the left costal margin and in contact with the diaphragm which separates it from the left pleura, the base of the left lung, the pericardium and the left sixth to ninth ribs and intercostal spaces. It is related to the costal attachments of the upper fibres of the transversus abdominis, separating it from the seventh to ninth costal cartilages. The upper and left part of this surface becomes posterolateral and is in contact with the spleen's gastric surface. The right part of the anterosuperior surface is related to the left and quadrate lobes of the liver and the anterior abdominal wall. When the stomach is empty, the transverse colon may be anterior to it. The whole surface is covered by peritoneum and part of the greater sac separates it from the above structures.



Postero-inferior surface. This is related to the diaphragm, the left suprarenal gland, upper part of the front of the left kidney, the splenic artery, anterior pancreatic surface, left colic flexure and the transverse mesocolon (upper layer), which together form the shallow *stomach bed* (**8**.119), over which the stomach slides, due to the intervening lesser sac. The spleen's gastric surface is usually included in the stomach bed, though separated from the stomach by the greater sac. The greater omentum and the transverse mesocolon separate the stomach from the duodenojejunal flexure and small intestine. The postero-inferior surface is covered by peritoneum, except near the cardiac orifice, where a small, triangular area contacts the left diaphragmatic crus and sometimes the left suprarenal gland. The left gastric vessels reach the lesser curvature at the right extremity of this area in the left gastropancreatic fold (p. 1341); from its left side the *gastrophrenic ligament*, continuous below with the splenicorenal and gastrosplenic ligaments, passes to the diaphragm's inferior surface.

A plane through the angular incisure of the lesser curvature and the left limit of the opposed bulge on the greater curvature arbitrarily divides the stomach into a large *body* (left) and a smaller *pyloric part* (right).

RADIOLOGY

The form and position of the stomach can be studied after swallowing a suitable 'meal' containing barium sulphate (**8**.122). During digestion it is divided by a muscular constriction in its body into a large, dilated, left region and a narrow, contracted, tubular right one. The constriction in the body follows no anatomical landmarks but moves gradually left as digestion progresses. The position of the stomach varies with posture, contents and the state of the intestines, it is also influenced by the tone of the abdominal wall and gastric musculature and by the individual's build. Most commonly the empty organ is J-shaped and, in the erect posture, the pylorus descends to the level of the second or the third lumbar vertebra, its most dependent part being subumbilical. The fundus usually contains gas. Variation in content mainly affects the body, the pyloric part remaining contracted during digestion. As the stomach fills it expands forwards and downwards but, when the colon or intestines are distended, the fundus presses on the liver and diaphragm and may evoke discomfort. When hardened in situ the contracted stomach is crescentic, the fundus directed backwards. Surfaces are superior and inferior, the former sloping gradually to the right, the greater curvature being anterior to and at a slightly higher level than the lesser.

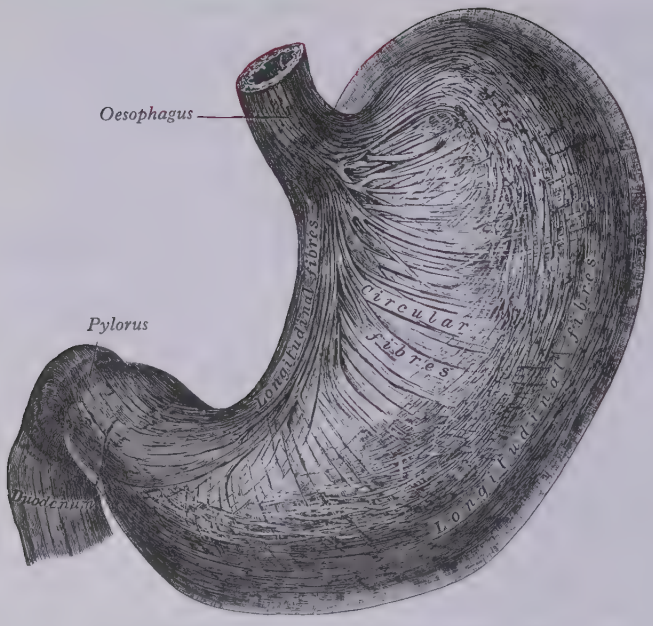
The position of the full stomach varies. When the intestines are empty the fundus expands vertically and forwards, the pylorus is displaced right and the whole organ becomes oblique. Its surfaces are then directed more forwards and backwards, the lowest part being the pyloric antrum which extends below the umbilicus. When intestinal distension interferes with downward expansion of the fundus, the stomach retains the horizontal position characteristic of the contracted viscus. Less commonly it may lie almost transversely, even in the erect posture, as the '*steer-horn*' type. Intermediate types of stomach, between J-shaped and 'steer-horn', also occur (Barclay 1936).

8.120 The parts of the stomach.

INTERIOR OF THE STOMACH

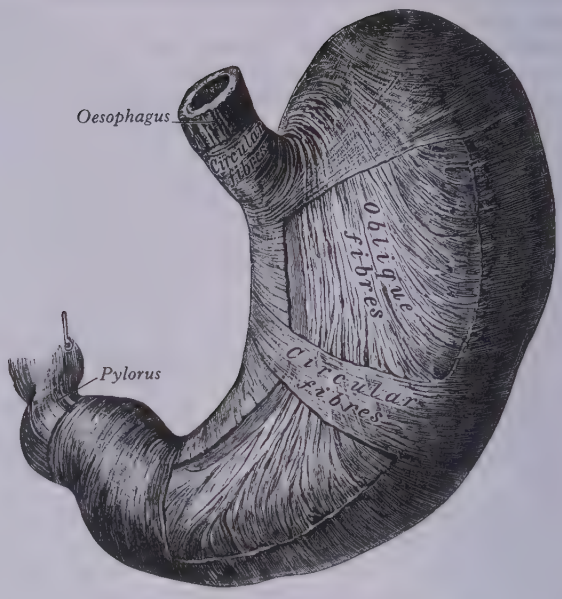
After death the stomach is usually fixed at some stage of the digestion, commonly as shown in **8**.123. When it is bisected in the plane of its curvatures, it shows two segments: (1) a large globular left part and (2) a narrow tubular right part; the transition is gradual, so their division is arbitrary. The cardiac incisure lies to the left of the abdominal part of the oesophagus and its projection into the cavity increases as the organ distends, supposedly acting as a valve preventing oesophageal regurgitation. The elevation opposite the angular incisure is at the beginning, and the circular thickening of the pyloric sphincter at the end, of the pyloric region.

Modelling of human fetal gastric epithelium (Lewis 1912) has shown that a *gastric canal* extends along the lesser curvature from the cardiac orifice to the angular incisure (**8**.120). Jefferson (1915) demonstrated such a canal radiologically in adults and examination during the act of swallowing radio-opaque fluid showed that it was first confined to the region adjacent to the lesser curvature, suggesting that contraction of oblique muscle fibres causes temporary separation of a canal along the lesser curvature.



The pyloric sphincter is a muscular ring formed by a marked thickening of the circular gastric muscle, some longitudinal fibres also interlacing with it (DiDio & Anderson 1968.)

A *cardiac sphincter* is sometimes described, formed from the circular fibres of the gastric wall. Radiological observation strongly suggests some force capable of delaying the entry of oesophageal contents but the histological evidence is inconclusive. Muscle fibres of the right crus of the diaphragm, decussating obliquely round the termination of the oesophagus, may compress or kink it at this level; but this is merely an anatomical speculation. Bowden & El-Ramli (1967) have described this part of the diaphragm (p. 592); they concluded that, while the right crus invariably embraces the oesophagus, this arrangement does not suggest an effective sphincter, though in some positions of the trunk a kinking effect might occur. That the sphincter may be oesophageal has also been suggested (see pp. 594, 1333).



THE GASTRIC STRUCTURE

The gastric wall consists of the usual serous, muscular, submucous and mucous layers, together with their vessels and nerves.

The serosa or visceral peritoneum covers the entire surface except: (1) along the greater and lesser curvatures at the attachment of the greater and lesser omenta, where the peritoneal layers leave space for vessels and nerves; and (2) a small postero-inferior area, near the cardiac orifice, where the stomach contacts the diaphragm at the reflexions of the gastrophrenic and left gastropancreatic folds.

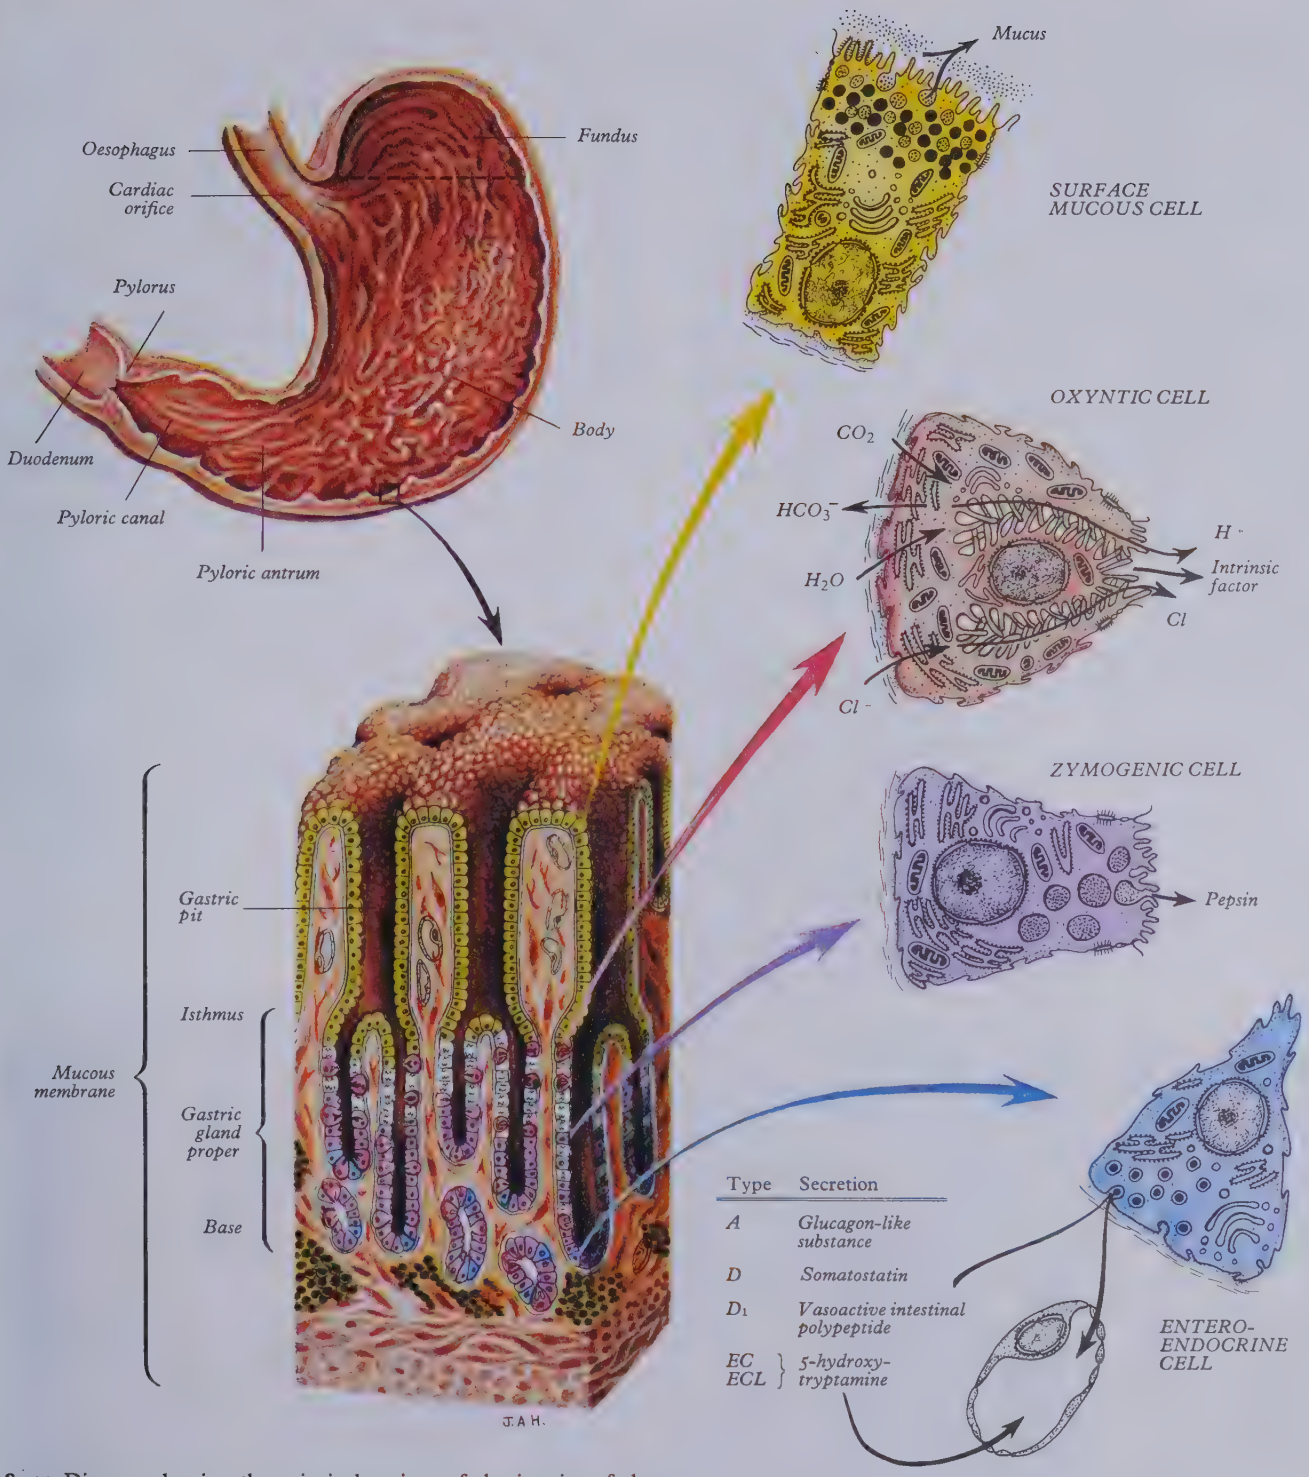
8.121A The longitudinal and circular gastric muscular fibres: anterosuperior aspect (Spalteholz).

8.121B The oblique muscular fibres of the stomach, shown by partial dissection of its wall: anterosuperior aspect.

The muscularis externa (8.121A,B) is immediately under the serosa, with which it is closely connected by subserous areolar tissue; it has longitudinal, circular and oblique layers of non-striated muscle fibres.

Longitudinal fibres are the most superficial and arranged in two groups. The first set is continuous with the longitudinal oesophageal fibres; radiating from the cardiac orifice, they are best developed near the curvatures and end proximal to the pyloric region. The fibres of the other group commence in the body and pass to the right, becoming more thickly arranged as they approach the pylorus; some superficial fibres pass to the duodenum, deeper ones turning in to interlace with the fibres of the pyloric sphincter.

Circular fibres form a uniform layer over the whole stomach internal to the longitudinal fibres. At the pylorus they are most abundant, aggregated into the annular *pyloric sphincter*; they are also continuous with the circular oesophageal fibres but sharply separated from those of the duodenum by a septum of connective tissue.



Oblique fibres, internal to the circular, are limited to the gastric body and are most developed near the cardiac orifice. They sweep

8.122B Radiograph of an atonic stomach after a barium meal. Note that this stomach contains the same amount of barium suspension as the stomach in 8.122A. Arrow 1 points to the shadow of the right breast, arrow 2 to the pylorus, arrow 3 to the upper part of the body of the stomach, where longitudinal folds can be seen in the mucous membrane. XX marks a wave of peristalsis.

8.123 Diagram showing the principal regions of the interior of the stomach and the histology and ultrastructure of its mucous membrane. Undifferentiated, dividing cells are shown in white.

down from the cardiac incisure more or less parallel with the lesser curvature, near which they present a free and well-defined margin (**8.121B**); on the left they blend with the circular fibres nearer the greater curvature.

Peristalsis in the pyloric antrum thoroughly mixes its contents, returning some of them to the body of the stomach and propelling some into the duodenum. The pyloric sphincter contracts intermittently during antral activity; but in the resting stomach it is relaxed, leaving the pylorus open (Atkinson et al 1957, Spira 1957). The control of transfer of the stomach contents through the pylorus is still not fully clarified. For an authoritative summary consult Hunt & Knox (1968).

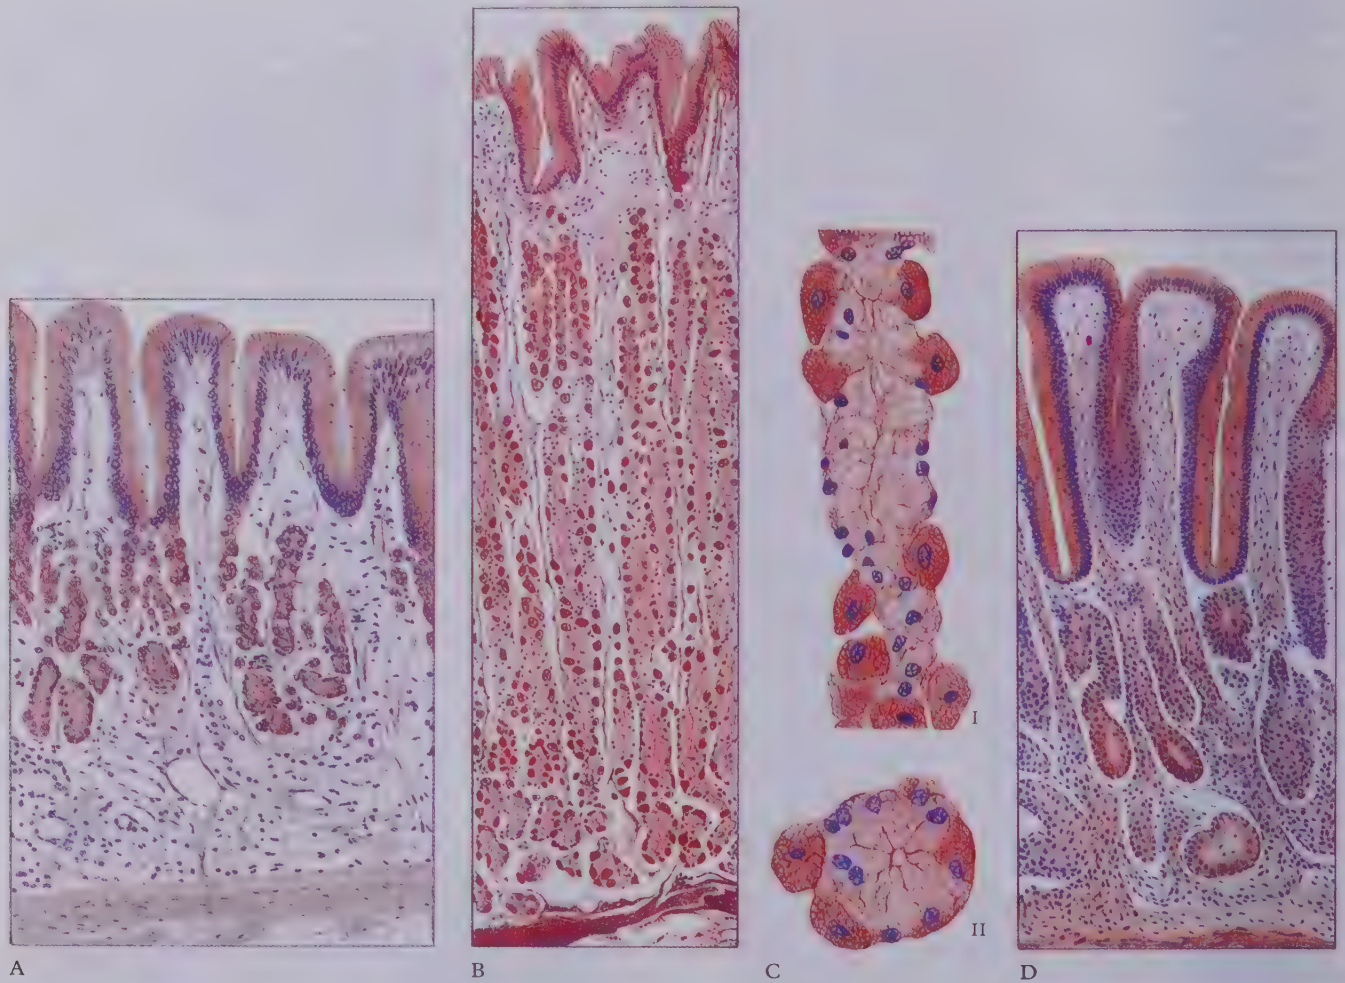
The submucosa is composed of loose, areolar tissue, connecting the mucosa to the muscularis externa.

The mucosa is thick, its surface smooth, soft, velvety and, over most of its surface, reddish brown; it is pink in the pyloric region. During contraction it is folded into numerous folds or rugae, mostly longitudinal and best marked towards the pyloric end and along the greater curvature (**8.123**). The rugae are obliterated by gastric distension. The detailed structure of the mucosa is described below.

Structure of the Gastric Mucosa

At low magnification the luminal surface of the mucosa (**8**.123) appears honeycombed by small depressions or alveoli, polygonal or slit-like, about 0.2 mm in diameter. These *gastric pits* contain the orifices of gastric glands. The whole surface, including the pits, is covered by simple secretory columnar epithelium, the *surface mucous cells*, which liberate mucus from their apices as a lubricant and also to protect the gastric lining against its own secretions of acid and enzymes. This epithelium commences abruptly at the cardiac orifice, where there is a sudden transition from the oesophageal stratified epithelium. The *gastric glands* comprise three categories: (1) cardiac, (2) main (in the body and fundus) and (3) pyloric (Ito & Winchester 1963).

Cardiac glands (**8**.124A) are confined to a small area near the cardiac orifice; some are simple tubular glands, others are compound racemose. Mucus-secreting cells predominate and oxyntic and zymogenic cells are few.



The main gastric glands are in the body and fundus, three to seven opening into each gastric pit; they are cytologically the most highly differentiated (**8**.124B), with at least four distinct cell types as well as undifferentiated cells.

(1) The *chief (peptic* or *zymogenic) cells*, usually basal in position, are cuboidal and protein-synthesizing, containing prominent secretory vacuoles, also much granular endoplasmic reticulum and a prominent Golgi complex; they are strongly basophilic because of their contained RNA. They are the source of gastric digestive enzymes (**8**.123).

(2) The *oxyntic (parietal) cells*, large, round and eosinophilic, are most numerous on the side walls of the glands and near their ducts. They occur only at intervals and with light microscopy seem to be applied to the exterior of other cells or partly intercalated between them. They bulge into the adjacent lamina propria, giving it a beaded appearance, and are connected with the lumina of the glands by fine processes between adjacent cells. Oxyntic cells have tortuous invaginations forming what appear to be intracellular canaliculi the surfaces of which are covered with microvilli, and which open directly into the lumen of the gastric gland on the apices of fine processes passing centrally between adjacent cells. Each possesses a large, round, central nucleus and the surrounding cytoplasm displays sparse endoplasmic reticulum, no secretory granules but very numerous, densely packed mitochondria. Minute smooth-walled membranous tubules converge on and open into the intracellular canaliculi (**8**.123). These cells are the source of chloride and hydrogen ions in the acid secretions of the stomach. They also elaborate and secrete *intrinsic factor* necessary for the absorption of vitamin B_{12} (Hoedemseker et al 1966).

(3) *Mucous ('neck') cells* are dispersed among other the types and are numerous at the necks of the glands. They are typical mucus-secreting cells, but their secretions are distinct histochemically from those of the superficial mucous cells.

(4) *Argentaffin cells* occur in all types of gastric gland but more commonly in those of the body and fundus. They are more usual in the deeper parts of the glands, lying between the zymogenic cells and the basal lamina; they rarely reach the lumen. Their

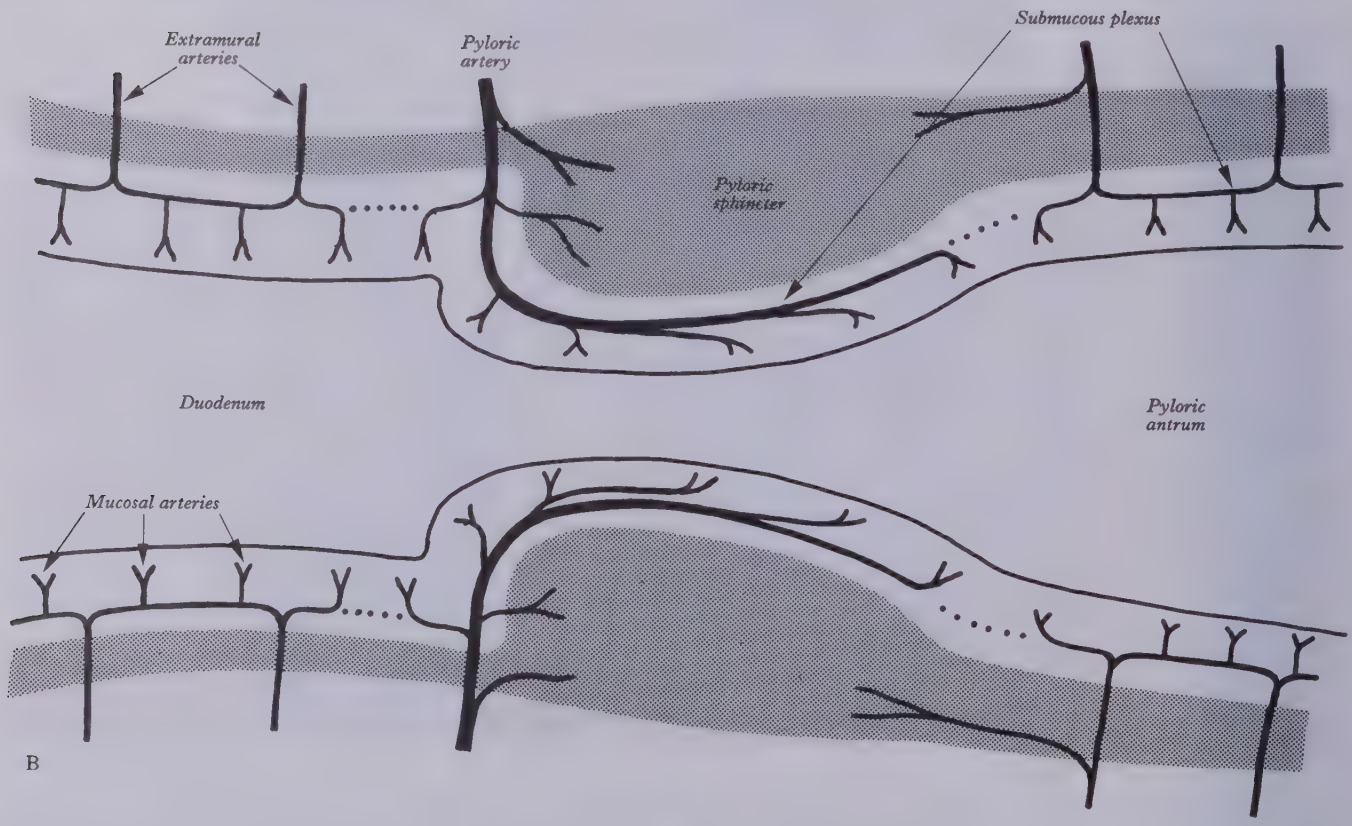
irregular nuclei are surrounded by granular cytoplasm stained strongly by silver salts. The cytoplasm, particularly that nearest to the basal lamina, contains many dense membrane-bound vacuoles of varying size, some large (0.3 μm diameter) and responsible for the staining reaction. They are part of the *gastro-enteropancreatic endocrine system* (p. 1376) and are subdivided into a variety of types on the basis of differences in their ultrastructure and secretions (**8**.123, 146).

(5) *Undifferentiated columnar cells* also exist in smaller numbers, at least some of them being stem cells from which other cells are continually replaced. Superficial mucous cells are replaced after about three days and mucous neck cells after about one week. Other cell types appear to live considerably longer.

Pyloric glands each consist of two or three short convoluted tubes opening into a conical pit, which occupies about two-thirds of the mucosal depth (**8**.124D). Epithelial cells are mostly mucous, oxyntic cells being few; enteroendocrine cells are, however, present. The enteric hormone *gastrin* has been isolated from human pyloric glands; it is released by mechanical stimuli and increases gastric motility and secretion by chief and oxyntic cells (see also p. 1376). Although oxyntic cells are few in pyloric glands, they are always present in both fetal and postnatal material; in adults they may appear in the duodenal mucosa but only proximally, near the pylorus (Leela & Kanagasuntheram 1968). Between the glands the lamina propria forms a connective tissue framework and contains lymphoid tissue which, especially in early life, collects in small masses, termed *gastric lymphatic follicles*, which resemble solitary intestinal follicles. In the mucosa, deep to the glands, is a thin stratum of non-striated muscle fibres, the *muscularis mucosae*, arranged as inner circular and outer longitudinal layers, with a third external, circular layer in places. The inner layer sends strands of myocytes between the glands, contraction probably aiding their emptying.



Vessels and Nerves

The arterial supply of the stomach comes from the left gastric artery (from the coeliac artery), right gastric and right gastro-epiploic (from the common hepatic) and the left gastro-epiploic

8.125 Dissection to show the duodenum, pancreas, stem arterial rami of the gastrointestinal tract and surrounding structures. The right and left hepatic veins have been cut away at their points of entry into the inferior vena cava. The superior hypogastric plexus is shown in front of the sacral promontory and the sympathetic nerves which form it are seen descending across the bifurcation of the aorta, the left common iliac vein and the body of the fifth lumbar vertebra. (In this specimen the left renal artery is situated anterior to the left renal vein at the hilum of the kidney.)

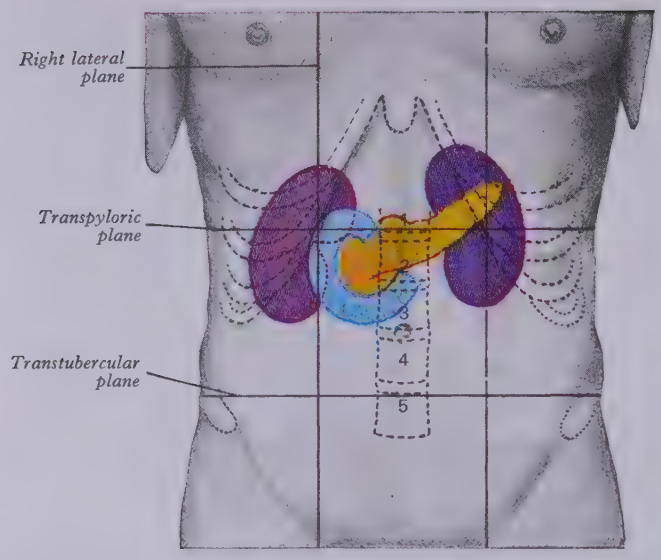
and short gastric (from the splenic) artery. These vessels not only anastomose extensively on the serosal aspect of the stomach (p. 768) but also form anastomotic networks within its walls at intramuscular, submucosal and mucosal levels; a true plexus of small arteries and arterioles is present in the submucosa. This *submucosal plexus*, from which the mucosa is supplied, shows considerable regional variation both in the gastric wall and also in the proximal duodenum. In view of a possible vascular factor in the genesis of peptic ulcers, the local details of angio-architecture are of interest. That of the mucosa of the body of the stomach was described recently by Raschke et al (1987). Arteriovenous anastomoses are said to occur in the gastroduodenal mucosa (Spanner 1932, De Busscher 1948, Barlow et al 1951, Boulter & Parkes 1963); dysfunction in these might produce local ischaemia and ulceration. Mucosal end-arteries have also been described and larger vessels such as the supraduodenal artery (p.769) have been similarly designated end-arterial. Such problems have been discussed anatomically by Piasecki (1974, 1977) and the results of his observations on fetal, neonatal and adult human stomachs, injected with India ink, are the basis of this account of gastric intramural arteries. From anastomotic arcades along the greater and lesser curvatures, formed by the main arteries of supply described above, many *anterior* and *posterior gastric arteries* pass to the anterior and posterior aspects, approximately transverse to the organ's long axis. Smaller rami, often paired, also pass directly to parts of the gastric wall subjacent to the omental attachments. All these vessels ramify on the external surface and penetrate the muscular layers to reach the submucosa and mucosa, forming subserosal, intramuscular and submucosal plexuses, the second being the best developed (**8**.126A,B). This muscular plexus is supplied by branches from the subserous and submucosal plexuses; the muscular vessels vary in direction in different muscular laminae, perhaps adaptating to directions of contraction. Submucosal arteries anastomose freely, but the incidence of anastomoses varies. Counts by Piasecki (1974) showed that while anastomoses along, e.g. the lesser curvature, increased in *number* from cardia to pylorus; the mean *calibre* of anastomosing arteries showed a reverse tendency. Mucosal arteries, which fill the capillary networks supplying the epithelium and its glands, are mainly from the submucosal plexus; but along both curvatures a few mucosal arteries come directly from subserosal sources, traversing the muscular layers and submucosa, often without lateral junctions with submucosal arteries; their frequency apparently increases from the cardiac to the pyloric regions; the capillary networks supplied by them are largely independent of those fed by adjacent submucosal arteries and the patch of mucosa supplied by such a vessel is perhaps more vulnerable to vascular obstruction. Mucosal arteries in general do not form lateral anstomoses but, since their submucosal feeders do, vascular obstruction is less likely. Piasecki also showed a different pattern of supply in the pyloric canal and sphincter. 'Pyloric arteries', rami of the right gastric and gastro-epiploic arteries, pierce the duodenum distal to the sphincter around its entire circumference, passing through the muscular layer to the submucosa where each divides into two or three rami, which turn into the pyloric canal, internal to the sphincter; they traverse the submucosa to the end of the pyloric antrum (**8**.126B), supplying the whole mucosa of the pyloric canal. Branches of these pyloric submucosal arteries may anastomose at their commencement with the duodenal submucosal arteries and, by their terminal rami, with corresponding gastric arteries. The pyloric sphincter is supplied by the gastric and pyloric arteries, whose rami leave their parent vessels in the subserosal and submucosal levels to penetrate the sphincter. In a more recent study, Piasecki (1986) has described arrangements in a large number of animals, including rodents, swine, cats, dogs and monkeys, with little modification from the pattern he found earlier in primates.

Gastric veins commence as straight vessels between the mucosal glands and drain into the submucosal veins. Their further arrangment has not received as much attention as that of the corresponding arteries; but larger veins generally accompany main arteries to their ultimate drainage into the splenic and superior mesenteric veins, while some pass directly to the portal vein. Smaller **lymphatic vessels** are said to resemble the veins in distribution. Regional lymph nodes and their drainage are described on p. 851.

Nerves are from several sources (Kyosola et al 1980). The *sympathetic supply* is mainly from the coeliac plexus through its extensions around the gastric and gastro-epiploic arteries. Some rami from the hepatic plexus reach the lesser curvature between the layers of the hepatogastric ligament (p. 1343). Rami of the left phrenic plexus pass to the cardiac end of the stomach, as does one from the left phrenic branch to the right crus of the diaphragm. Inconstant gastric branches come from the left thoracic splanchnic nerves and the thoracic and lumbar sympathetic trunks.

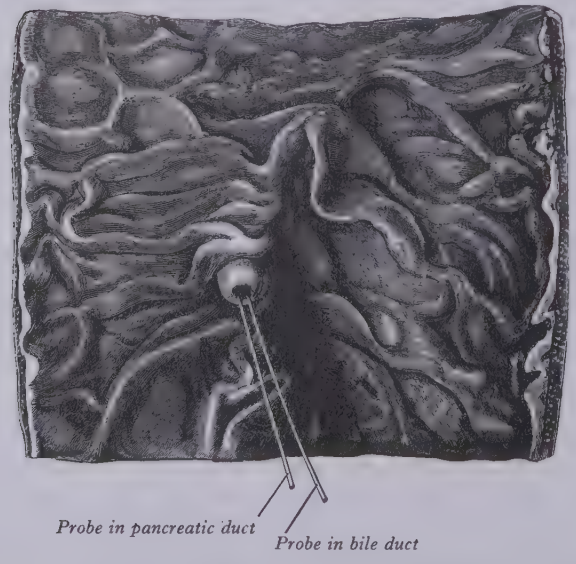


The *parasympathetic supply* is from the vagus nerves (Mackay & Andrews 1983). Usually one or two rami branch on the anterior and posterior aspects of the gastro-oesophageal junction; the anterior nerves are mostly from the left vagus and the posterior from the right vagus, emerging from the oesophageal plexus. The anterior nerves supply filaments to the cardiac orifice and divide near the oesophageal end of the lesser curvature into branches: (1) *the gastric branches* (4-10) radiate on the anterior surface of the body and fundus; one, larger than the others, lies in the lesser omentum near the lesser curvature (*greater anterior gastric nerve*); (2) *the pyloric branches*, generally two, one of which traverses the lesser omentum almost horizontally to the right, towards its free edge, then turns down on the left side of the hepatic artery to reach the pylorus, while the other, usually arising from the greater anterior gastric nerve, passes obliquely to the pyloric antrum. The posterior nerves produce two groups of branches, gastric and coeliac: (1) *gastric branches* radiate over the posterior surface of the body and fundus and extend to the pyloric antrum but do not reach the pyloric sphincter; the largest (*greater posterior gastric nerve*) passes posteriorly along the lesser curvature, giving branches to the *coeliac plexus*; (2) *coeliac branches*, larger than the gastric, pass in the lesser omentum to the coeliac plexus. No true plexuses occur on either the anterior or posterior gastric surfaces, but they do in the submucosa and between the layers of the muscularis externa. The latter corresponds to the myenteric (Auerbach's) plexus and contains many neurons. They distribute many axons containing a variety of neurotransmitters and neuromodulators (Burnstock 1986) and also sensory fibres to the muscular tissue and the mucosa.

The vagus has both secretory and motor effects on the stomach; vagal stimulation evokes a secretion rich in pepsin and increases gastric motility; after vagotomy the stomach is flaccid and empties only slowly. The sympathetic nerve supply is vasomotor to the gastric blood vessels and provides the main pathway for gastric pain fibres.

The Small Intestine

The small intestine, a coiled tube, extends from the pylorus to the ileocaecal valve, where it joins the large intestine. It is usually said to be 6–7 m long, gradually diminishing in diameter towards its termination. However, it is longer after death owing to the loss of muscle tone; its average length in living adults is perhaps about 5 m (vide infra). In 109 adult subjects shortly after death it ranged from 3.35–7.16 m in women and from 4.88–7.85 m in men, the average being 5.92 m in women and 6.37 m in men (Underhill 1955). Length was correlated with the height of the individual but was independent of age; the large intestine was much more constant in length. Jit & Grewal (1975), reviewing the topic, reported findings in 137 Indian subjects confirming these associations with height and noting lack of a correlation with weight. They observed that fixation in formalin caused contraction which sometimes reached 44%. Various observers have also passed flexible tubes through the alimentary tract, recording total lengths of 2.7–4.5 m (see Jit & Grewal 1975).



The small intestine occupies the central and lower parts of the abdominal cavity, usually within the colonic loop; it is related in front to the greater omentum and abdominal wall; a portion may reach the pelvis in front of the rectum. It consists of a short, curved sessile section, the *duodenum*, and a long, greatly coiled part attached to the posterior abdominal wall by the mesentery (p. 1344), the proximal two-fifths being the *jejunum*, the distal three-fifths, the *ileum*.

8.127 Surface projection of the duodenum, pancreas and kidneys. The lumbar vertebrae are numbered.

THE DUODENUM

The duodenum (**8**.125) is 20–25 cm long (*12* in., hence the name) and is the shortest, widest and most sessile part of the small intestine. It has no mesentery, and is thus only partially covered by peritoneum. It is constantly curved in an incomplete circle, enclosing the head of the pancreas. It is situated entirely above the level of the umbilicus. Arising from the pylorus, it passes backwards, up and to the right for about 5 cm, inferior to the posterior part of the quadrate lobe, to the neck of the gallbladder; its direction varies slightly according to the distension of the stomach. It then curves abruptly (*superior duodenal flexure*) to descend about 7.5 cm anterior to the medial part of the right kidney, usually to the level of the lower border of the third lumbar vertebral body, just medial to the lateral plane (**8**.127). At a second bend (*inferior duodenal flexure*), it turns horizontally left across the vertebral column for about 5–10 cm, just above the umbilical level, with a slight upward slope; it then ascends in front and to the left of the abdominal aorta for about 2.5 cm, ending opposite the second lumbar vertebra in the jejunum. At this union it turns abruptly forwards; this *duodenojejunal flexure* is about 2.5 cm left of the midline and 1 cm below the transpyloric plane. For descriptive purposes it is hence divided into parts: first (superior), second (descending), third (horizontal) and fourth (ascending).

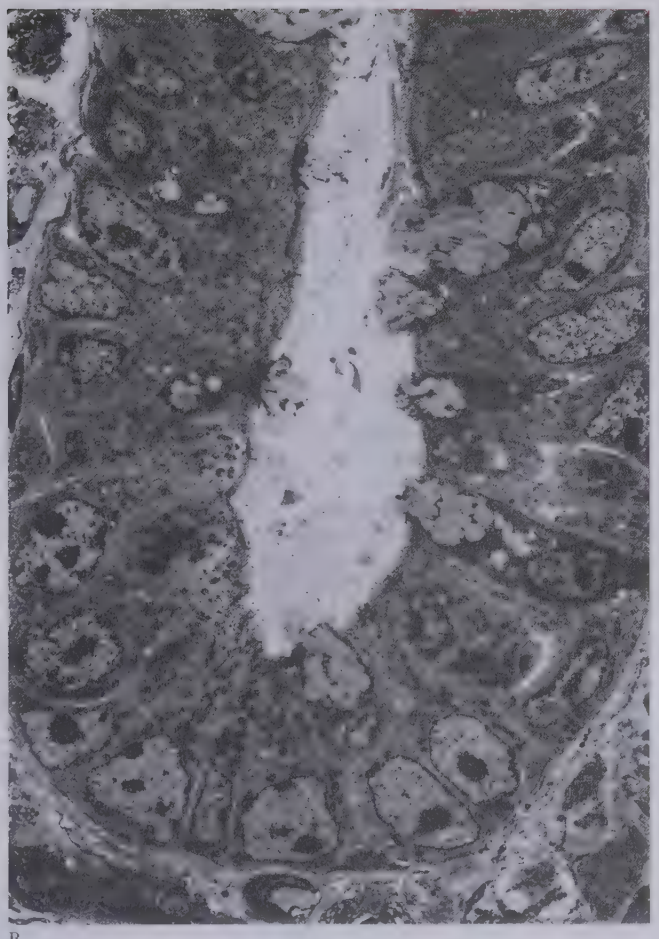
8.128 Interior of the descending (second) part of the duodenum, showing the major duodenal papilla.

Duodenal Relations

The superior (first) part, about 5 cm long, is the most mobile section, extending from the pylorus to the neck of the gallbladder. Peritoneum covers its anterior aspect but it is bare of this posteriorly, *except near the pylorus* where it takes a small part in the formation of the anterior wall of the omental bursa; here the lesser omentum is attached to its upper border and the greater omentum to its lower (proximal half). It is related above and in front with the quadrate lobe of the liver and gallbladder and more posteriorly above with the epiploic foramen, behind with the gastroduodenal artery, bile duct and portal vein and posteroinferiorly with the head and neck of the pancreas. It is usually stained by bile after death especially on its anterior surface where it is related to the gallbladder.

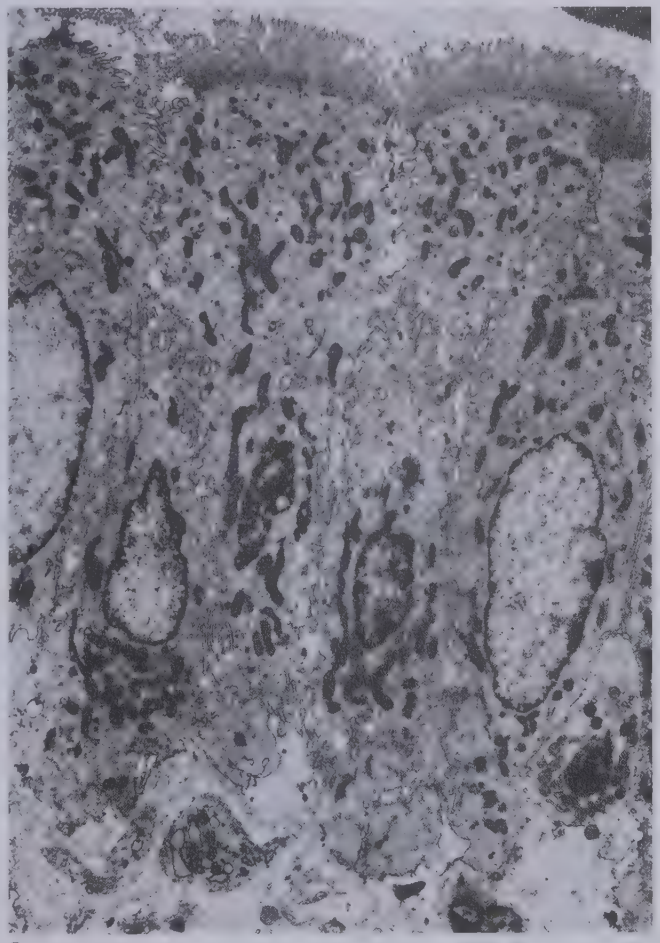
The descending (second) part, from 8–10 cm long, descends from the neck of the gallbladder along the right side of the vertebral column to the lower border of the third lumbar vertebral body. Crossed by the transverse colon, it is connected to it by some areolar tissue and above and below this attachment it is covered in front with peritoneum. It is related in front, from above downwards: to the right lobe of the liver, transverse colon and the root of its mesocolon and to the jejunum; behind it is variably related to the right kidney near to its hilum, being connected to it by areolar tissue, to the right renal vessels, the edge of the inferior vena cava and psoas major. Medial to it are the head of the pancreas and bile duct, while lateral is the right colic flexure. A small part of the pancreatic head is sometimes embedded in the duodenal wall. The bile and pancreatic ducts come into contact at its medial side, entering its wall obliquely and uniting to form the *hepatopancreatic ampulla* (p. 1394). The narrow, distal end of this opens on the summit of the *major duodenal papilla*, sited posteromedially in the descending duodenum (**8**.128, 150), 8–10 cm distal to the pylorus. An accessory pancreatic duct may open about 2 cm proximal to the major papilla on a *minor duodenal papilla*.

The horizontal (inferior or third) part, about 10 cm long, passes from the right of the lower border of the third lumbar vertebra, sloping slightly up and to the left across the inferior vena cava, to end in the fourth part in front of the abdominal aorta. Its anterior surface is covered with peritoneum, except in the median plane where it is crossed by the superior mesenteric vessels and mesenteric root. Its posterior surface is covered by peritoneum only at its left end, where the left layer of the mesentery sometimes covers it. The posterior surface rests upon: the right ureter, right psoas major, right testicular (or ovarian) vessels, the inferior vena cava and the abdominal aorta (with the origin of the inferior mesenteric artery). Its superior aspect is related to the head of the pancreas, its inferior to coils of the jejunum.



The ascending (fourth) part, about 2.5 cm long, ascends on or immediately to the left of the aorta, to the level of the upper border of the second lumbar vertebra, where it turns forwards into the jejunum at the *duodenojejunal flexure*; it is anterior to the left sympathetic trunk, left psoas major, left renal and gonadal vessels and the inferior mesenteric vein. To the right it gives attachment to the upper part of the root of the mesentery, its left layer being continued over the duodenum's anterior surface and left side. To its left are the left kidney and ureter; above is the body of the pancreas; in front are the transverse colon and transverse mesocolon, the latter separating the duodenojejunal flexure from the omental bursa and stomach.

The superior part of the duodenum is slightly mobile, while the rest is almost fixed, being sessile upon neighbouring structures. Radiologically, after a barium meal, the superior part appears as a triangular, homogeneous shadow, the 'duodenal cap' (**8**.122).



The terminal part and the duodenojejunal flexure are said to be positioned by the '*suspensory muscle of the duodenum*' (suspensory muscle, or ligament of Treitz), often described as being in two parts: (1) a slip of *striated* muscle derived from the diaphragm near its oesophageal opening, ending in connective tissue near the

coeliac artery and (2) a fibromuscular band of *non-striated* muscle, passing from the duodenum (third and fourth parts and duodenojejunal flexure) to blend with the same pericoeliac connective tissue. Treitz (1853) described both entities, naming the former *der Hilfsmuskel* (the accessory muscle). Subsequent authorities (Lockwood 1886, Low 1907) regarded them as a digastric muscle, naming the whole the suspensory *muscle* of Treitz, a misnomer perpetuated in most textbooks. Confusion was increased by Haley & Peden (1943), who derived the 'suspensory muscle' from the right crus, and by Argeme et al (1970), who described an intermediate tendon but regarded this as part of a 'false' digastric muscle. Jit (1952, 1977) has persistently repeated the dual nature of the original description by Treitz, supporting it by embryological and histological evidence. The diaphragmatic slip (Hilfsmuskel) has no satisfactory official name. It is supplied, according to Jit, by myelinated nerve fibres probably from the phrenic nerve (pp. 594, 1128) and is sometimes considered an aberrant part of iliocostalis thoracis. The suspensory muscle proper (non-striated) is supplied by autonomic fibres from the coeliac and superior mesenteric plexuses (Jit & Grewal 1977). Descriptions of the duodenal attachments of the muscle vary; none of these accounts contain a convincing view of its function,

the usual suggestion being that it augments duodenojejunal flexure, acting like a valve.

Vessels and Nerves

Arteries supplying the duodenum are from the right gastric, supraduodenal, right gastro-epiploic and superior and inferior pancreaticoduodenal arteries (pp. 769, 772; **6**.109.) The superior part receives two leashes of small rami, one from the hepatic artery proper and one from the gastroduodenal artery. These rami also supply the adjacent pyloric canal, with some anastomosis in the muscular layer across the pyloroduodenal junction (p. 1355). *Veins* end in the splenic, superior mesenteric and portal veins. *Nerves* are from the coeliac plexus.

THE JEJUNUM AND ILEUM

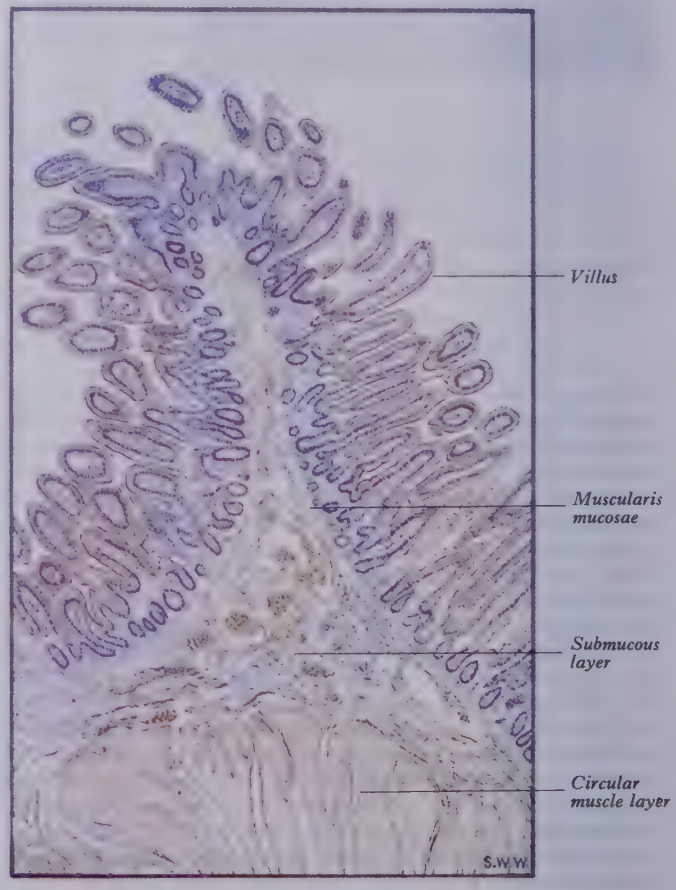
The rest of the small intestine extends from the duodenojejunal flexure to the ileocaecal valve, ending at the junction of the caecum and ascending colon. It is arranged in a series of coils attached to the posterior abdominal wall by the mesentery. It is completely covered by peritoneum, except along its mesenteric border where the two mesenteric layers diverge to enclose it. Its proximal two-fifths is the *jejunum*, the rest the *ileum*; the division is arbitrary, as the character of the intestine changes only gradually, but samples from these two 'parts' show characteristic differences.

The jejunum, with a diameter of about 4 cm, is thicker walled, redder and more vascular. Its circular mucosal folds (p. 1360) are large and frequent and its villi larger. Aggregated lymphatic follicles (p. 1363) are almost absent from the proximal (upper) jejunum; distally they are still fewer and smaller than in the ileum and are often discoidal. The circular folds can be felt through its wall and, since they are absent from the distal ileum, palpation allows a crude distinction between upper and lower intestinal levels. The jejunum lies largely in the umbilical region but may extend into surrounding areas. The first coil occupies a recess between the left part of the transverse mesocolon and the left kidney.

The ileum has a diameter of 3.5 cm; its wall is thinner than in the jejunum. A few circular folds occur proximally but these are small and disappear almost entirely in its distal part. Aggregated lymphatic follicles are, however, larger and more numerous than in the jejunum. The ileum is mainly in the hypogastric (pubic) and pelvic regions. Its terminal part usually lies in the pelvis, from which it ascends over the right psoas major and right iliac vessels to end in the right iliac fossa, opening into the medial side of the junction between the caecum and colon.

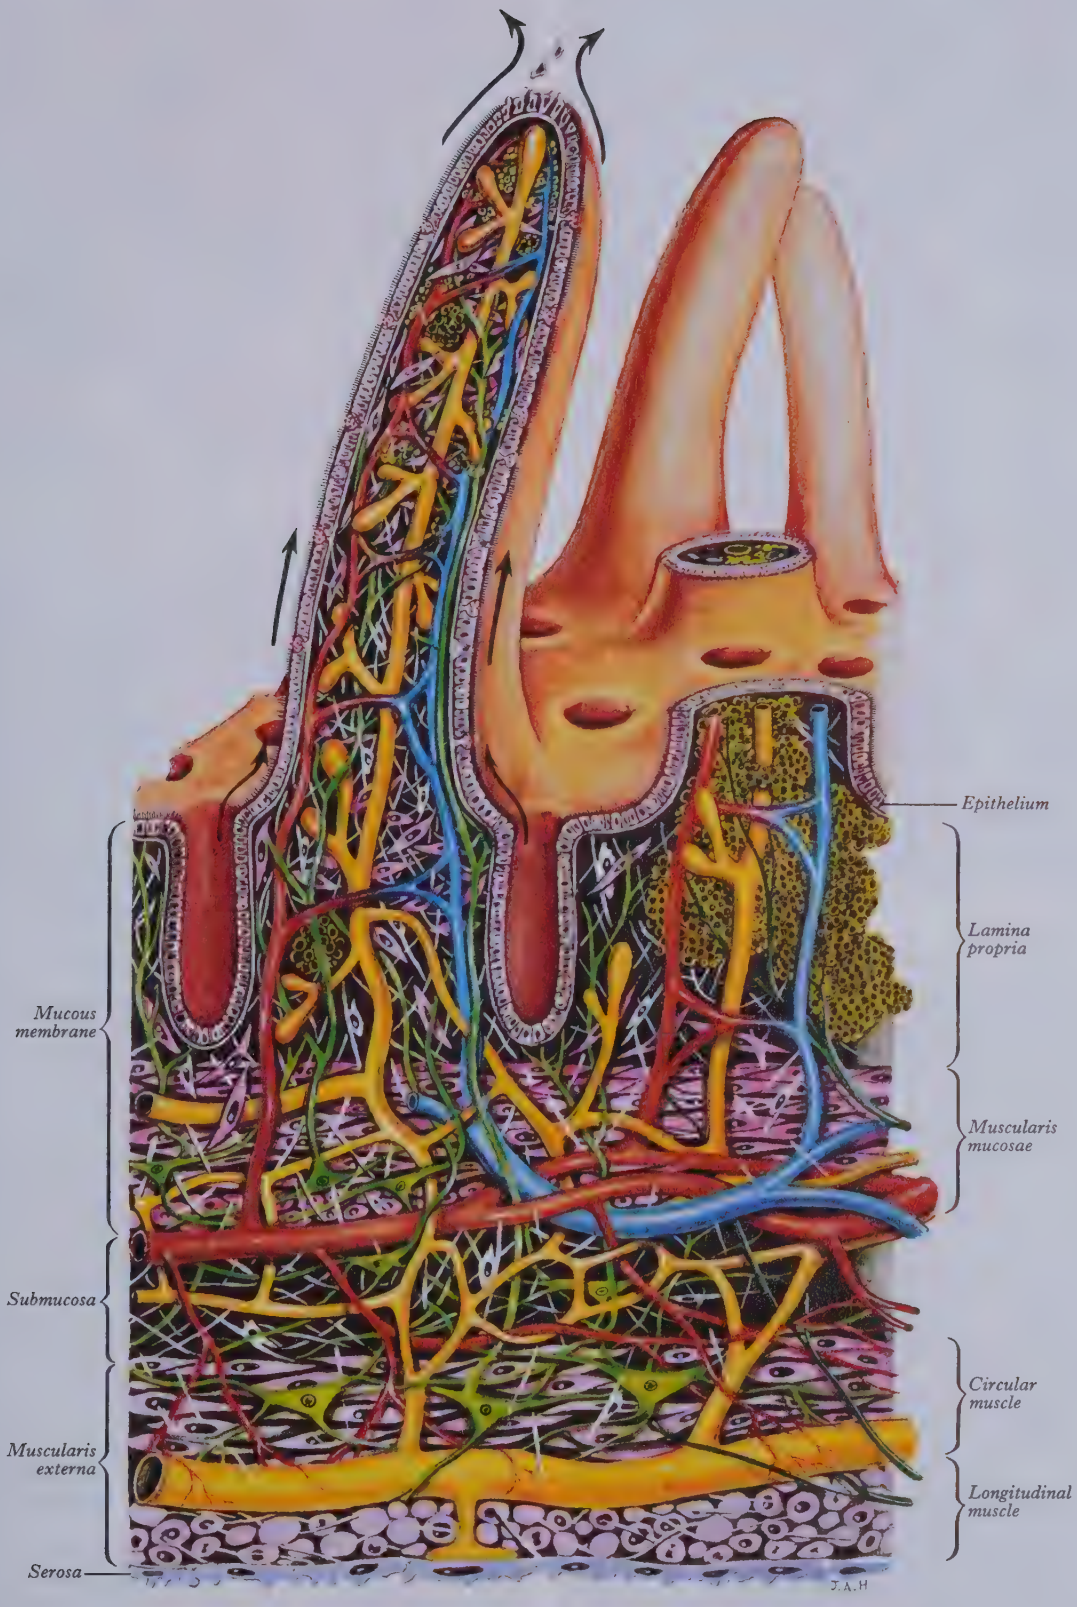
The fan-like mesenteric attachment of the jejunum and ileum to the posterior abdominal wall allows free movement, each coil adapting to changes in form and position.

The mesentery (p. 1344), like a complex fan, has a root, about 15 cm long, attached to the posterior abdominal wall along a line running diagonally from the left side of the second lumbar vertebral body to the right sacro-iliac joint, crossing successively: the horizontal part of the duodenum, aorta, inferior vena cava, right ureter and right psoas major (**8**.113). Its average breadth from its root to the intestinal border is about 20 cm, but is greater at intermediate levels. Its two peritoneal layers contain: the jejunum, ileum, jejunal and ileal branches of the superior mesenteric vessels, nerves, lacteals and lymph nodes, together with a variable amount of fat.

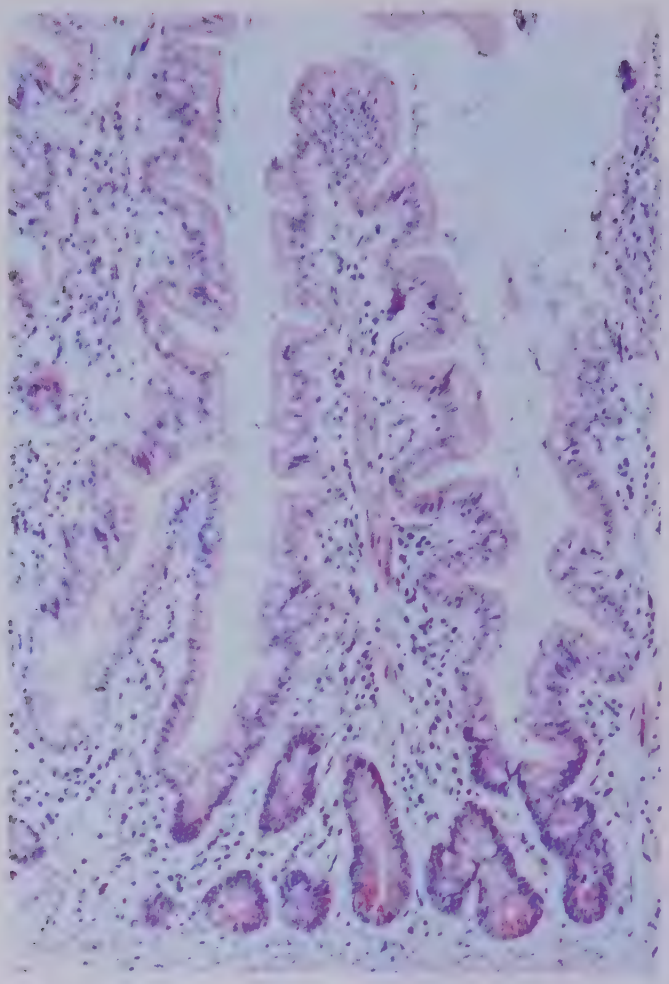


The ileal diverticulum (of Meckel) projects from the antimesenteric border of the distal ileum in about 3% of subjects, its average position being about 1 m above the ileocaecal valve and its average length about 5 cm. Its calibre is like that of the ileum, its blind extremity being free or connected with the abdominal wall or some other part of the intestine by a fibrous band. It represents the vitelline (yolk) duct's persistent proximal part (pp. 141, 233, 235); its mucosa is ileal in type but small areas may have a gastric structure, with oxyntic cells secreting acid. Sometimes heterotopic areas of pancreatic or other tissues occur in its wall. In a study of 1816 late fetal and neonatal cadavers Miyabara et al (1974) found a diverticulum in 61 individuals (3.4%). Of these, gastric mucosa was present in 11, jejunal mucosa in two, colonic mucosa in two and pancreatic tissue in one.

STRUCTURE OF THE SMALL INTESTINE

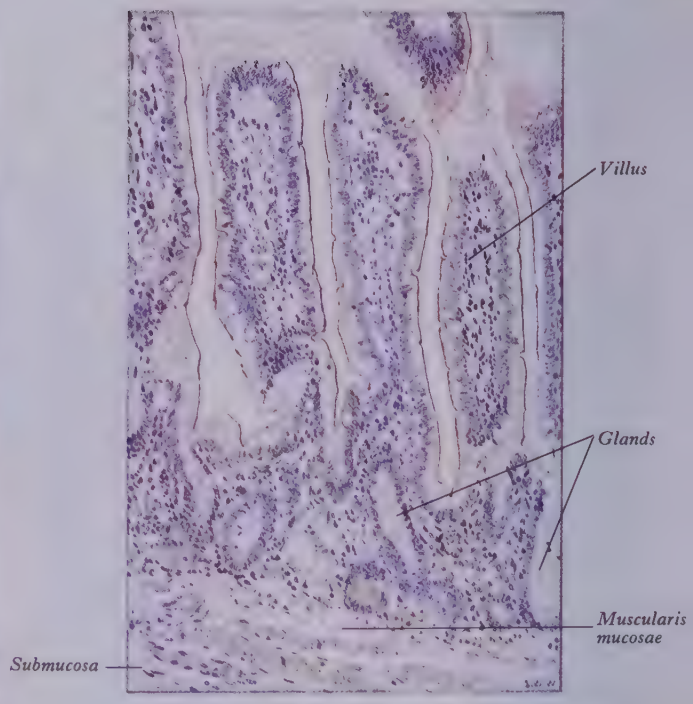


The intestinal wall has the usual serous, muscular, submucous and mucous layers (**8**.131). The serosa is visceral peritoneum with a subserous stratum of loose connective tissue. The *muscularis externa* is thicker in the proximal intestine, consisting of a thin external longitudinal and a thick internal circular layer of non-striated myocytes. The submucosa is loose connective tissue carrying blood vessels, lymphatics and nerves. The mucosa is thick and very vascular in the proximal small intestine, but thinner and less vascular in the distal. It forms *circular folds*



8.130A Internal aspect of a representative sample of the proximal jejunum, showing circular folds.

8.130B Section through a circular fold from the human small intestine. Stained with haematoxylin and eosin. Magnification × 19.



8.131 A three-dimensional reconstruction of the architecture of the intestinal villi and subjacent wall (the principal layers of the latter are indicated): arteries and arterioles (red), veins and venules (blue), central lacteals and other lymphatic channels (orange), aggregations of lymphocytes (yellow), neural elements (green), non-striated muscle fibres (magenta), fibroblasts (white). Note the orifices of the intestinal crypts (of Lieberkühn). Types of cells in the epithelium include absorptive cells, goblet cells and entero-endocrine cells. Arrows indicate the direction of cell migration. The various layers are not drawn to scale.

(sometimes spiral) and the whole surface is covered by filiform or linguiform *intestinal villi*.

The circular folds (*plicae circulares* or *'valves' of Kerkring*, 8.130, 134) are large, crescentic folds of mucosa which project into the intestinal lumen transverse to the long axis. Unlike gastric folds they are not obliterated by distension. Most extend round about one-half or two-thirds of the luminal circumference; some are complete circles, some bifurcate and join adjacent folds, some are spiral but extend little more than once round the lumen, though occasionally two or three times. Larger folds are about 8 mm deep at their broadest, but most are smaller. Larger and smaller folds often alternate. Plicae begin to appear about 2.5–5 cm beyond the pylorus. Distal to the major duodenal papilla they are large and close together, as they also are in the proximal half of the jejunum; but from here to midway along the ileum they diminish, disappearing almost wholly in distal ileum, hence the thinness of this part of the intestinal wall. The circular folds slow the passage of contents and increase the absorptive surface (8.134).

Intestinal villi are highly vascular processes just visible to the naked eye and project from the entire intestinal mucosa, giving it a velvety texture. Large and numerous in the duodenum and jejunum, they are smaller and fewer in the ileum. In the first part of the duodenum they are broad ridges, changing to tall foliate villi in the distal duodenum and proximal jejunum, beyond which they gradually shorten to a finger-like form in the distal jejunum and ileum (Verzár & McDougall 1936, McMinn & Mitchell 1954). They vary in density from 10–40 per square millimetre and from about 0.5–1.0 mm in height. They increase the surface area about eightfold.

The mucosa (8.131) has three layers. Next to the submucosa is the *muscularis mucosae*, with external longitudinal and internal circular layers of non-striated myocytes; it extends into the circular folds and follows their surface profile. Internal to it is connective tissue, the lamina propria, in which are fibroblasts and connective tissue fibres, lymphocytes, eosinophilic leucocytes, macrophages, mast cells, capillaries, lymphatic vessels and non-myelinated nerve fibres. Plasma cells are numerous and lymphocytes in many regions are clustered in solitary and aggregated lymphatic follicles, some extending through the muscularis mucosae into the submucosa. Internal to the lamina propria a basement membrane supports an epithelium composed mainly of

8.132D Part of a transverse section of the ileum, showing zymogenic (Paneth) cells containing orange-stained zymogen granules at the base of an intestinal gland. 'Undifferentiated' epithelial cells are also visible. Mallory's azan stain. Magnification × 400.

Magnification × 4800.

columnar cells, except over the lymphatic follicles where they are partly replaced by follicle-associated epithelial cells (*microfold* or *membrane* (M) cells, pp. 833, 1362), which may be specialized for transport of antigens (Owen & Nemamic 1978). Extending into the mucosa between the intestinal villi are simple, tubular, *intestinal glands (crypts of Lieberkühn)*, reaching almost to the muscularis mucosae. In the duodenum there are also branched tubulo-alveolar *duodenal mucous glands* (of *Brunner*), their ducts extending through the muscularis mucosae to expand into the submucosa; their secretions contain mucosubstances, bicarbonate ions and a small amount of enzyme helping to activate trypsinogen from the pancreas.

Structure of Intestinal Villi

A villus has a core of reticular tissue containing a lymph vessel or lacteal, blood vessels, nerves and non-striated myocytes, covered by columnar epithelium on a basement membrane (**8**.131, 132A).

The lacteal, usually single but occasionally double, starts in a closed, dilated extremity near the villous summit and descends to empty into a lymphatic plexus in the lamina propria. Its wall is a single layer of endothelial cells.

Myocytes derived from the muscularis mucosae cluster around the lacteal from the base to the summit of the villus, some being attached to both the basement membrane of the epithelium and the lacteal. Contraction of these myocytes therefore 'milks' the lacteals.

Blood vessels form a capillary plexus in the lamina propria, enclosed in reticular tissue; capillaries are lined by fenestrated endothelium, probably to ensure the rapid uptake of nutrients diffusing from epithelium (Clementi & Palade 1969).

The epithelium of the villi is mainly of (1) absorptive columnar cells and (2) interspersed goblet cells.

(1) **The columnar cells, enterocytes** (1.4), are granular, with a clear oval basal nucleus. At the surface is a refractile, vertically striated zone, about 1 μm in depth, the *striated* or *brush border*, rich in alkaline phosphatase and concerned in active absorption; electron microscopy shows it to be composed of minute parallel

8.133B Electron micrograph of the apical region in a columnar cell from the jejunum (rat) showing the regular series of microvilli which constitutes the striated border of light microscopy. Filaments can be seen passing from the microvilli to the terminal web. Magnification *c.* × 32 500.

8.134A Radiograph showing the small intestine, taken during a barium follow-through. The feathery appearance of the profile of the small intestine is due to the plicae circulares; constrictions due to peristalsis can also be seen. Provided by Shaun Gallagher; photography by Sarah Smith, UMDS, Guy's Hospital Campus, London.

cylindrical microvilli, about 1 μm long and 0.1 μm broad. External to the villar plasma membrane, electron microscopy show a thick glycocalyx (p. 20) composed of fine filaments, rich in mucosubstances. In the cytoplasmic core of each microvillus are fine filaments basally continuous with a plexiform band of similar filaments in the cell's apical cytoplasm, the *terminal web*, containing occasional vesicles (**8**.133B). Lateral plasma membranes of columnar cells are often interdigitated; they have typical juxtaluminar junctional complexes (p. 24, **1**.13), and scattered desmosomes; basally they are separated from adjacent cells by intercellular canaliculi. The basal plasma membranes are usually smooth and adjoin a basement membrane about 20 nm wide. Rod-shaped mitochondria are scattered in the cytoplasm with some granular and agranular endoplasmic reticulum. The Golgi apparatus is supranuclear and the apical region, beneath the terminal web, contains numerous lysosomes. At the summits of intestinal villi these cells are often in the process of disintegrating, their cytoplasm darkly staining and their microvilli stunted and degenerate. Changes in the microvillous surface area have also been shown to occur during reproduction (in female rats) and during ageing (Penzes & Regius 1985).

The roles of these cells in digestion and absorption have attracted much attention. The absorption of amino acids and simple carbohydrates is probably facilitated by diffusion across cell membranes, materials traversing the cells to subjacent capillary arrays in the lamina propria. Lipid absorption appears to be by diffusion of small molecules (fatty acids, etc.) through the luminal membrane, the lipid accumulating in vacuoles in the apical cytoplasm, before reaching the subjacent lymphatics. Examination of striated borders isolated by fractionation and centrifugation has shown that enzymes such as disaccharidases are bound to their surfaces, where much intestinal digestion may occur, perhaps in the cell coat in close proximity to the site of absorption.

(2) **Goblet cells** have elongated, basal nuclei and an apical region distended with membrane-bound mucin granules. The golgi apparatus is well developed and supranuclear in position; the perinuclear granular endoplasmic reticulum is abundant. Microvilli are less frequent and irregular and their terminal web is rudimentary. The mucin is said to be discharged by fusion of the granules with the plasma membrane in a merocrine manner (**8**.1A, 133A).

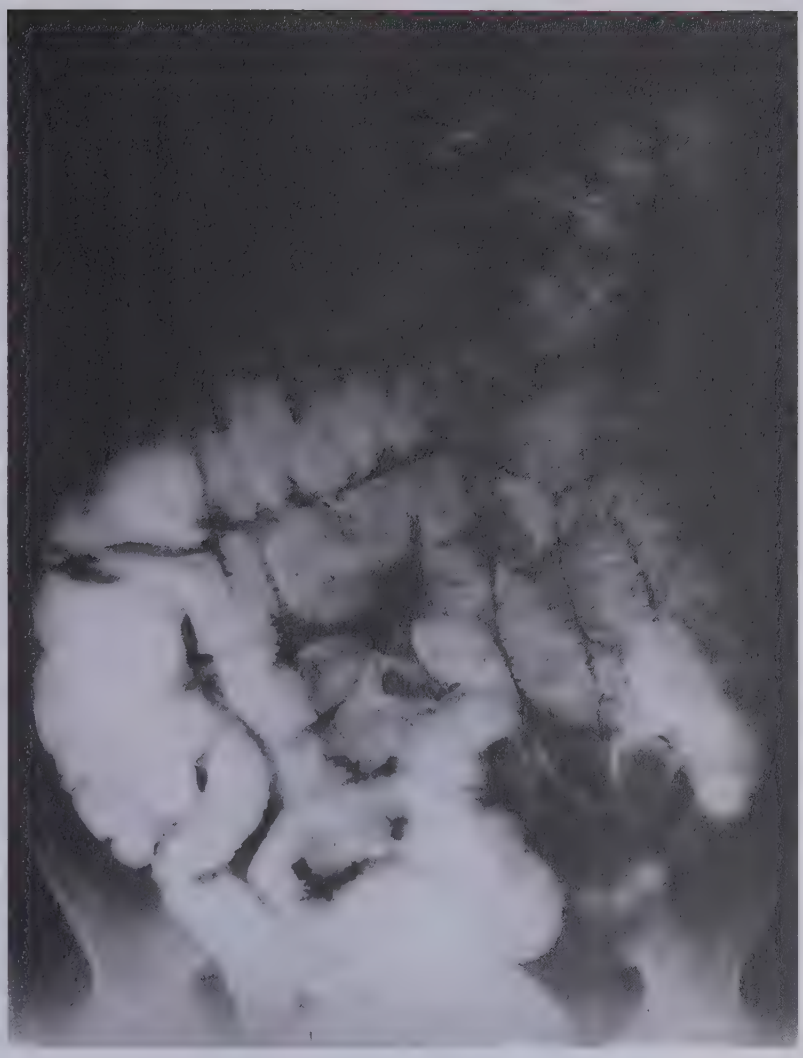
Intestinal glands are numerous throughout the intestinal mucosa. They are tubular, perpendicular pits, opening at small circular apertures and visible with a simple lens as minute dots between the villi. Their thin walls consist of columnar epithelium on a basement membrane, associated with which is a rich capillary plexus (**8**.131). The epithelium consists of (a) undifferentiated stem cells, (b) zymogenic (Paneth) and (c) argentaffin cells.

(a) **Undifferentiated stem cells** are the most numerous and proliferate by mitotic division, their progeny ascending out of the intestinal glands along the sides of the villi, where they differentiate into columnar or goblet cells; eventually they reach the apices of villi and are shed. Thus the villous epithelium is continually renewed. The apical surfaces of these cells, when not dividing, have fewer and more irregular microvilli than do the columnar cells, with occasional pseudopodia. Their lateral plasma membranes are smooth, but intercellular junctions are similar in both types of cell. Their nuclei are basal and the terminal webs poorly developed. Membrane-bound secretory granules are believed to be discharged by both apocrine and merocrine methods. These cells multiply at the rate of 1 cell per 100 per hour, one of the most rapid proliferation rates in the body (Lipkin et al 1963, MacDonald et al 1964).

(b) **Zymogenic cells** (of Paneth) are numerous in the deeper parts of the intestinal crypts, particularly in the duodenum. They are rich in zinc and contain acidophilic granules (**8**.132D) staining with e.g. phosphotungstic haematoxylin. Electron microscopy shows irregular apical microvilli and prominent membrane-bound vacuoles containing a granular matrix with crystalline inclusions in the supranuclear cytoplasm. These vacuoles are PAS positive and they contain some carbohydrate. Scattered mitochondria, lysosomes and much granular endoplasmic reticulum are present, especially in the basal region. The functions of zymogenic cells are not certain, but there is evidence that they secrete lysozyme, an antibacterial substance. For further details, see e.g. Rodning et al (1982).

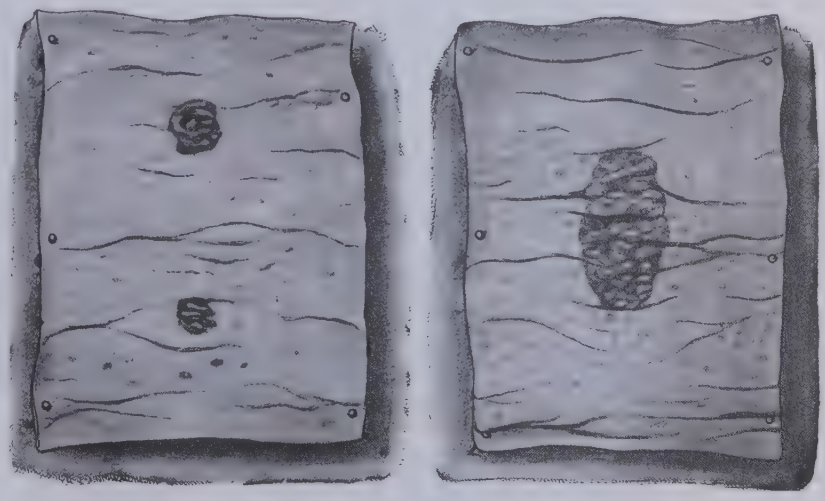
(c) **Argentaffin or enterochromaffin cells** are present among the cells lining the intestinal glands, and less commonly over the villi. They are pyramidal or columnar cells containing cytoplasmic granules which stain black with silver salts (hence *argentaffin*) and brown with chromium salts (hence *enterochromaffin*). They have been classified as one or more types of APUD cell (Pearse 1980, see also pp. 1376, 1379). Distributions of these and other cells of the gastro-entero-endocrine system are shown in **8**.146C.

Duodenal glands (of Brunner), limited to the duodenum (**8**.129), are sited *in the submucous connective tissue*, i.e. their ducts traverse the muscularis mucosae. Largest and most numerous near the pylorus, and forming an almost complete layer in the superior part and proximal half of the descending duodenum, they gradually diminish and disappear at the duodenojejunal junction. They are small, compound and acinotubular, each having several alveoli lined by short columnar epithelium and apparently containing a single type of exocrine cell in humans, a typical mucous element. Nuclei of these cells, small and basal, vary during the secretory cycle. The golgi apparatus is extensive and mucin droplets numerous. Many argentaffin cells (vide



supra) are present among the mucinogenic cells. These glands secrete a watery fluid rich in bicarbonate, which helps to neutralize the acid secretions of the stomach as the food enters the duodenum. The cells may also secrete a trypsinogen-activating factor which converts this enzyme to trypsin after secretion from the pancreas.

Solitary lymphatic follicles, scattered throughout the intestinal mucosa, are most numerous in the distal ileum, their luminal surfaces being covered by rudimentary villi, except at their summits. Each follicle, surrounded by the openings of intestinal glands, consists of dense reticular tissue packed with lymphocytes and a dense capillary network. Reticular spaces are continuous with larger lymph spaces around the follicle, communicating thus with the lacteals. They are partly submucosal, partly mucosal and have 'M' cells (p. 1361) in their surface epithelium.



Aggregated lymphoid follicles (Peyer's patches, **8**.135A) are circular or oval, each containing 10–260 follicles, and varying in length from 2 to 10 cm. Like other lymphoid tissue (except lymph nodes) solitary and aggregated lymphoid follicles are most prominent around puberty, when they may number up to 300, thereafter diminishing in number and size although many persist into old age (Cornes 1965). Aggregated follicles, largest and most numerous in the ileum, are small, circular and few in the distal jejunum and only occasional in the duodenum. They are usually antimesenteric in site and arrayed axially. Each is a group of solitary follicles covered by columnar epithelial and 'M' cells (p. 1361); villi are usually absent. An abundant vascular plexus surrounds each follicle from which fine branches permeate the lymphoid tissue. Efferent lymphatic plexuses are especially abundant. These and similar masses of unencapsulated lymphoid tissue provide B- and T-lymphocytes for the defence of the alimentary tract and form part of the system known as *gut-associated lymphoid tissue* (see p. 832). In typhoid fever follicles may ulcerate, such ulcers being oval, their long axes along the gut; hence subsequent fibrosis does not constrict the intestine.

Vessels and nerves. Jejunal and ileal *arteries* (**8**.136A,B) stem from the superior mesenteric, branches of which, reaching the mesenteric border, extend between the serosal and muscular layers. From these, numerous rami traverse the muscle, supplying it and forming an intricate submucosal plexus from which minute vessels pass to glands and villi (see p. 1361). Anastomoses between the terminal intestinal arteries are few and alternate vessels are often distributed to opposite sides of the gut. The *veins* follow the arteries. (For a detailed investigation of the distribution and variations in coeliac and superior mesenteric arteries consult Nesebar et al 1969.) The *lymph vessels* (lacteals) are arranged at two levels, mucosal and muscular. Lymph vessels of villi commence, as described on p. 1361, form an intricate plexus in mucosa and submucosa, are joined by vessels from lymph spaces at the bases of solitary follicles and drain to larger vessels at the mesenteric aspect of the gut. Lymph vessels of the muscular tunic form a close plexus running mostly between the muscle layers; they communicate everywhere with mucosal vessels and open like them into the lacteal drainage at the attached border of the gut.

Innervation is by the vagi and thoracic splanchnic nerves through the coeliac ganglia and superior mesenteric plexuses. Fibres pass to the *myenteric plexus* (p. 1331) of nerves and ganglia between the circular and longitudinal layers of the muscularis externa, which they supply. From this a secondary, *submucous plexus* is derived, formed by branches perforating the circular muscular layer; it also contains ganglionic neurons from which fibres pass to the muscularis mucosae and the rest of the mucosa. Nerve bundles in the submucous plexus are finer. Ganglion cells in both plexuses are essentially parasympathetic (vagal). An old controversy on the source of postganglionic neurons in the enteric ganglia was renewed by Andrew (1971); endodermal and mesodermal origins have been suggested, but the evidence (though largely equivocal) indicates the neural crest as their source. In general the sympathetic system inhibits peristalsis but stimulates the sphincters and muscularis mucosae. The parasympathetic generally augments peristalsis and inhibits the sphincters, the results of parasympathetic stimulation depending on the state of contraction or relaxation of the organ at the time of stimulation. The parasympathetic also augments intestinal

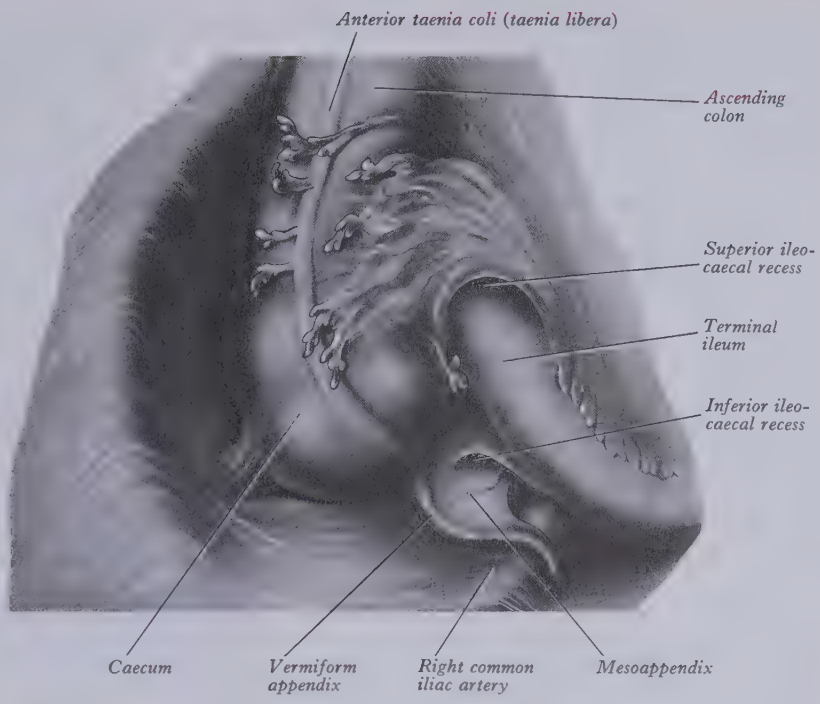
8.136 Specimens of the jejunum (A) and ileum (B) from a subject in whom the superior mesenteric artery was injected with a red coloured mass of gelatin before fixation. Subsequently the specimens were dehydrated and then cleared in benzene followed by methyl salicylate. The largest vessels present are the jejunal and ileal branches of the superior mesenteric artery and these are succeeded by anastomotic arterial arcades, which are relatively few in number (1–3) in the jejunum, becoming more numerous (5–6) in the ileum. From the arcades, straight arteries pass towards the gut wall; frequently, successive straight arteries are distributed to opposite sides of the gut. Note the denser vascularity of the jejunal wall. Specimens prepared by Michael C E Hutchinson and photographed by K Fitzpatrick, Department of Anatomy, Guy's Hospital Medical School, London.

secretion. For evaluation of the 'interstitial' cells (of Cajal) in the intestinal wall, consult Rogers & Burnstock (1966) and for a comparative study see Faussone-Pellegrini (1987). It seems probable that these are connective tissue cells and not neurons. Evidence suggests that some neurons in the intestinal ganglia may be afferent (Féher & Vajda 1974).

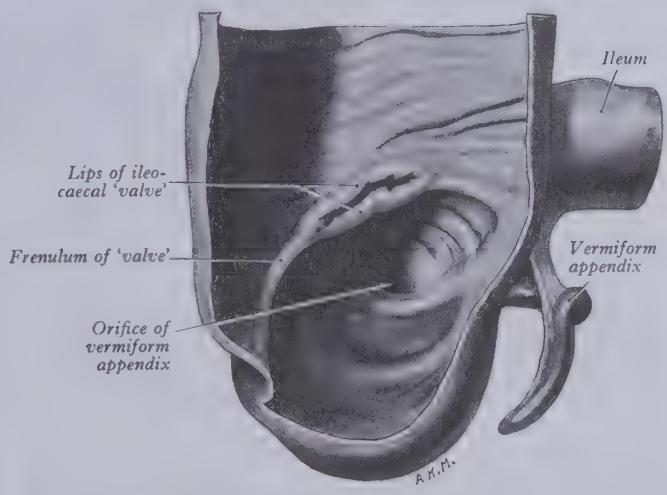
The Large Intestine

The large intestine, extending from the distal end of the ileum to the anus, is about 1.5 m long; its calibre is greatest near the caecum and gradually diminishes to the rectum, where it enlarges just above the anal canal. Its function being chiefly absorption of fluid and solutes, it differs in structure, size and arrangement from the small intestine. (1) It has a greater calibre. (2) It is for the most part more fixed in position. (3) Its longitudinal muscle, though a *complete* layer, is concentrated into three longitudinal *taeniae coli*. (4) The colonic wall is puckered into *sacculations* (*haustrations*) by the taeniae (so it is said) but sacculation is probably not thus fully explained (p. 1374; see also Hamilton 1946, Pace 1968). (5) Small adipose projections, *appendices epiploicae*, are scattered over the free surface of the whole colon, but are absent from the caecum, vermiform appendix and rectum.



The large intestine curves around the coils of the small intestine, commencing in the right iliac region as a dilated *caecum* (*intestinum crassum caecum*). (The term *caecum*, like rectum, duodenum, etc. is an adjective, used by linguistic abbreviation as a noun.) The caecum leads to the *vermiform appendix* and *colon*, the latter ascending in the right lumbar and hypochondriac regions to the inferior aspect of the liver; here it bends (*right colic flexure*, **8**.125) to the left and, with an antero-inferior convexity, loops across the abdomen as the *transverse colon* to the left hypochondriac region, where it curves again (*left colic flexure*, **8**.125) to descend through the left lumbar and iliac regions to the lesser pelvis. Here it forms a sinuous loop, the *sigmoid colon* (**8**.142), continuing along the lower posterior pelvic wall as the *rectum* and *anal canal*.

THE CAECUM



The caecum (**8**.137A,B) lies in the right iliac fossa; its surface projection occupies the triangular area between the right lateral and transtubercular planes and the inguinal ligament. It is a large cul-de-sac continuous with the ascending colon at the level of the ileal opening on the medial side and below this with the vermiform appendix. Its average axial length is about 6 cm and its breadth about 7.5 cm. It is superior to the lateral half of the inguinal ligament, resting posteriorly on the right iliacus (with the lateral cutaneous nerve of the thigh interposed) and psoas major, separated from both by covering fasciae and peritoneum. Posterior to it is the *retrocaecal recess* (p. 1345) frequently containing the vermiform appendix. Anteriorly, it usually contacts the anterior abdominal wall, but the greater omentum and, when it is empty, some coils of the small intestine may intervene. Usually it is entirely covered by peritoneum, but sometimes incompletely, when the upper part of the posterior surface is sessile and connected to the iliac fascia by areolar tissue. Commonly, however, the caecum is mobile, and may even herniate through the right inguinal canal. It can also usually be delivered through an appropriate incision in the anterior abdominal wall at appendicectomy.

Caecal Variations

The caecum has been classified into four types (Treves 1885). In early fetal life it is short, conical and broad at the base, with an apex turned superomedially towards the ileocaecal junction. As the fetus grows, the caecum increases more in length than breadth, to form a longer tube with a narrower base but retaining the same inclination. Distal growth later ceases, but the proximal part continues to grow in breadth, so that at birth a narrow vermiform appendix extends from the apex of a conical caecum. This *infantile form* persists throughout life in about 2%, regarded by Treves as the *first* type; the three taeniae coli (p. 1374) start from the appendix and are equidistant from each other. In the *second type*, the caecum becomes quadrate by outgrowth of a saccule on each side of the anterior taenia; these saccules are of equal size and the appendix arises from the depression between them instead of from the apex of a cone. This type occurs in about 3%. In the *third type* (normal in humans) the two saccules grow at unequal rates, the right more rapidly, forming a new 'apex'; the original apex, with the appendix attached, is pushed towards the ileocaecal junction; the taeniae still start from the appendicular base but are not equidistant, the growth of the right saccule pushing between the anterior and posterolateral taeniae. This type occurs in about 90%. The *fourth type* is merely an exaggeration of the third, the right saccule growing still further and the left atrophying so that the original caecal apex and appendix are near the ileocaecal junction, the anterior taenia also turning medially to it. This type occurs in about 4%. In a more recent study (Pavlov & Pétrov 1968) of 82 males and 44 females (adolescent and adult), the third type was designated *ampullary*, accounting for 78%. An *infundibular* type, approximating to the infantile conical category,

occurred in 13%; 9% were intermediate. The caecum was mobile 20% more often in females. (For further analyses consult Balthazar & Gade 1976.)

THE ILEOCAECAL VALVE

The ileum opens into the posteromedial aspect of the large intestine, at the junction of the caecum and colon (**8**.137B). A surface marking of this structure is the intersection of the right lateral and transtubercular planes; about 2 cm below this the vermiform appendix opens into the caecum. The ileocaecal orifice has a so-called 'valve', consisting of two flaps projecting into the lumen of the large intestine (Decarvalho et al 1987). In the distended, fixed caecum the flaps are semilunar. The upper, approximately horizontal, is attached to the junction of the ileum and colon, the lower, longer and more concave, to the junction of the ileum and caecum. At their ends the flaps coalesce, continuing as narrow membranous ridges, the *frenula* of the valve. The anterior or left end of the aperture is rounded, the right or posterior is narrow and pointed. In the natural state the valvular lips project as thick folds into the caecal lumen, the orifice appearing like a slit or oval. Circular and longitudinal muscle layers of the terminal ileum continue into the valve to form a sphincter. However, direct observation of the living ileocaecal 'valve' does not corroborate this description (Rosenberg & DiDio 1969); in nine cases, studied by caecostomy, the ileal projection was papillary in shape. Radiological evidence also contradicts the concept of an effective ileocaecal valve at this junction.

Accumulations of circular fibres, sometimes described as sphincters, have been observed at various levels in all parts of the colon (DiDio & Anderson 1968, Rosenberg & DiDio 1969). The functional reality of most of these remains doubtful. Such sphincteric mechanisms must, of course, be balanced by antagonistic, dilatatory actions.

The margin of the ileocaecal valve is a reduplication of the intestinal mucosa and *circular* muscle; longitudinal fibres are partly reduplicated as they enter the valve (Jit & Singh 1956), but the more superficial and the peritoneum continue uninterruptedly from the small to the large intestine. The ileal valvular surfaces are covered with villi and have the structure of the mucosa of the small intestine; their caecal aspects display no villi but numerous orifices of tubular glands peculiar to the colonic mucosa. It is usually said that the valve not only prevents reflux from the caecum to the ileum but is probably also a sphincter regulating the passage of ileal contents into the caecum; the valve is kept in tonic contraction by sympathetic innervation. Entry of food into the stomach initiates contraction of the small intestine, expelling ileal contents into the large intestine (the gastro-ileal reflex).

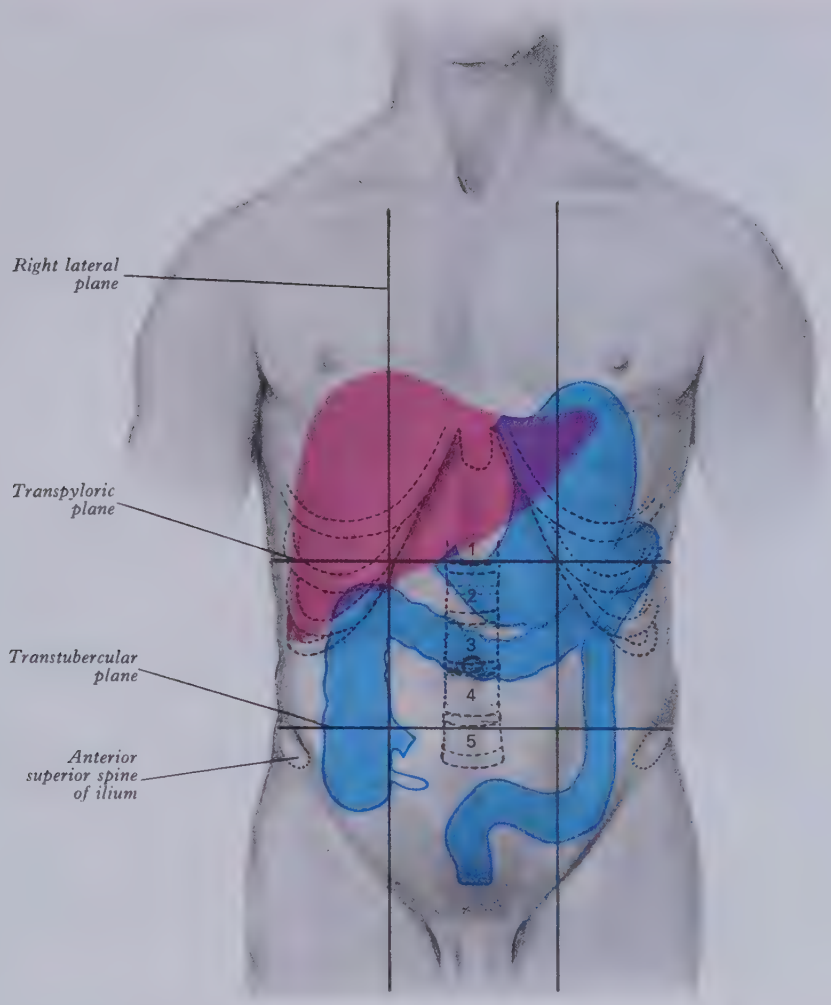
THE VERMIFORM APPENDIX



The vermiform appendix (**8**.137A,B) is a narrow, vermian (worm-shaped) tube, arising from the posteromedial caecal wall, 2 cm or less below the end of the ileum. It may occupy one of several positions: (1) behind the caecum and lower ascending colon *(retrocaecal and retrocolic)*; (2) dependent over the pelvic brim *(pelvic* or *descending)*, in females in close relation to the right uterine tube and ovary; (3) lying below the caecum *(subcaecal)*; (4) in front of the terminal ileum when it may be in contact with the anterior abdominal wall; or (5) behind the terminal ileum. In 10 000 subjects (Wakeley 1933) the vermiform appendix was retrocaecal and retrocolic (65.28%), pelvic (31.01%), subcaecal (2.26%), pre-ileal (1.0%) and post-ileal (0.4%). Subsequent literature, anatomical and surgical, shows much contradiction of this classic study. Buschard & Kjaeldgaard (1973), reporting a short series (234 autopsies), compared the results of several studies dating from 1885–1973, Wakeley's remaining by far the largest. They classified all positions as either *Anterior* (pelvic and ileocaecal) or *Posterior* (retrocaecal and subcaecal). All but three of 11 series quoted found *anterior* positions more frequent. Like Wakeley they observed *posterior* positions more commonly in their own Danish series; in German autopsies the finding was reversed. Collins (1932), in the second largest series (4680), returned percentages the reverse of Wakeley's, the ratio of anterior to posterior being 78.5% to 21.5% (Collins) and 32.4% to 67.6% (Wakeley). In view of these disagreements, such figures are of dubious value. Perhaps observers have used differing criteria or possibly there are demographic variations. For the present, however, such percentages remain unreliable.

The usual *surface marking* for the appendicular base is the junction of the lateral and middle thirds of the line joining the right anterior superior iliac spine to the umbilicus *(McBurney's point)*; but this is merely a useful surgical approximation, with considerable variation. The three taeniae coli on the ascending colon and caecum converge on the base of the appendix, merging into its longitudinal muscle. The anterior caecal taenia is usually distinct and traceable to the appendix, affording a guide to it. The appendix varies from 2–20 cm in length, the average being about 9 cm. It is longer in children and may atrophy or diminish after mid-adult life. It is connected by a short *mesoappendix* to the lower part of the ileal mesentery. This fold is usually triangular, extending almost to the appendicular tip along the whole tube.

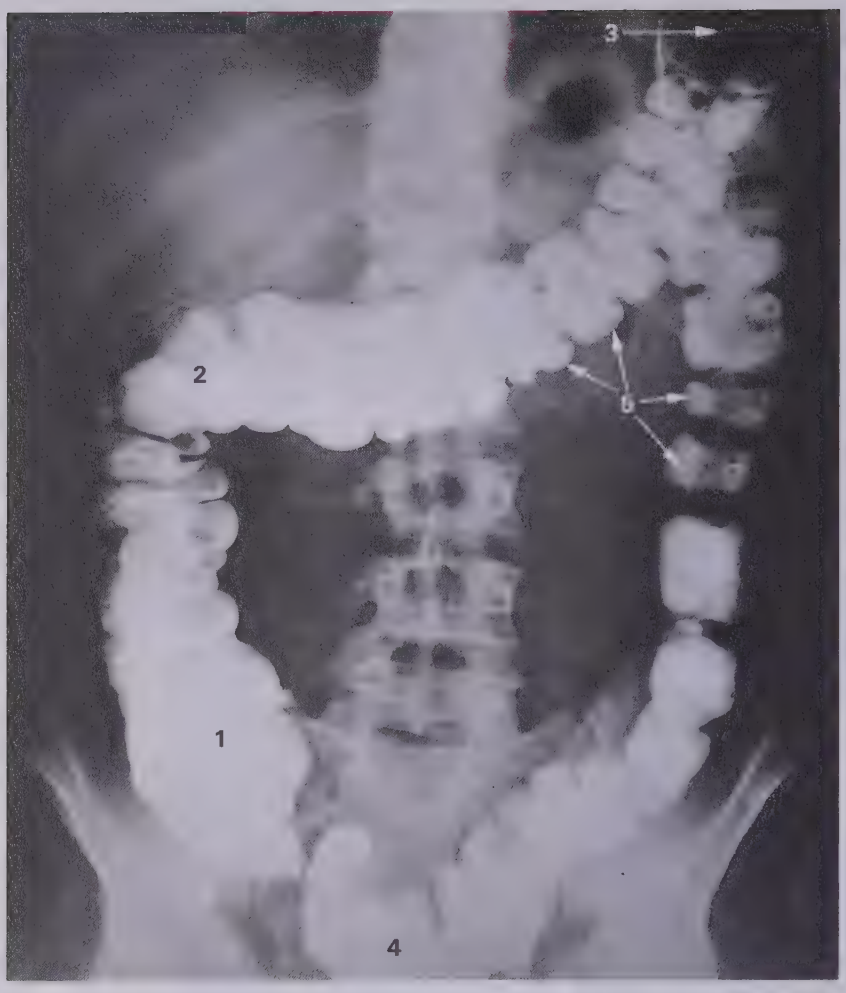
The main *appendicular artery*, a branch from the lower division of the ileocolic (p. 773), runs behind the terminal ileum to enter the mesoappendix a short distance from the appendicular base. Here it gives off a recurrent branch which anastomoses at the base of the appendix with a branch of the posterior caecal artery, the anastomosis sometimes being large. The main appendicular artery approaches the tip of the organ, at first near to and then in the edge of the mesoappendix. The terminal part of the artery, however, lies on the wall of the appendix and may be thrombosed in appendicitis, resulting in distal gangrene or necrosis. The arterial supply of the appendix may vary considerably. Accessory arteries are common; in 80% of subjects there are two or more arteries of supply (Solanke 1968).

The canal of the appendix is small and opens into the caecum by an orifice lying below and a little behind the ileocaecal opening. The orifice is sometimes guarded by a semilunar mucosal fold forming a valve. The lumen may be partially or wholly obliterated in the later decades of live. In view of its rich vascularity and histological differentiation, the appendix is probably a specialized rather than a degenerate or vestigial structure. The caecum and appendix in man and anthropoid apes is considered to be less primitive than in monkeys. A comparative study of the primate vermiform appendix has been made by Scott (1980).

Structure. The mural layers are essentially as in the rest of the large intestine. The *serosa* is a complete investment, except along the mesenteric attachment; there is a subserous layer of connective tissue. The *longitudinal muscular fibres* form a complete, uniformly thick layer, except over a few small areas where both muscular layers are deficient, leaving the serosa and submucosa in contact. At the base the longitudinal muscle thickens to form rudimentary taeniae continuous with those of the caecum and

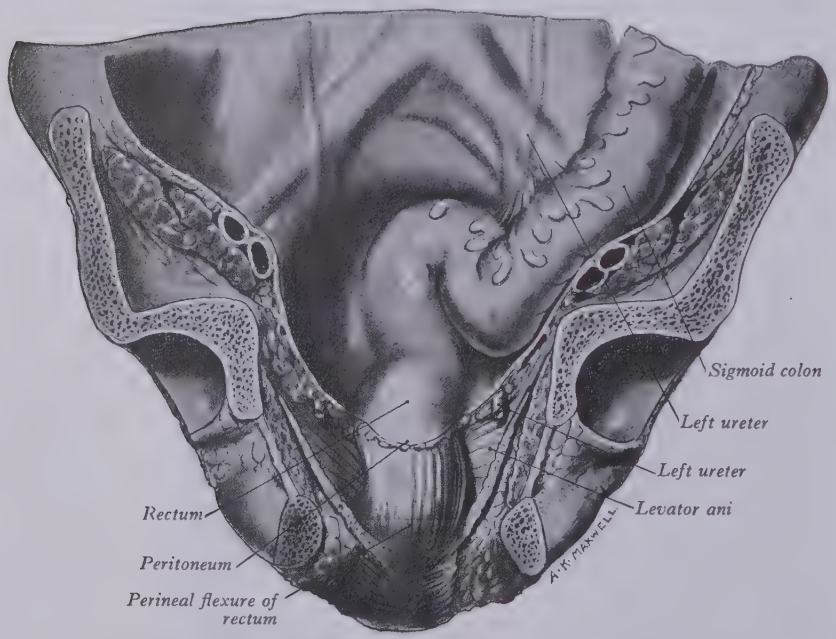
8.139 Surface projection of the stomach, liver and colon. The outlines of the lumbar vertebral bodies and intervertebral discs, lower ribs, xiphoid process and parts of the iliac crests are indicated.

colon. The *circular muscular fibres* form a thicker layer separated from the longitudinal by connective tissue. The *submucosa* is well developed, containing many lymphoid masses which cause the mucosa to bulge into the lumen, narrowing it irregularly. The *mucosa* is covered by columnar epitheliocytes and attenuated antigen-transporting 'M' cells (Owen & Nemanic 1978). Glands (crypts similar to those of the colon) are few and penetrate deeply into the lymphoid tissue (**8**.138), which in the normal human appendix is situated primarily in the lamina propria and extends into the submucosa; follicular and parafollicular zones containing B- and T-lymphocytes (p. 824) can be distinguished; clustered lymphocytes also appear between the epithelial cells, where some may possibly differentiate into plasma cells (Gorgollón 1978). Lymphoid tissue in the lamina propria contains many plasma cells, with lymphocytes, eosinophil and other leucocytes, mast cells and macrophages embedded in a fibrocellular reticulum. The submucosal follicles (germinal centres) are organized like those of other examples of gut-associated lymphoid tissue (p. 824; see also Kaiserling et al 1974). The *lymphoid masses* are a local defence against infection; it has also been suggested that they may be a homologue of the avian *bursa of Fabricius* (p. 671) concerned in the acquisition of immunological competence by certain lymphocytes. However, experimental evidence argues against this function (p. 761). In many mammals, particularly herbivores, the caecum and appendix are large and constitute a highly important site of digestion of cellulose by symbiotic bacteria.



THE COLON

The colon is conveniently considered in four parts: ascending, transverse, descending and sigmoid.



The ascending colon, about 15 cm long and narrower than the caecum, ascends to the inferior surface of the right lobe of the liver, on which it makes a shallow depression; here it turns abruptly forwards and to the left, at the *right colic flexure* (**8**.125). In surface projection it ascends lateral to the right lateral plane (**8**.139) from the transtubercular to midway between the subcostal and transpyloric planes. It is covered by peritoneum except where its posterior surface is connected by areolar tissue to the iliac fascia, and to the iliolumbar ligament, quadratus lumborum, aponeurosis of transversus abdominis and the perirenal fascia on the front of the inferolateral area of the right kidney. The lateral femoral cutaneous nerve, usually the fourth lumbar artery, and sometimes the ilio-inguinal and iliohypogastric nerves, cross behind it. Sometimes it possesses a distinct but narrow mesocolon. In a series of 100 subjects, 52% had neither an ascending nor descending mesocolon, 14% had both, 12% an ascending and 22% a descending mesocolon (Treves 1885). Anteriorly it is in contact with the coils of the ileum, the greater omentum and the abdominal wall.

The right colic flexure is at the junction of the ascending and transverse colon; the latter turns down, forwards and to the left. Posterior is the inferolateral part of the anterior surface of the right kidney; above and anterolaterally is the right lobe of the liver; anteromedially is the descending part of the duodenum and fundus of the gallbladder. Its posterior aspect is not covered by peritoneum and is in direct contact with renal fascia. It is not so acute as the left colic flexure.

The transverse colon (**8**.118, 140A), about 50 cm long, extends from the right colic flexure in the right lumbar region, across into the left hypochondriac region, here curving sharply

8.140B Oblique coronal section through the pelvis to expose the anterior aspect of the rectum.

down and backwards below the spleen as the *left colic flexure*. The transverse colon describes an arch, its concavity usually directed back and up; near its splenic end an abrupt U-shaped curve may descend lower than the main arch. Its surface projection (**8.**139) extends from a point, situated just lateral to the right lateral plane and midway between the subcostal and transpyloric planes, to the umbilicus and then up and left to a point just superolateral to the intersection of the left lateral and transpyloric planes. A precise projection is difficult to define, varying much even in the same individual. Commonly it is in the lower umbilical or upper hypogastric region. It frequently descends in a V-shaped manner, the apex being well below the level of the iliac crests (p. 1334). In a radiological assessment in the upright position, its lowest level in 1000 young adults was found to vary much, even reaching the true pelvis; levels varied as much as 17 cm in the same individual between upright and recumbent positions (Moody 1927).

The posterior surface at its right end is devoid of peritoneum and is attached by areolar tissue to the front of the descending part of the duodenum and the head of the pancreas; but from the latter to the left colic flexure it is almost completely invested by peritoneum, connecting it to the anterior border of the body of the pancreas by the *transverse mesocolon*. Above the transverse colon are the liver and gallbladder, the greater gastric curvature and the lateral end of the spleen; below is the small intestine, in front are the posterior layers of the greater omentum and behind are the descending part of the duodenum, the head of the pancreas, the upper end of the the mesentery, the duodenojejunal flexure and coils of the jejunum and ileum.

The left colic flexure (**8.**125), the junction of the transverse colon and descending colon in the left hypochondriac region, is related to the lower part of the spleen and pancreatic tail above and medially with the front of the left kidney. It is so acute that the end of the transverse colon usually overlaps the front of the descending colon. The left flexure is above and on a more posterior plane than the right flexure and is attached to the diaphragm level with the tenth and eleventh ribs by the *phrenicocolic ligament*, which lies below the anterolateral pole of the spleen (p. 1344).

The descending colon (**8.**125), about 25 cm long, descends through the left hypochondriac and lumbar regions, at first following the lower part of the lateral border of the left kidney and then descending in the angle between the psoas major and quadratus lumborum to the iliac crest; it then curves downwards and medially in front of the iliacus and psoas major to end in the sigmoid colon at the inlet of the lesser pelvis. (It is sometimes described as ending at the iliac crest, the part between this and the pelvic inlet being named the *iliac colon*.) In surface projection (**8.**139) it descends just lateral to the left lateral plane, from a little above and left of the intersection of the transpyloric and left lateral planes as far as the inguinal ligament. Peritoneum covers all but its posterior surface, which is connected by areolar tissue to fascia over the inferolateral region of the left kidney, the aponeurosis of transversus abdominis, the quadratus lumborum, iliacus and psoas major (**8.**125). Crossing behind it are the following left structures: subcostal vessels and nerve, iliohypogastric and ilio-inguinal nerves, fourth lumbar artery (usually), the lateral femoral cutaneous, femoral and genitofemoral nerves, the testicular (or ovarian) vessels and the external iliac artery. The descending colon is smaller in calibre, more deeply placed, and more frequently covered behind by peritoneum than the ascending colon (p. 1367). Anteriorly are the coils of the jejunum, except for its lower part which is palpable when the abdominal muscles are relaxed.

The sigmoid colon (pelvic colon) (**8.**140B) begins at the pelvic inlet, continuing in the descending part; it forms a variable loop of about 40 cm and is normally in the lesser pelvis. The loop first descends in contact with the left pelvic wall, then crosses the pelvic cavity between the rectum and bladder in males, and rectum and uterus in females, and may reach the right pelvic wall; finally it turns back to the midline level with the third piece of the sacrum, where it bends downwards and ends in the rectum. It is closely surrounded by peritoneum, forming a mesentery, the *sigmoid mesocolon* (p. 1344), which diminishes in length from the centre towards its ends, where it disappears; the loop is fixed at its

junctions with the descending colon and rectum but quite mobile between them. Its relations are therefore variable. *Laterally* are: the left external iliac vessels, the obturator nerve, ovary or ductus deferens and the lateral pelvic wall, *posteriorly* the left internal iliac vessels, ureter, piriformis and sacral plexus; *inferiorly* the bladder in males or uterus and bladder in females; *superiorly* and to the *right* it is in contact with terminal coils of the ileum.

The position and shape of the sigmoid colon vary much, depending on (1) its length, (2) the length and mobility of its mesocolon, (3) the degree of distension (when distended it rises into the abdominal cavity, sinking again into the lesser pelvis when empty), (4) the condition of the rectum, bladder and uterus. (When these are distended the sigmoid colon tends to rise and to fall when they are empty.) Racial variation has been noted (Lisowski 1969): in some groups, particularly Ethiopians, the incidence of a suprapelvic loop, perhaps conducive to volvulus, is particularly high.

THE RECTUM

The rectum (**8**.140B, 141A,B) is continuous with the sigmoid colon at the level of the third sacral vertebra, the junction being at the lower end of the sigmoid mesocolon. It descends along the sacrococcygeal concavity, with an anteroposterior curve, the *sacral flexure*. It thus curves down and back, then downwards, and finally down and forwards to join the anal canal by passing through the pelvic diaphragm (p. 604). The *anorectal junction* is 2–3 cm in front of and slightly below the coccygeal tip; from this level (in males opposite the apex of the prostate) the anal canal passes down and backwards from the lower end of the rectum, this backward bend of the gut being termed the *perineal flexure* of the rectum. The rectum also deviates in three lateral curves: the upper is convex to the right, the middle (the most prominent) bulges to the left and the lower is convex to the right. Both ends of the rectum are in the median plane (**8**.141A). The rectum is about 12 cm long, with the same diameter as the sigmoid colon above (about 4 cm in the empty state), but its lower part is dilated as the *rectal ampulla*. The rectum differs from the sigmoid colon in having no sacculations, appendices epiploicae or mesentery; the taeniae blend about 5 cm above the rectosigmoid junction, forming two wide muscular bands which descend, anterior and posterior, in the rectal wall. Peritoneum is related only to the upper two-thirds, covering its front and sides above, and lower down, only its front, from which it is reflected on to the bladder in males, forming the rectovesical pouch, and on to the posterior vaginal wall in females, forming the recto-uterine pouch. The level of this reflexion is higher in males, the rectovesical pouch being about 7.5 cm (about the length of the index finger) from the anus; in females the recto-uterine pouch is about 5.5 cm from the anus. In the male fetus, peritoneum extends on to the front of the rectum as far as the lower limit of the prostate (p. 1433). On the sigmoid colon, peritoneum is firmly attached to the muscle layer by fibrous connective tissue but as it descends on to the rectum it is more loosely attached by fatty areolar tissue, allowing for considerable expansion.

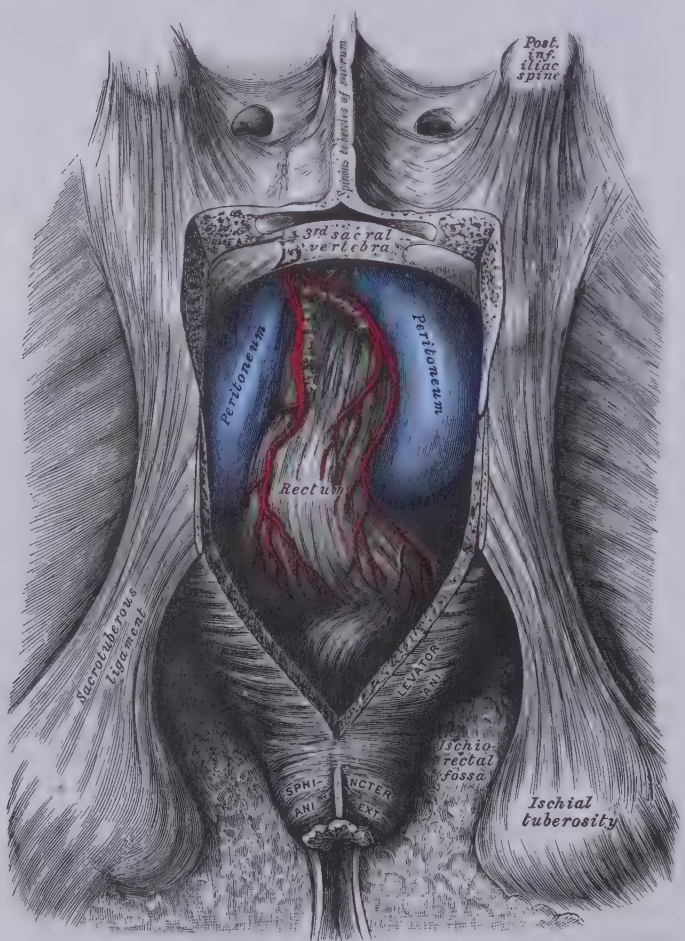
In the empty rectum, the mucosa in its lower part presents a number of longitudinal folds, effaced during distension. There are also permanent semilunar *transverse* or *horizontal folds*, most marked in rectal distension. Two forms of horizontal fold have been recognized (Jit 1961); one consists of the mucosa, a circular muscle layer and part of the longitudinal muscle, and an indentation on the rectal exterior; the other is devoid of longitudinal muscle and has no external marking. Their number is variable but there are commonly three folds. An upper one, near the beginning of the rectum, may be on the left or right; occasionally it encircles the gut, constricting its lumen. The middle fold is largest, most constant and lies immediately above the ampulla, projecting from the anterior and right wall just below the level of the anterior peritoneal reflexion; circular muscle is more marked in it. The lowest fold, inconstant and on the left, is about 2.5 cm below the middle fold. Sometimes a fourth occurs on the left about 2.5 cm above the middle fold.

It has been suggested (Paterson 1912) that the rectum consists of two functional parts, above and below the middle fold, the upper containing faeces and being free to distend into the peritoneal cavity, the lower more confined, enclosed in a tube of condensed extraperitoneal tissue and (except during defaecation) normally empty; in chronic constipation or after death it may contain faeces. (Note that the rectum above the middle fold is considered to develop from the hindgut and the part below with the upper anal canal, from the cloaca or post-allantoic gut.) Others (O'Beirne 1833, Hurst 1919) have considered the sigmoid colon a faecal reservoir, the rectum being normally empty and the entry of faeces into it exciting defaecation. Experimental distension of the rectum and anal canal results in the desire to defaecate and causes the relaxation of the anal sphincters (Denny-Brown & Robertson 1935).

Relations of the Rectum

Posterior to the rectum in the median plane are: the lower three sacral vertebrae, coccyx, median sacral vessels, ganglion impar and branches of the superior rectal vessels; while on each side, particularly on the left, are: the piriformis, the anterior rami of the lower three sacral and coccygeal nerves, sympathetic trunk, lower lateral sacral vessels, the coccygei and the levatores ani. The rectum is attached to the sacrum along the lines of the anterior sacral foramina by fibro-areolar tissue enclosing: the sacral nerves and the pelvic splanchnic nerves from the anterior rami of the second to fourth sacral nerves, which join the pelvic plexuses on the rectal wall; rami of the superior rectal vessels, lymphatic vessels, lymph nodes, and loose perirectal fat. *Anterior in males* above the site of the peritoneal reflexion from the rectum, are the upper parts of the base of the bladder and of the seminal vesicles, the rectovesical pouch and its contents (terminal coils of the ileum and sigmoid colon); below the reflexion are: the lower parts of the base of the bladder and of the seminal vesicles, deferent ducts, terminal parts of the ureters and the prostate. *In females*, above the reflexion are: the uterus, upper vagina, recto-uterine pouch and contents (terminal coils of the ileum and sigmoid colon), while below the reflexion is the lower part of the vagina. *Laterally*, the upper part of the rectum is related to the pararectal fossa and contents (sigmoid colon or lower ileum), while below the peritoneal reflexion laterally are the pelvic sympathetic plexuses, coccygei and levatores ani and branches of the superior rectal vessels.

THE ANAL CANAL



The anal canal (Milligan et al 1937, Gabriel 1945, Wilde 1949, Goligher et al 1955, Fowler 1957) begins where the rectal ampulla suddenly narrows, passing down and backwards to the anus (**8**.141B,C). It is about 4 cm long in adults, its anterior wall being slightly shorter than its posterior. When empty its lumen is a sagittal or triradiate longitudinal slit. *Posterior* is a mass of fibromuscular tissue, the *anococcygeal ligament*, separating it from the tip of the coccyx; *anteriorly* it is separated by the *perineal body* (p. 607) from the membranous urethra and penile bulb or from the lower vagina; *laterally* are the ischiorectal fossae. Over its whole length it is surrounded by sphincters which normally keep it closed.

The lining of the canal varies along its course. The mucosa of the lower part of the rectum is pale pink and semitransparent, the branching pattern of the superior rectal vessels being visible through it. The upper half (15 mm) of the anal canal is also lined by mucosa, plum-red in colour due to blood in the subjacent internal rectal venous plexus. The epithelium is variable. In the upper part it is similar to that of the rectum, consisting of simple columnar cells, some secretory and others absorptive, with numerous tubular glands or crypts. In the lower half, this gives way to non-keratinized stratified squamous epithelium, finally merging with the keratinized stratified squamous epithelium of the perianal epidermis (Walls 1958). In this part of the canal are six to 10 vertical folds, the *anal columns*, well marked in children but sometimes less defined in adults. Each column contains a terminal radicle of the superior rectal artery and vein, these radicles being largest in the left-lateral, right-posterior and right-anterior quadrants of the wall of the canal; enlargements of venous radicles in these three sites constitute primary internal haemorrhoids. The lower ends of the columns are linked by small

crescentic mucous folds, the *anal valves*, above each of which is a small recess or *anal sinus*. The sinuses, deepest in the posterior wall, may retain faecal matter and become infected, leading to abscess formation in the anal canal wall; anal valves may be torn by hard faeces, producing an anal fissure (p. 1373). Anal valves are situated along the *pectinate line*, opposite the middle of the sphincter ani internus and commonly considered to be the site of the anal membrane in early fetal life, thus representing the junction of the endodermal (cloacal) and ectodermal (proctodeal) parts of the canal. Small epithelial anal papillae may occur on the edges of the anal valves, perhaps remnants of the anal membrane. However, the junction of ectodermal and endodermal parts may be at the lower border of the pecten (Johnson 1914).

The anal canal extends about 15 mm below the anal valves, as the *transitional zone* or *pecten*, whose epithelium is non-keratinized, stratified squamous and intermediate in thickness between that of the mucosa of the upper part of the canal and the epidermis in its lowest part; only the latter contains sweat glands. The transitional zone overlies part of the internal rectal venous plexus and is shiny and bluish. Its submucosa contains dense connective tissue, contrasting with the lax connective tissue in the upper half of the anal canal and suggesting the firm support and anchorage of the pectineal lining to the surrounding anal muscle. The transitional zone ends below at a narrow sinuous zone, the '*white line*' (of Hilton). In the living this 'line' is bluish pink and rarely visible (Ewing 1954), its only interest being that it is at a level between the subcutaneous part of the external sphincter and the lower border of the internal sphincter; digital examination in the living reveals an *anal intersphincteric groove* at this site. Below the white line, the final 8 mm or so of the anal canal is lined by true skin, dull white or brown in colour and containing sweat and sebaceous glands. There is much variation in the epithelial zones described above and frequently the various types interpenetrate, the zones being poorly defined.

Near the anal sinuses, *anal glands* (Fowler 1957, McColl 1967) extend upwards or downwards into the submucosa, occasionally penetrating deeply into the internal sphincter. Each consists of one to six spiral or straight tubules, sometimes branched, and lined by two or three layers of mucous secretory cells. The duct of each gland, lined by stratified columnar epithelium, opens into a small depression, an *anal crypt*. The glands are surrounded by lymphocytes in a form similar to lymphatic follicles and the submucosal non-striated muscle is thick in their vicinity. Occasionally the termination of a duct is not canalized and secretions may then form a cyst. The glands are sometimes infected, producing an abscess or fistula. They vary widely in number and depth of penetration, even extending into the submucosa above the anorectal junction. (For details of comparative anatomy and pathology see McColl 1967.) In this series, 50 normal anal canals were examined; half had anal glands passing right through the internal sphincter; the average number of such extensions was four but they may reach 16. McColl considered that these human glands were not homologous with the *anal scent glands* of some other mammals.

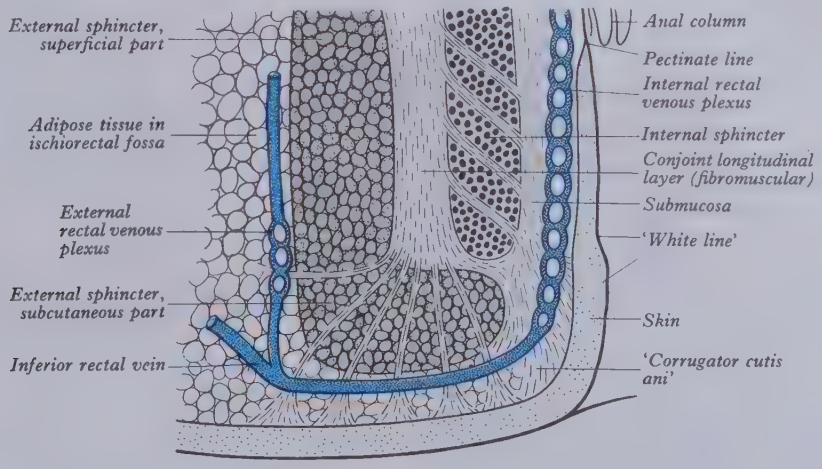
ANAL MUSCULATURE

The anal walls are surrounded by a complex of sphincters (**8**.141), divisible into internal and external parts. At the anorectal junction, the rectal circular muscle is thickened (5–8 mm) as a non-striated **sphincter ani internus** around the upper three-quarters (30 mm) of the anal canal and ends below at the white line (vide supra et infra).

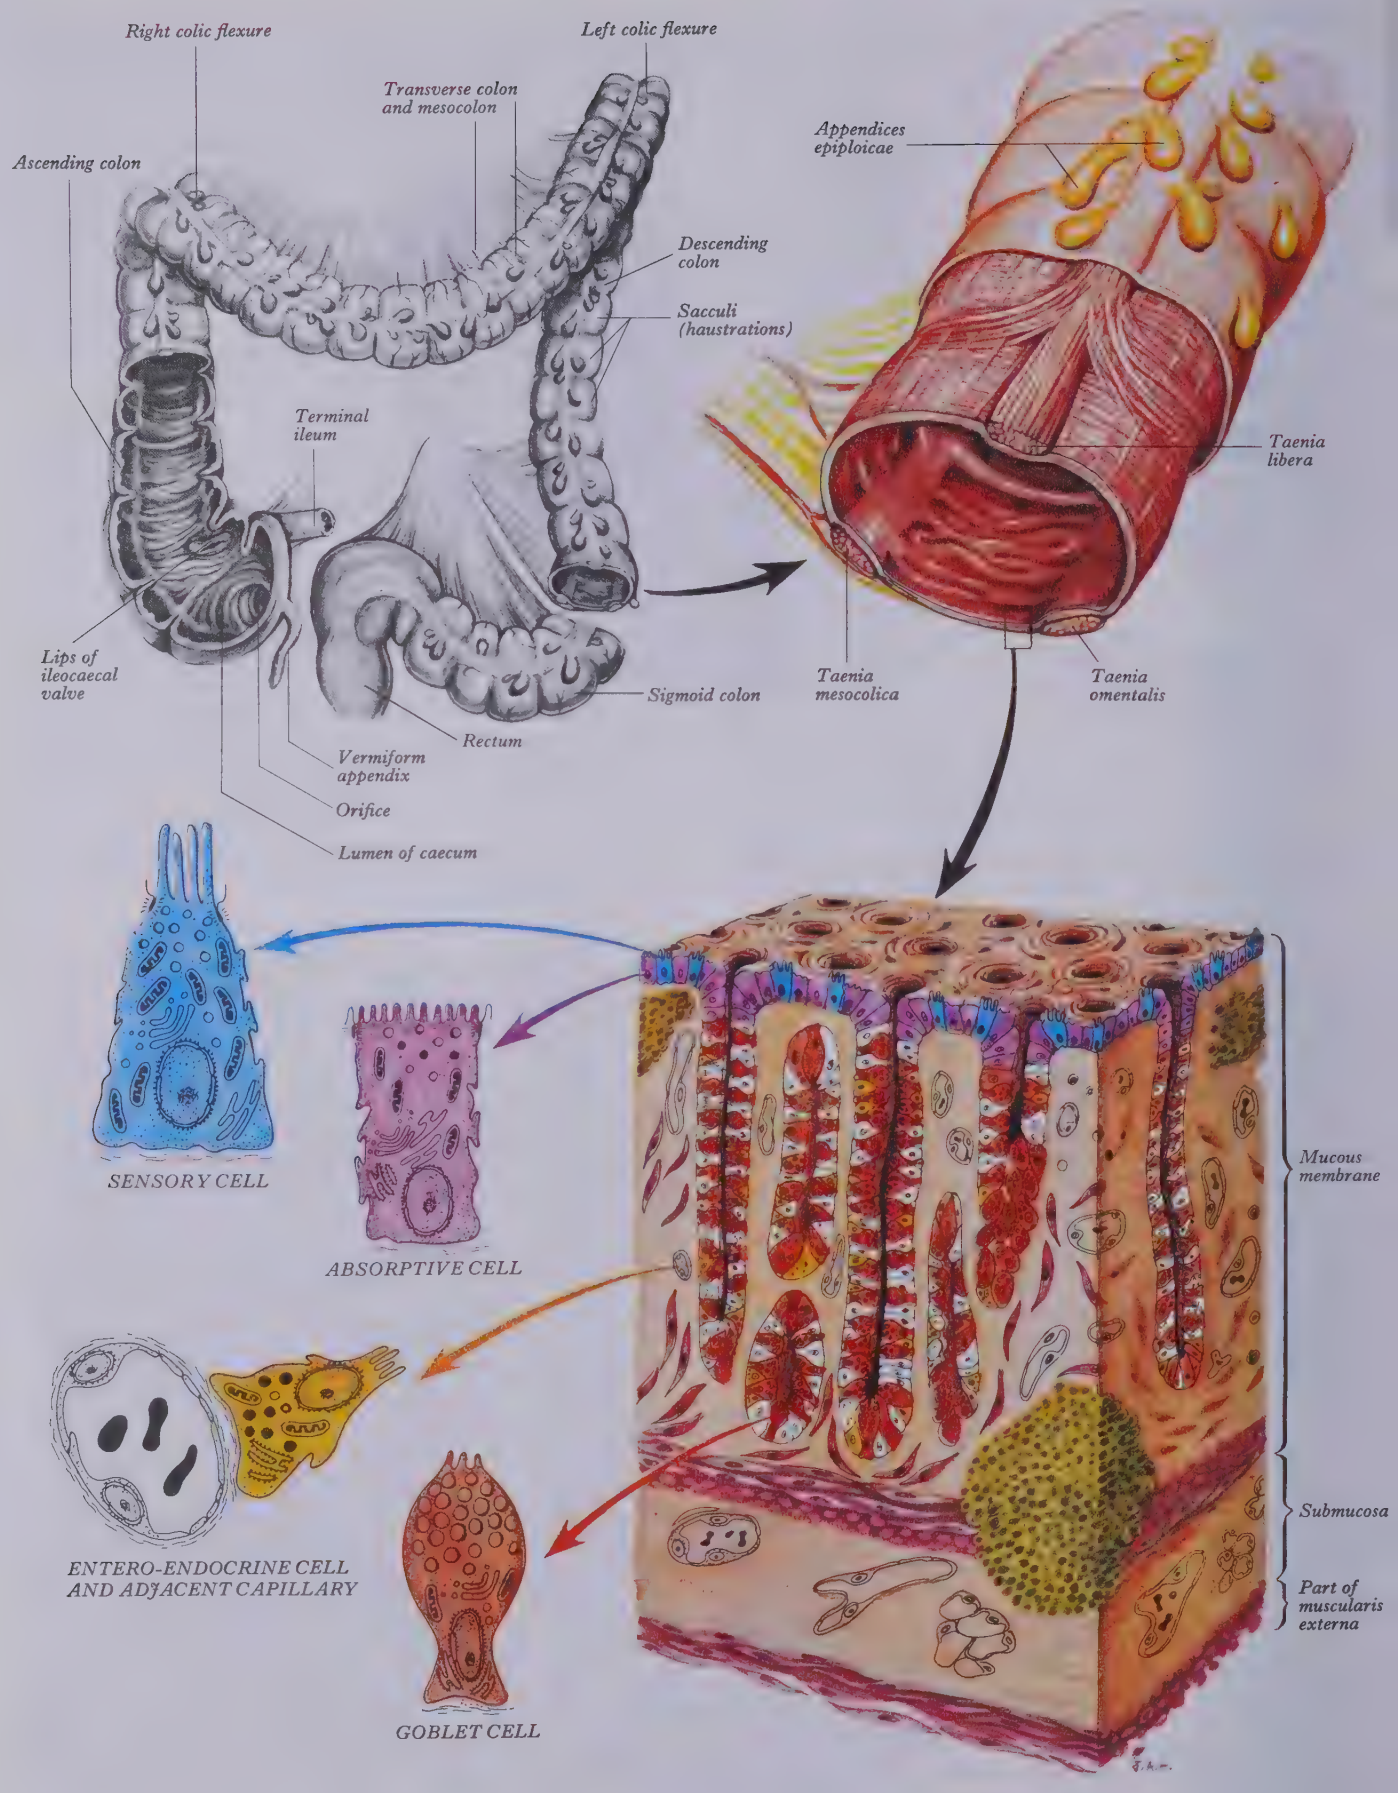
The sphincter ani externus (**8**.141B) surrounds the whole anal canal; it is usually described as consisting of three parts, all composed of skeletal muscle. These are, from inferior to superior, the subcutaneous, the superficial and the deep portions. The *subcutaneous part* is a flat band, about 15 mm broad, around the lower anal canal and lies horizontally below the lower borders of the internal sphincter and superficial part of the external sphincter; it lies beneath the skin at the anal orifice and is inferior to the white line. Anteriorly a few fibres join the perineal body (or the superficial transverse perineal muscles); posteriorly some are usually attached to the anococcygeal ligament. The *superficial part* is elliptical and superior to the subcutaneous; it is the only part attached to bone, arising from the posterior surface of the terminal coccygeal segment by the median anococcygeal raphe; anteriorly it surrounds the *lower* part of the internal sphincter and is chiefly attached to the perineal body. The *deep part* is a thick annular band around the *upper* part of the internal sphincter; its deeper fibres blend inseparably with the puborectalis (p. 605); anterior to the anal canal many fibres decussate into the superficial transverse perineal muscles, especially in females. Some posterior fibres are usually attached to the anococcygeal raphe. However, a clear separation into three parts has also been denied (Goligher et al 1955). In females according to Oh & Kark (1972) the muscle is a single band, anteriorly at least. (See also Wendell-Smith & Wilson 1977.)

Muscle tone in both internal and external sphincters keeps the canal and anus closed; during defaecation (Shafik 1986) they relax and the lower anal canal opens out and flattens, the mucosa of its upper part appearing on the surface. The external sphincter can be voluntarily contracted to occlude the anus more firmly. Its nerve supply is derived from the inferior rectal branch of the pudendal nerve (S.2 and 3) and the perineal branch of the fourth sacral nerve.

At the anorectal junction the pubococcygeal fibres of levator ani fuse with the longitudinal non-striated rectal muscle to form a *conjoint longitudinal coat* for the anal canal between the internal and external sphincters (**8**.141B,C). Distally, this layer is increasingly fibro-elastic; at the white line it breaks up into 9–12 circumferential septa which diverge mainly through the subcutaneous part of the external sphincter to become attached to the dermis of circumanal skin. These septa are largely elastic fibres; the most peripheral passes between the subcutaneous and superficial parts of the external sphincter into the ischiorectal fat. The



8.141B Diagram of a coronal section of the rectum and anal canal and the adjacent structures (adapted from Rauber-Kopsch, *Lehrbuch und Atlas der Anatomie des Menschen*, 1919). The internal pudendal vessels, the dorsal nerve of the penis and the perineal nerve are shown transected in the lateral wall of the ischiorectal fossa, where they are traversing the 'lunate fascia' (pudendal canal).



most central (juxta-anal) septum is said to pass between the internal sphincter and the external's subcutaneous part to reach the anal lining at the white line as the *anal intermuscular septum*, producing an *anal intersphincteric groove*. Wilde (1949), Goligher et al (1955) and Fowler (1957), however, considered that the longitudinal fibres in this position (compared with those penetrating the subcutaneous part of the external sphincter) were too scanty to warrant a name, maintaining that the groove is due to the muscle masses of the internal sphincter above and the subcutaneous part of the external sphincter below and to the contraction of the latter. In the anal submucosa, inferior to the anal sinuses, is a layer of non-striated muscle, yellow elastic fibres and fibrous connective tissue, derived mainly from strands of the conjoint longitudinal coat, which descends inwards between fascicles of the internal sphincter (**8.141C**); some of the strands end by turning laterally around the lower edge of the internal sphincter to rejoin the main longitudinal layer; but most continue inferolaterally, superficial to the subcutaneous part of the external sphincter, to the dermis of the skin from the white line to well beyond the anus. These attachments corrugate the region; hence the term *corrugator cutis ani muscle*. Wilde (1949) considered these fibres to be exclusively elastic, but Goligher et al (1955) noted non-striated muscle fibres among them. Fowler (1957), finding no muscle fibres here, ascribed puckering of the perianal skin to the combined effects of levator ani and the subcutaneous part of the external sphincter.

A *muscularis mucosae* has been described in the anal canal immediately above the pectinate line and possibly extending below it (Jit 1974).

Between the subcutaneous part of the external sphincter and the skin of the anal canal is the inferior part of the internal rectal venous plexus; veins link the external and internal rectal plexuses,

8.141C Part of **8.141B** enlarged to show greater detail.

thus connecting the portal and systemic venous systems. The radiating elastic septa end in a network dividing the narrow cleft between the subcutaneous part of the external sphincter and the skin into a compact honeycomb, which may explain the severe pain produced by pus or blood collecting here, and the localization of a haemorrhage following the rupture of a vein from the external rectal plexus. The submucosa above the white line, containing the upper part of the internal rectal venous plexus, forms a *submucous space* and that below the white line, containing its lower part, forms a *perianal space*; they are separated by the dense submucous layer of non-striated muscle and fibrous connective tissue referred to above, which is especially well marked below the anal valves.

Fowler (1957) concluded that the anal canal proper extends between two palpable muscular landmarks, the *anorectal ring* above and the *intersphincteric ring* below. In the relaxed state, the lower border of the internal sphincter and intersphincteric groove lie at the anal orifice, the subcutaneous external sphincter being lateral to it; only when the external sphincter contracts is the orifice withdrawn around the lower part of the 'apparent' anal canal. At the anorectal junction the puborectalis, deep external and internal sphincters collectively form the *anorectal ring* of muscle, which is palpable in the canal; surgical division of this results in rectal incontinence. Its anterior part is less well marked, since relatively few fibres of the puborectalis pass in front of the anorectal junction, most forming posterolateral loops around the gut at this site, slinging the anorectal junction forwards towards the pubis.

Correlated with the *dual development* of the anal canal, the part above the anal valves arising from the endodermal cloaca and the part below this from the ectodermal proctodeum (p. 233), the following facts emerge. The lining of the *ectodermal part* is skin, supplied by spinal nerves (inferior rectal), the 'somatic' inferior rectal artery, a venous drainage via the inferior rectal passing to the internal pudendal vein (systemic) and by lymphatics draining with the perianal skin to the superficial inguinal lymph nodes. In the *endodermal part* the mucosa is supplied by autonomic nerves, the arterial supply (Griffiths 1961) coming mainly from the superior rectal artery, the venous drainage by the superior rectal vein, a tributary (via the inferior mesenteric) of the portal venous system; the lymphatics drain with those of the rectum (p. 854). In portal obstruction, the collateral circulation opened up by anastomosis between the portal and systemic veins in the anal canal may cause these veins to dilate. The differing nerve supply of the two parts accords with the response to stimuli; the lower part responds to touch, pain and heat like skin; the upper part, like the gut at large, has a high threshold for such stimuli but responds readily to tension. The effects of the difference in innervation of the two parts are apparent in haemorrhoids, which may be covered by skin inferiorly *and* mucosa superiorly; to thrombose such varicose veins by injection, a needle is inserted into the insensitive *mucosal* part. Fissure *in ano* (tearing of anal valves) is very painful because it involves the lower, sensitive, *dermal* part of the anal canal.

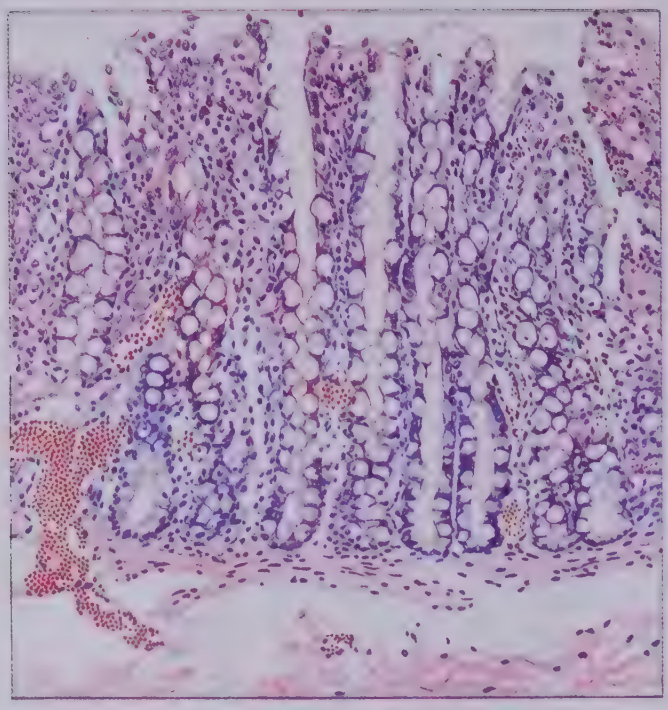
RECTAL EXAMINATION

On inserting the index finger through the anal orifice in rectal examination, the finger is first resisted by the subcutaneous external sphincter and then by the internal sphincter, superficial and deep parts of the external sphincter and the puborectalis; beyond this it may reach the inferior (or even middle) transverse rectal fold. Many structures related to the canal and lower rectum may be palpated.

In *males* through the anterior rectal wall, the penile bulb and (particularly with a catheter in the urethra) the membranous urethra are first identified; about 4 cm from the anus the prostate can be felt and beyond this the seminal vesicles (if enlarged) and the base of the bladder (especially if distended). Posteriorly pelvic surfaces of the lower sacrum and coccyx are palpable and laterally the ischial spines and tuberosities and (if enlarged) the internal iliac lymph nodes. Pathological thickening of the ureters, swellings in the ischiorectal fossa and abnormal contents of the rectovesical recess may also be detected.

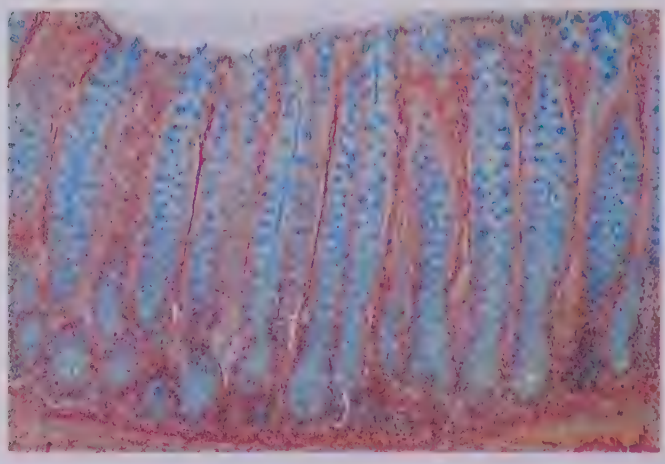
In *females* the uterine cervix is palpable through the anterior rectal wall; its degree of dilatation during parturition may be assessed in this manner. Pathological conditions causing tenderness or changes in the shape, size, consistency or position of the ovaries, uterine tubes, broad ligaments and recto-uterine pouch may be detected.

In both sexes, tenderness of an inflamed vermiform appendix (if pelvic) can be elicited.



RECTAL FASCIAE AND 'SPACES'

Parts of the pararectal pelvic fascia are composed of loose connective tissue, whilst others are denser, with particular orientations and attachments; the latter are often considered to be rectal 'supports' requiring surgical division to mobilize the organ. From the lower sacrum's anterior surface a strong avascular condensation proceeds to the posterior aspect of the anorectal junction (*fascia of Waldeyer*). Around the middle rectal vessels fascia extends from the posterolateral pelvic wall (level with the third sacral vertebra) to the rectum as the *lateral rectal ligaments*. Anteriorly, between the rectum and the seminal vesicles and prostate, the *rectovesical fascia* (p. 1433) is more loosely attached to the seminal vesicles and prostate than to the rectum and in rectal excision it must be separated from them.



In addition to the ischiorectal fossae (p. 606) several '*spaces*' of surgical import are related to the rectum and anal canal. The *pelvirectal space* comprises the loose extraperitoneal connective tissue above the levator ani; it is divided into anterior and posterior regions by the *lateral rectal ligaments*. The *submucous space* of the anal canal is between the mucosa (above the white line) and the internal sphincter; it contains the superior part of the internal rectal venous plexus and lymphatics; above, it is continuous with the rectal submucosa, below with the *perianal space* (p. 1370), the lateral part of which is bounded above by the most lateral elastic septum traversing the subcutaneous part of the external sphincter. The septum divides the ischiorectal fossa into a superior part containing coarsely lobulated fat and a smaller, lower, perianal space containing fine, compact fat. The perianal space contains the subcutaneous part of the external sphincter, the external rectal venous plexus and terminal rami of the inferior rectal vessels and nerves. The radiating septa traversing the subcutaneous part of the external sphincter tend to divert pus in the perianal space to the anal canal at the white line or to the surface of the perianal skin, rather than to the main ischiorectal fossa. Since the perianal space surrounds the lower anal canal, pus on one side may spread around it.

STRUCTURE OF THE LARGE INTESTINE

The layers of mural tissue in the large intestine are like those in the small (p. 1358). The *serosa* or *visceral peritoneum* is variable in extent. Along the colon the peritoneum forms small fat-filled *appendices epiploicae*, most numerous on the sigmoid and transverse colon but absent from the rectum. Subserous loose connective tissue attaches the peritoneum to the *muscularis externa*, which has outer longitudinal and inner circular layers of non-striated muscle. The *longitudinal fibres* form a continuous layer (Hamilton 1946) but are also aggregated as longitudinal bands or *taeniae coli*, between which the longitudinal layer is less than half the circular layer in thickness. In the caecum and colon three taeniae appear, varying from 6–12 mm in width. The *taenia libera* is anterior in the caecum, the ascending, descending and sigmoid colon, but inferior in the transverse. The *taenia mesocolica* is posteromedial in the caecum, the ascending, descending and sigmoid colon, but posterior in the transverse, being located at the attachment of the transverse mesocolon. The *taenia omentalis* is posterolateral in the caecum, the ascending, descending and sigmoid colon, but anterosuperior in the transverse colon, being located where the posterior (ascending) layers of the greater omentum meet

this part of the large intestine. These bands are said to be shorter than the other intestinal layers, thus producing puckering or haustration of the caecum and colon into *sacculi*. When they are removed, the tube lengthens and loses its sacculation. In the descending colon the taeniae thicken at the expense of the rest of the longitudinal layer, while there is a real increase in its total bulk in the sigmoid colon, where the longitudinal fibres are more scattered. They form a layer which completely encircles the rectum, but are thicker on its anterior and posterior aspects, producing recognizable broad anterior and posterior bands. At the rectal ampulla a few strands of the anterior longitudinal fibres pass forwards to the perineal body (p. 607), as the *musculus recto-urethralis*. In addition, two fasciculi of non-striated muscle pass antero-inferiorly from the front of the second and third coccygeal vertebrae to blend with the longitudinal muscle fibres on the posterior wall of the anal canal, forming the *rectococcygeal muscles* (Wesson 1951). The *circular fibres* form a thin layer over the caecum and colon, aggregated particularly in the intervals between the sacculi; in the rectum they are a thick layer; in the anal canal they form the sphincter ani internus. Older observations of an interchange of fascicles between circular and longitudinal layers have been confirmed in a study of 112 cadavers (from early fetal life to 88 years); interchanges of fibres, especially near the taenia coli, are commonplace. Deviation of longitudinal fibres from the taeniae to the circular layer may, in some instances, explain the haustration of the colon (Pace 1968).

The *submucosa* and *muscularis mucosae* are like those in the small intestine. The *mucosa* is pale, smooth, non-villous and raised into numerous crescentic folds between the sacculi; in the rectum it is thicker, darker, more vascular, and more loosely attached to the muscularis mucosae. The *epithelium* of the caecum, colon and upper rectum (**8**.145) consists of scattered mucus-secreting (goblet) cells, columnar absorptive cells (Pittman & Pittman 1966) and M cells (p. 1366) overlying lymphoid follicles in the lamina propria. It extends into numerous tubular glands or crypts providing a large surface for mucous secretion and absorption of water, salts and other materials, functions important in lubricating the passage of contents and in resorption of many substances secreted into the alimentary canal in its more proximal zones. The large intestine also provides an environment for a large bacterial flora, essential in many animals for digestion and for the metabolism of organic compounds to supplement vitamin intake. The columnar cells, which have luminal microvilli, are linked by juxta-luminal junctional complexes; their cytoplasm contains a subapical terminal web and the usual cytoplasmic organelles. Many also contain secretory granules in their apical cytoplasm. Their secretion appears to be mucoid, but is also rich in antibodies of the IgA type, providing some protection against pathogenic micro-organisms (Schofield & Atkins 1970). Other columnar cells possess an apical tuft of long microvilli (**8**.144A,B) and may be sensory (Silva 1966).

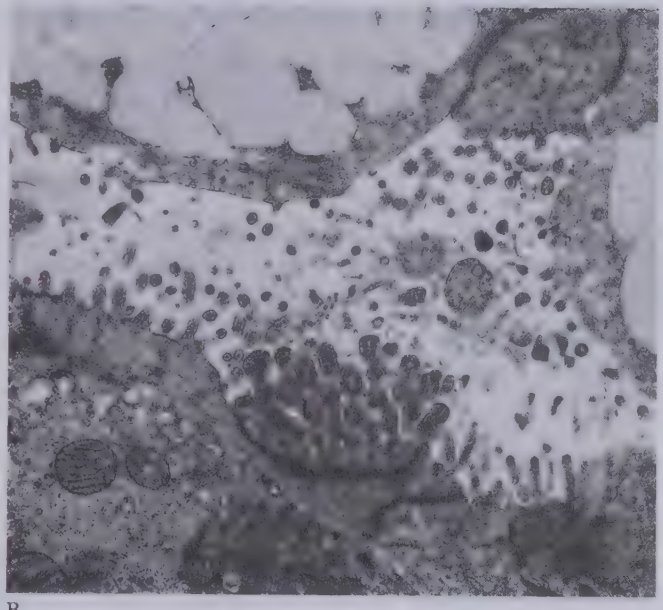
Glands of the large intestine are minute, perpendicular tubules of mucosal epithelium, longer, more numerous and in closer apposition than those of the small intestine. Their openings (**8**.145) produce a cribriform appearance; they are lined by short columnar epithelium, consisting mostly of goblet cells (**8**.143), between which are columnar absorptive cells.

Solitary lymphoid follicles, most abundant in the caecum, vermiform appendix and rectum, are scattered over the rest of the large intestine (Langman & Rowlands 1986). They are like those of the small intestine (p. 1363).

VESSELS AND NERVES OF THE LARGE INTESTINE

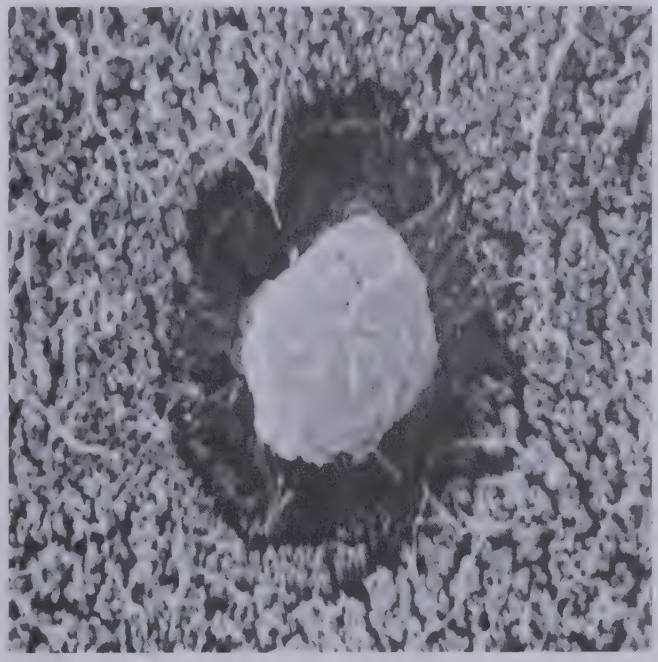
The *arteries* which supply the parts of the large intestine derived from the mid-gut (caecum, appendix, ascending colon and right two-thirds of the transverse colon) are derived from colic branches of the superior mesenteric artery; those supplying hind-gut derivatives (left part of the transverse, descending and sigmoid colon, rectum and upper anal canal) are derived from the inferior mesenteric (and its terminal branch, the superior rectal) and the middle rectal arteries (a branch of the internal iliac). Their large branches ramify between and supply the muscular layers, divide into small submucosal rami and enter the mucosa. Rectal and anal canal arteries are: (1) The superior rectal (the continuation of the inferior mesenteric). This is the main rectal vessel, dividing into two rami descending one each side of the rectum, their terminal branches piercing the muscular coat to enter the rectal submucosa and descending into the anal columns as far as the anal valves, where they form looped anastomoses. (2) The middle rectal arteries which traverse the 'lateral rectal ligaments' to supply the muscle of the lower rectum, anastomosing freely with each other but forming only poor anastomoses with the superior and inferior rectal arteries. (3) The inferior rectal arteries (from the internal pudendals), which supply the internal and external sphincters, the anal canal below its valves and the perianal skin. (4) The median sacral artery which supplies the posterior wall of the anorectal junction and of the anal canal.

The veins of the large intestine are the superior and inferior mesenteric, draining the regions supplied by the corresponding arteries. The veins of the rectum and anal canal are: (1) The



superior rectal veins, which pass from the internal rectal plexus in the anal canal and ascend in the rectal submucosa as about six vessels of considerable size to pierce the rectal wall about 7.5 cm above the anus, uniting to form the superior rectal vein, which continues as the inferior mesenteric. (2) The middle rectal veins, from the submucosa of the rectal ampulla which drain chiefly its muscular walls. (3) The inferior rectal veins, which drain the external rectal plexus and lower anal canal. Anastomoses occur between portal and systemic veins in the wall of the anal canal (pp. 816, 820).

The *nerve supply* is (except in the lower anal canal) sympathetic and parasympathetic. The caecum, appendix, ascending colon and right two-thirds of the transverse colon (derivatives of the mid-gut) have a sympathetic supply from the coeliac and superior mesenteric ganglia, and a parasympathetic supply from the vagus; the nerves are distributed in plexuses around the rami of the superior mesenteric artery. The left third of the transverse colon, the descending and sigmoid colon, rectum and upper anal canal (derivatives of the hind-gut) take their sympathetic supply from the lumbar part of the trunk and the superior hypogastric plexus by means of periarterial plexuses on rami of the inferior mesenteric artery. The sympathetic supply of the colon is largely vasomotor. The parasympathetic supply is from the pelvic splanchnic nerves (nervi erigentes), from which rami pass to the inferior hypogastric plexuses to supply the rectum and upper half of the anal canal: some fibres ascend through the superior hypogastric plexus to accompany the inferior mesenteric artery to the transverse, descending and sigmoid colon (p. 1166). Rami of the pelvic splanchnic nerves ascend on the posterior abdominal wall behind the peritoneum, independently of the inferior mesenteric artery, to be distributed directly to the left colic flexure and descending colon (Mitchell 1953). The ultimate distribution in the wall of the large intestine is as in the small intestine (p. 1563). Adrenergic and cholinergic activity in the nerve supply of the taenia coli, and distribution of the nerve fibres, suggest that (in guinea-pigs) few non-striated myocytes are directly innervated, propagation of excitation being chiefly through gap junctions between myocytes (Bennett & Rogers 1967).



Sympathetic nerves to the rectum and upper anal canal pass mainly along the inferior mesenteric and superior rectal arteries and partly via the superior and inferior hypogastric plexuses, the latter supplying the lower part of the rectum and the internal anal sphincter. Parasympathetic rami from the pelvic splanchnic nerves pass forwards as long strands (about 3 cm long) from the sacral nerves to join the inferior hypogastric plexuses on the sides of the rectum, being motor to the rectal musculature and inhibitory to the internal anal sphincter. The external sphincter ani is supplied by the inferior rectal ramus of the pudendal nerve ($S_{2,3}$) and the perineal ramus of the fourth sacral nerve (p. 1149). In rectal surgical excision, dissection must be kept close to its wall to avoid damage to these nerves with consequent bladder dysfunction and, in males, loss of penile erection. Afferent impulses mediating sensations of distension pass in afferent fibres in the parasympathetic nerves, pain impulses in the sympathetic *and* parasympathetic nerves supplying the rectum and the upper part of the anal canal. In colonic *aganglionosis (megacolon)* postganglionic autonomic neurons are reduced or absent in the colonic wall (Bodian et al 1961, Bodian 1966, Soltero-Harrington et al 1969). Garrett et al (1969) have studied the myenteric plexus and ganglionic neurons by electron

microscopy and histochemical techniques for transmitter substances reporting that in megacolon a variable diminution and sometimes absence of ganglion cells occurred, but that innervation of the muscle layers was defective even when ganglionic neurons were present.

The *lymph nodes and vessels* of the large intestine are described on p. 854.

The Gastro-entero-pancreatic Endocrine System

The gastro-entero-pancreatic (GEP) endocrine system (Fujita 1973) consists of scattered, often solitary, hormone-producing cells of the gastrointestinal mucosa and pancreas. Electron microscopy of ultra-thin (0.07 μm) sections and immunocytochemistry of adjacent semi-thin (1 μm) sections of resin-embedded tissue has led to the identification of many types of GEP endocrine cell types and their secretory products (p. 1377). Of at least 15 human types so far recognized (p. 1377), one, type B, is restricted to the pancreatic islets and at least three occur in both gastrointestinal mucosa and pancreas.

The ultrastructure of human GEP endocrine cells has been detailed by Rubin (1972), Sasagawa et al (1973), Capella et al (1976) and Cavallero et al (1976) and summarized by Solcia (1981). Endocrine cells are scattered in the gastrointestinal mucosa, with their bases resting on the basal lamina. Those of the mucosa in the main part of the stomach (the 'oxyntic mucosa') do not usually reach the lumen and are referred to as 'closed', while most of those in the pyloric and intestinal mucosae do so and are therefore termed 'open'. Their osmiophilic secretory granules vary in shape, size and ultrastructure in the different cell types, being usually infranuclear, while the Golgi complexes are supranuclear; luminal aspects of 'open' cells display microvilli of variable number, length and shape. Typical entero-endocrine cells are shown in Fig. 8.146A,B. Human *P cells* contain very small (100–140 nm) secretory granules slightly reactive to Grimelius' silver stain (Capella et al 1977); rare in normal adult tissues, they may contain a bombesin-like polypeptide (Polak et al 1976). *EC cells*, which contain osmiophilic, argentaffin, Grimelius' silver-reactive granules, are classified as EC_1, EC_2 and EC_n; in addition to 5-hydroxytryptamine, the EC_1 cells store substance P (Heitz et al 1977), EC_2 cells store motilin (Polak et al 1975) and EC_n cells an unidentified material. The *D_1 cells* contain argyrophilic granules about 140–190 nm in diameter (Capella et al 1977) and store a vaso-active intestinal peptide-like material. *PP cells*, common in the pancreatic islets but rare in the exocrine pancreas, store pancreatic polypeptide in granules of 150–170 nm; they are equivalent to F cells identified in other mammals (Baetens et al 1976). Human *D, B* and *A cells* are described with the endocrine pancreas (p. 1383). *X cells*, identified in human oxyntic mucosa by Solcia et al (1977), are of unknown function. Human *ECL cells* (Vassallo et al 1971) store a reducing amine, possibly 5-hydroxytryptamine, in granules with intensely argyrophilic cores; histamine may also occur. Human *G cells* (Vassallo et al 1971) manufacture gastrin and possibly enkephalin (Polak et al 1978), and have slightly argyrophilic granules with floccular contents. *S cells* (Capella et al 1976) are scattered in duodenojejunal mucosa and produce secretin (Larsson et al 1977); they are similar to D_1 cells but differ in their secretory product. Human *I cells* (Capella et al 1976), commonest in the duodenum and jejunum but rare in the ileum, are sources of cholecystokinin-pancreozymin (pancreaticozymin) (Buchan et al 1977). Human *K cells* (Capella et al 1976) contain large granules (approximately 350 nm in diameter) with osmiophilic, argyrophobic cores; like I cells, they are commonest in the duodenum and jejunum. K cells produce gastric inhibitory peptide. Human *N* and *L cells* are difficult to distinguish cytologically; granules of N cells are, however, generally homogeneous and about 300 nm in diameter, while those of L cells sometimes have argyrophilic cores and tend to be smaller (about 260 nm). N cells produce neurotensin (Orci et al 1976), L cells enteroglucagon or glicentin.

Concentrations of endocrine cells in the gastrointestinal mucosa are minute and generally decrease progressively in an aboral direction (8.146C).

Certain common features of GEP endocrine cells allow other classifications. They all produce peptides and/or amines active as hormones or neurotransmitters and contain neuron-specific enolase, an isoenzyme of the glycolytic enzyme enolase (Polak et al 1980). They thus belong to the *APUD cell series* (Pearse 1968, 1977, 1980) and modulate not only autonomic activity but also each other. The APUD concept is detailed elsewhere (p. 1466). The discovery of supposedly similar neurohormones and neurotransmitter peptides in cerebral neurons and some GEP endocrine cells, with other neuronal characteristics of the latter, has led to their designation as *paraneurons* (Fujita 1976). Peptides common to brain and gastrointestinal mucosa include: substance P, somatostatin, vaso-active intestinal peptide, bombesin, neurotensin, cholecystokinin and the opiatoid enkephalin (Bloom & Polak 1978). GEP endocrine cells are presumed to have superficial receptor sites, stimulation of which by 'secretogogues' triggers stimulus-secretion coupling (Kanno 1973), as in chromaffin cells (Douglas 1968); they can thus also be termed *receptosecretory cells* (Fujita 1976).

The mode of action of endocrine cells restricted to the gastrointestinal mucosa remains in doubt. Their ultrastructure and proximity to capillaries suggest that their secretory products are endocrinal, exerting distant, diffuse effects via the blood. However, of their many products, only the following have been shown to act as circulating hormones: gastrin, secretin, cholecystokinin-pancreozymin, gastric inhibitory peptide, motilin and enteroglucagon (Bloom & Polak 1978). Basic differences exist between endocrine cells in gastric and intestinal mucosae and those in most other endocrine organs: they are not aggregated into glands but scattered among their local targets; most are close to the alimentary lumen, allowing their specialized plasmalemmae to detect and respond to luminal stimuli; there are no common hyposecretory or hypersecretory syndromes; relations between plasma hormone levels and functional response (e.g. modulation of neural control of gut motility) is not stoichiometric. Wingate (1976) has suggested that gastrointestinal hormones may have local 'paracrine' *and* distant 'endocrine' effects; direct actions on gastrointestinal myocytes, on adjacent endocrine cells, on other enterocytes and on local neurons are speculative but feasible. Although the gut might be regarded as the largest

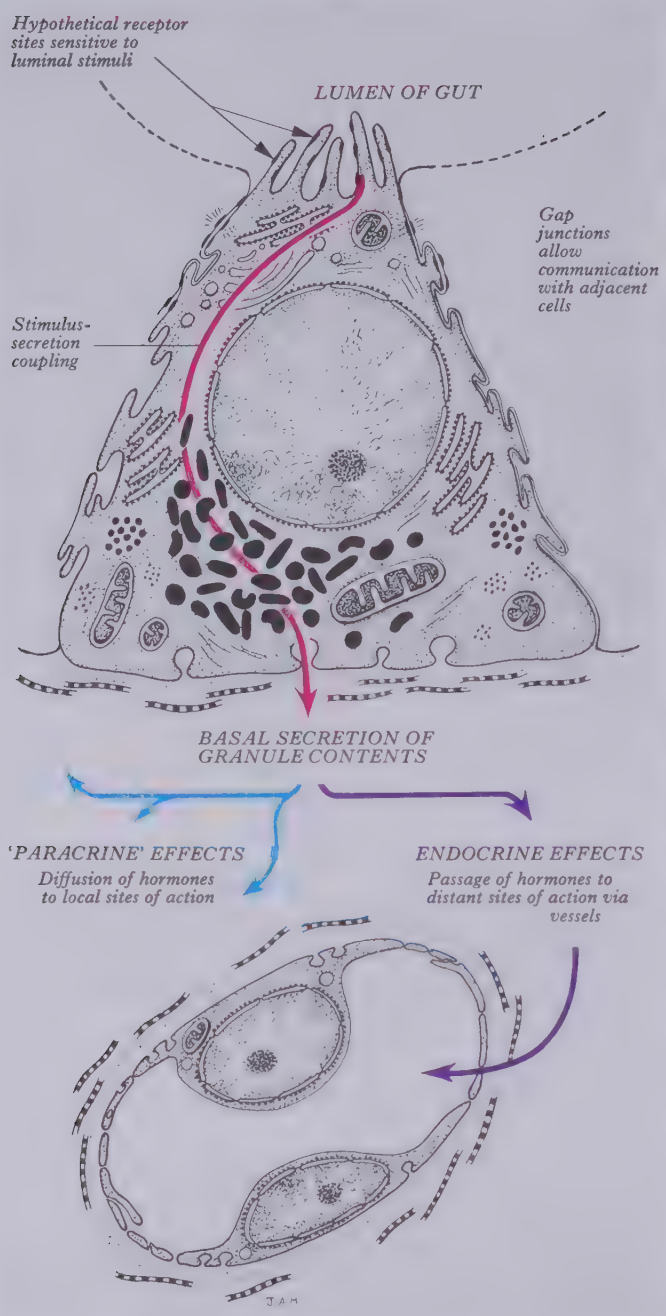
Abbreviations used for secretory products:
5-HT = 5-hydroxytryptamine
VIP = Vaso-active intestinal peptide
H = Histamine
GIP = Gastric inhibitory peptide
GLI = Glicentin

(Based mainly on the Lausanne 1977 classification of gastro-entero-pancreatic endocrine cells reported by Solcia et al in 1978).

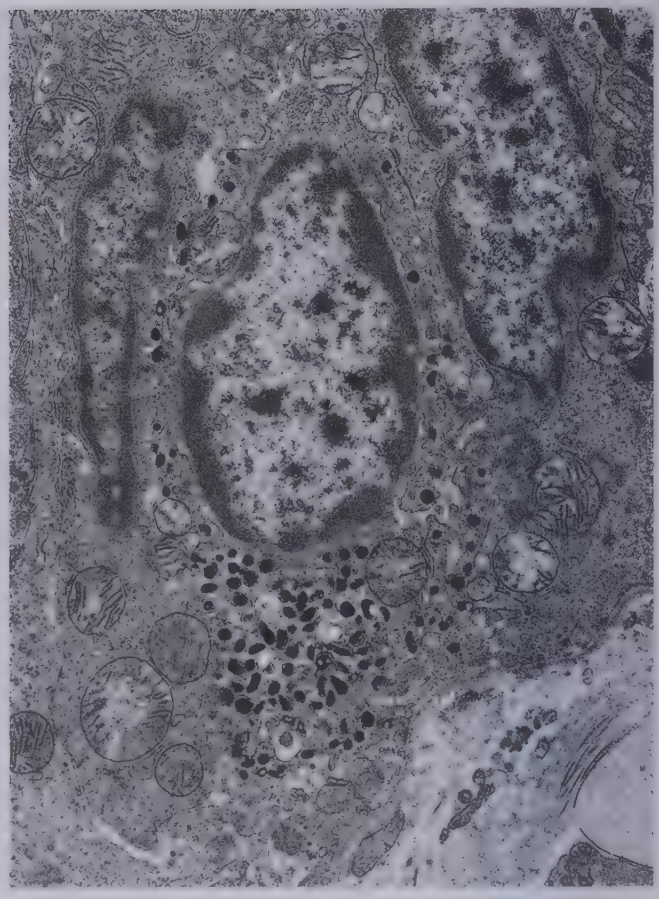
endocrine organ (Pearse 1974), it is perhaps more properly regarded as a region in which neural, paracrine and endocrine controls of activity are intimately linked.

Applied Anatomy of the Intestine: Hernia



The rarity of rupture of the jejunum and ileum by external injury is due to their elasticity and mobility; the more fixed duodenum, particularly its horizontal part across the vertebral column, is more vulnerable. In external hernia the ileum is most frequently involved; in the large intestine it is usually the caecum or sigmoid colon. The chief sites of hernia are inguinal, femoral and umbilical.

Inguinal Hernia



Here a viscus is protruded through the inguinal region of the abdominal wall. The principal varieties are oblique and direct.

(1) *Oblique (indirect) inguinal hernia.* Here the intestine is pushed through the lateral inguinal fossa (behind the deep inguinal ring), preceded by a pouch of parietal peritoneum and extraperitoneal areolar tissue. It enters the inguinal canal at its deep ring and is invested by internal spermatic fascia enclosing the spermatic cord. As it traverses the canal it pushes up the arching fibres of transversus abdominis and obliquus internus, is covered by the cremasteric fascia and muscle and lies anterior to the cord. Emerging at the superficial inguinal ring, it is invested by the external spermatic fascia and also, as it descends into the scrotum, by superficial fascia and skin. The hernia may become constricted at the deep ring, with interference to its blood supply (strangulation). When this is relieved the deep ring should be cut superolaterally to avoid the inferior epigastric vessels. Most oblique inguinal hernias follow congenital defects in the processus vaginalis (p. 258). Obliteration of this may be complete at birth or it may begin late and be completed only after birth; closure begins at the deep inguinal ring and epididymal head, extending until all of the intervening region becomes a fibrous cord. Complete or partial failure of closure of the processus entails variations in the relation of the hernial protrusion to the testis and tunica vaginalis; e.g. if the processus is fully patent, the herniated gut descends in front of the testis into the tunica vaginalis (*complete congenital hernia*); in this case, the processus and tunica form the hernial sac. In *incomplete congenital hernia* (hernia into the funicular process), the herniating gut descends to the top of the testis, where the processus is sealed off from the tunica vaginalis (**8**.147). Although the above types are called congenital, actual extrusion into a pre-existing peritoneal sac may not occur until adult life and then be produced by an increased intra-abdominal pressure or sudden muscular strain. (For a critique of the anatomy of inguinal hernia consult Lytle 1979.)

(2) *Direct inguinal hernia.* Here the protrusion is through some part of the inguinal triangle, which is bounded inferiorly by the

medial half of the inguinal ligament, medially by the lower lateral border of rectus abdominis and laterally by the inferior epigastric artery. It overlies the medial inguinal fossa and, partly, the supravesical fossa (p. 1338). A direct hernia is either through *(a)* the *medial inguinal fossa*, where only extraperitoneal tissue and transversalis fascia separate the peritoneum from the aponeurosis of the external oblique, or *(b)* the *supravesical fossa* and *falx inguinalis* (conjoint tendon), which lies in front of the fossa. In the first form, herniation is lateral to the conjoint tendon, propelling before it the peritoneum, extraperitoneal tissue and transversalis fascia to enter the inguinal canal, which it traverses to emerge from the superficial ring, covered by external spermatic fascia. Its coverings are like those of the oblique form, except that a part of the general layer of transversalis fascia replaces the internal spermatic fascia, the hernia being between the innermost and middle coverings of the spermatic cord. In the second, more frequent form, the hernia is either between the fibres of the falx inguinalis, or the falx is gradually distended to form a complete covering. The hernia thus enters the lower end of the canal, escapes at the superficial ring medial to the cord and is covered by external spermatic fascia, superficial fascia and skin. Its coverings differ from those of oblique hernia, the conjoint tendon replacing the cremaster and part of the transversalis fascia replacing the internal spermatic fascia. In all varieties the most superficial covering is the external spermatic fascia, the outermost covering of the cord. An oblique inguinal hernia is within the cord, sharing all its coverings; a direct hernia acquires an additional covering from the transversalis fascia.

Direct inguinal hernia is much less frequent than the oblique type, and occurs more often in males. Its main peculiarities are: *(a)* it is sited above the body of the pubic bone, *(b)* the inferior epigastric artery is *lateral* (not medial) to the neck of the sac; *(c)* the spermatic cord is posterolateral, not directly posterior as in oblique hernia. A direct hernia is always of the acquired type. The stricture in both varieties of direct hernia is usually at the neck of the sac or at the superficial ring. Where the conjoint tendon is split, constriction may occur at the edges of the fissure. In all cases of inguinal hernia, whether oblique or direct, it is correct to divide the stricture upwards, parallel to the inferior epigastric artery to avoid damaging that vessel.

Femoral Hernia

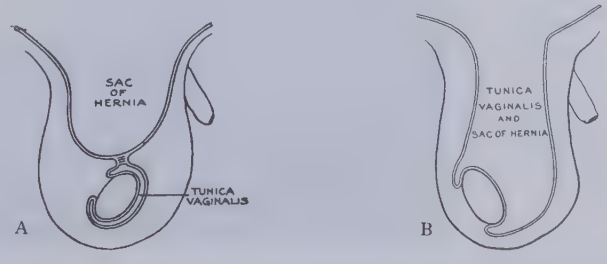
A femoral hernia protrudes through the femoral ring (p. 781), which is normally closed by a femoral septum of modified extraperitoneal tissue and is therefore a weak spot, especially in females, where the ring is larger and subject to profound changes during pregnancy. Femoral hernia is hence more common in women. When a section of intestine bulges through the ring, it pushes out a hernial sac of peritoneum. It is covered by extraperitoneal tissue (the femoral septum) and descends along the

8.146C Approximate quantitative distribution of a selection of human gastro-entero-pancreatic (GEP) endocrine cells (highly diagrammatic, after Bloom & Polak 1978, with permission from Churchill Livingstone).

femoral canal to the saphenous opening, where it is prevented from descending along the femoral sheath by the narrowing of the latter, by the vessels and by the close attachment of the superficial fascia and sheath to the lower part of the rim of the saphenous opening (p. 638). The hernia hence turns forwards, distending the cribriform fascia and curving upwards over the inguinal ligament and the lower part of the external oblique aponeurosis. While in the canal the hernia is usually small, due to the resistance of its surrounds; but with escape into the inguinal loose connective tissue it enlarges. Thus a femoral hernia first descends, then ascends forwards; hence pressure to reduce it should be directed in the reverse order, with the thighs passively flexed for greatest relaxation.

Covering a femoral hernia are (from within outwards): the peritoneum, femoral septum, femoral sheath, cribriform fascia, superficial fascia and skin. A fibrous covering, the *fascia propria*, just outside the peritoneal sac but frequently separated from it by adipose tissue, may be easily mistaken for the sac, and its contained extraperitoneal fat for omentum; the fat may resemble a lipoma, but dissection will reveal the true hernial sac in its centre. The fascia propria is merely a femoral septum thickened to form a membranous sheet by hernial pressure. The intestine reaches only to the saphenous opening in *incomplete femoral hernia* in contradistinction to *complete hernia* where it passes through the opening. The small size of an incomplete hernia renders it difficult to detect and therefore dangerous, especially in the corpulent. The site of strangulation varies: it may be at the hernial sac's neck; more often it is at the junction of the falciform margin of the saphenous opening with the free edge of the pectineal part of the inguinal ligament; or it may be at the saphenous opening (p. 638). The stricture should be divided superomedially for a distance of 4–6 mm to avoid all normally positioned vessels and other important structures. (However, an abnormal obturator artery may be a complication, see p. 778.)

The pubic tubercle is an important landmark in distinguishing inguinal from femoral hernias; the hernia's neck is superomedial to it in inguinal hernia but inferolateral in the femoral form.



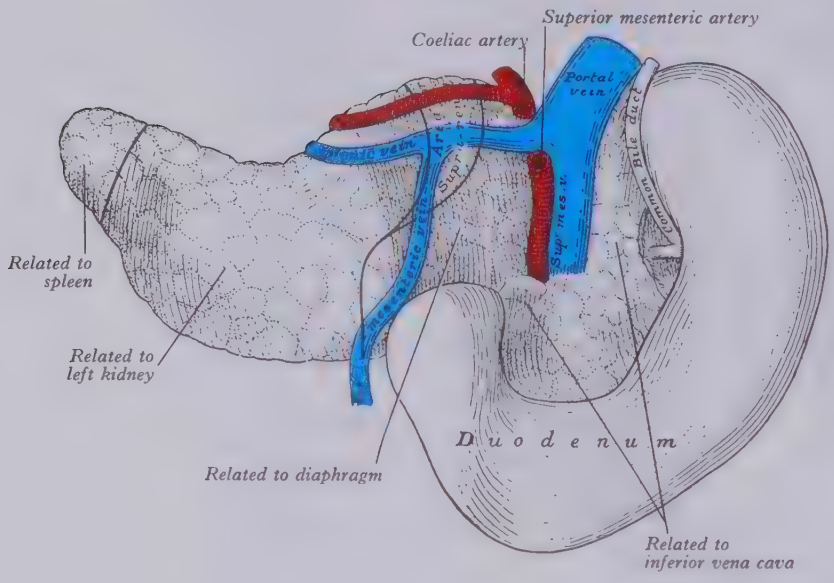
Umbilical Hernia

There are three varieties of umbilical hernia.

(1) *Congenital umbilical hernia.* This is due to the failure of retraction of the umbilical loop of the gut (p. 232).

(2) *Infantile umbilical hernia.* This is due to stretching of umbilical scar tissue, usually within three years of birth, and is associated with increased intra-abdominal pressure.

(3) *Acquired umbilical hernia.* This is really through the linea alba, usually just above the umbilicus (para-umbilical hernia) and occurs most frequently in obese multiparous females.



8.147 Diagrams representing varieties of oblique inguinal hernia: A. incomplete congenital; B. complete congenital.

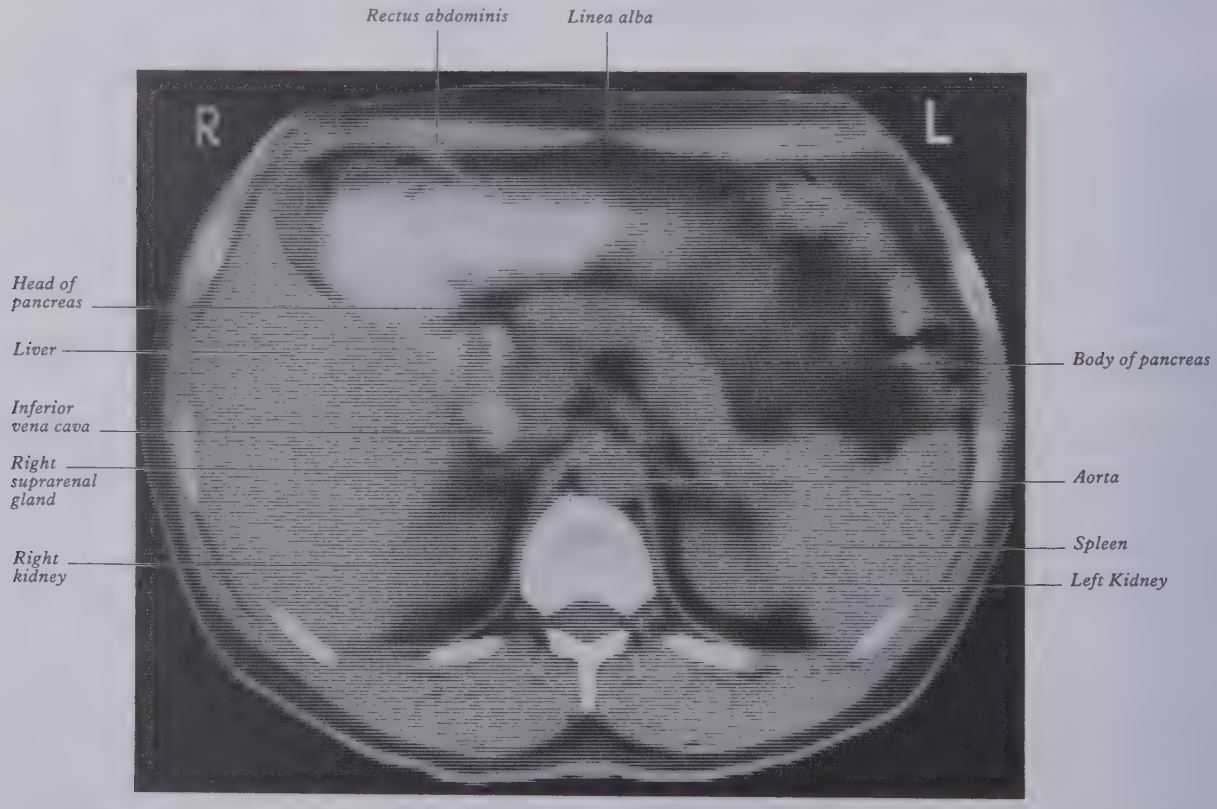
Rarely, hernia may occur at other sites, e.g. through the *lumbar triangle* (p. 610), *obturator foramen, greater* or *lesser sciatic foramen* or *ischiorectal fossa*. *Incisional hernia* may occur at the sites of abdominal scars, particularly if the wound becomes infected.

For variations of medical and surgical importance in the small intestine and also in the colon consult Goligher (1967) and Kanagasuntheram (1970).

The Pancreas

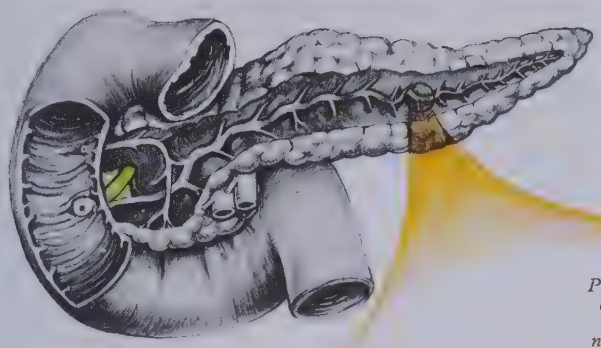
The pancreas is a soft, lobulated, greyish-pink gland, 12–15 cm long, extending nearly transversely across the posterior abdominal wall from the duodenum to the spleen, behind the stomach. Its broad, right extremity or *head* is connected to the *body* by a slightly constricted *neck*; its narrow, left extremity is the *tail*. It ascends slightly to the left in the epigastric and left hypochondriac regions.

8.148 Posterior aspect of the pancreas and duodenum.



RELATIONS OF THE PANCREAS

The structures related to the pancreas are best considered with respect to its different parts (**8**.125, 148, 149, 150).



The head, flattened anteroposteriorly, lies within the duodenal curve. Its upper border is overlapped by the superior duodenal segment, the other borders being grooved by the adjacent margin of the duodenum, which they variably overlap in front and behind. Sometimes a small part of the head is actually embedded in the wall of the descending duodenum. From the lower left part of the head the *uncinate process* projects upwards and to the left behind the superior mesenteric vessels. In or near the groove between the duodenum and the right and lower borders of the head are the anastomosing superior and inferior pancreaticoduodenal arteries (pp. 769, 772; **6**.109).

Anterior surface. From the head's anterosuperior aspect the neck juts forwards, upwards and to the left, merging with the body. The boundary between head and neck, on the right and in front, is a groove for the gastroduodenal artery; on the left and behind it is a deep incisure containing the union of the superior mesenteric and splenic veins to form the portal vein. Below and to the right of the neck the head's anterior surface is at first in contact with the transverse colon, separated only by areolar tissue; still lower the surface is covered by peritoneum continuous with the inferior layer of the transverse mesocolon (**8**.93) and in contact with the jejunum. The uncinate process is crossed anteriorly by the superior mesenteric vessels.

Posterior surface. The head is related posteriorly to the inferior vena cava which ascends behind it, covering almost all of this surface. Also it is related to the terminal parts of the renal veins and the right crus of the diaphragm. The uncinate process lies in front of the aorta. The bile duct is lodged either in a superolateral

groove on the posterior surface or within the gland's substance (p. 1394).

The neck, about 2 cm long, projects anterosuperiorly and to the left from the head, merging into the body. Its anterior surface, covered with peritoneum, adjoins the pylorus, with part of the omental bursa intervening; the gastroduodenal and anterior superior pancreaticoduodenal arteries descend in front and to the right of the junction of the neck and head; the posterior surface is related to the superior mesenteric vein and the beginning of the portal vein.

The body, prism-like in section, has three surfaces: anterior, posterior and inferior (more precisely anterosuperior, posterior and antero-inferior, all obliquely orientated).

The concave *anterior surface* faces anterosuperiorly, is covered by peritoneum continuous antero-inferiorly with the *anterior* ascending layer of the greater omentum (**8**.112) and is separated from the stomach by the omental bursa. On reaching the taenia mesocolica, the greater omentum's *posterior* ascending layer fuses with the anterosuperior surface of the transverse mesocolon, while the anterior layer continues up to the mesocolon's root and is then reflected up over the anterior pancreatic surface.

The *posterior surface*, which is devoid of peritoneum, is in contact with the aorta and the origin of the superior mesenteric artery, the left crus of the diaphragm, left suprarenal gland and with the left kidney and renal vessels, particularly the vein. It is closely related to the splenic vein which courses from left to right and separates it from the structures mentioned. The left kidney is also separated from the pancreas by perirenal fascia and fat.

The narrow *inferior surface* broadens to the left and is covered by the peritoneum of the postero-inferior layer of the transverse mesocolon; inferior to it are the duodenojejunal flexure and coils of the jejunum; its left end rests on the left colic flexure.

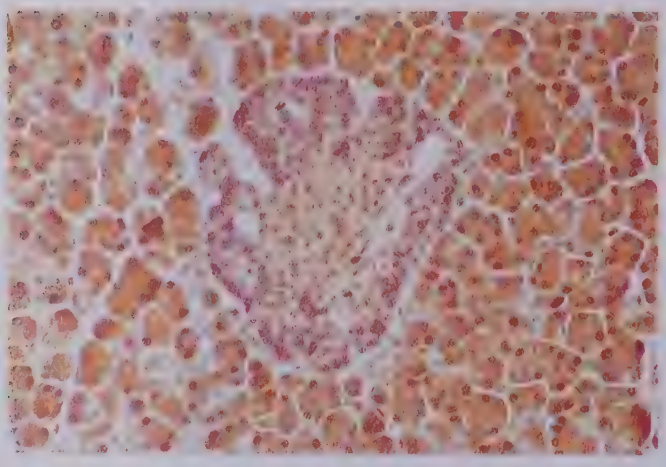
The *superior border* is blunt and flat to the right, narrow and sharp to the left near the tail. An *omental tuberosity* usually projects from the right end of the superior border above the level of the lesser curvature of the stomach, in contact with the posterior surface of the lesser omentum. It is related above to the coeliac artery, its common hepatic branch coursing to the right just above the gland, while its sinuous splenic ramus runs to the left along this border.

The *anterior border* separates anterior and inferior surfaces; along it the two layers of the transverse mesocolon diverge, one passing up over the anterior surface, the other backwards over the inferior surface. The *inferior border* separates posterior and inferior surfaces, the superior mesenteric vessels emerging from under its right end.

The tail is narrow, usually reaching the inferior part of the gastric surface of the spleen. It is contained between the two layers of the splenorenal (lienorenal) ligament with the splenic vessels.

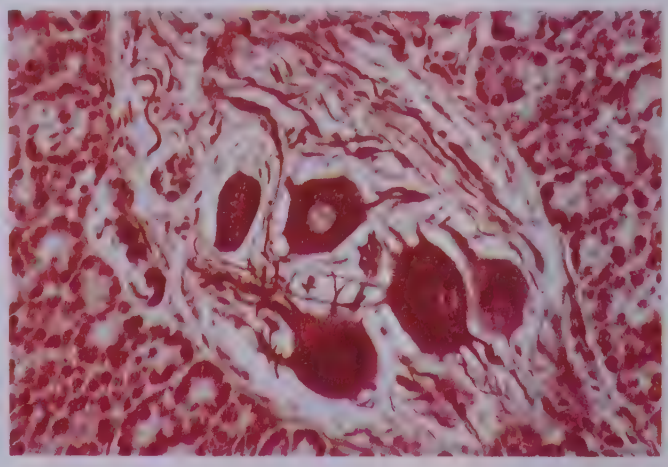
The main pancreatic duct traverses the gland from left to right, being nearer its posterior than its anterior surface (**8**.150). It begins by the junction of lobular ducts in the tail and, running to the right in the body, receives further lobular ducts which join it almost at right angles (a 'herringbone pattern'). Much enlarged, it reaches the neck of the gland, turning down, backwards and right towards the bile duct, which lies on its right side. The two ducts enter the wall of the descending part of the duodenum obliquely and unite in a short dilated *hepato-pancreatic ampulla* or ampulla of the bile duct (p. 1394); the narrow distal end of this opens on the summit of the *major duodenal papilla*, posteromedial in this part of the duodenum, and 8–10 cm distal to the pylorus. Usually they do not unite until very near the orifice on the papilla. Sometimes they open separately. Frequently an *accessory pancreatic duct* drains the lower part of the head (**8**.150), ascending in front of the main duct, with which it communicates, and opening on a small rounded *minor duodenal papilla*, about 2 cm anterosuperior to the major. The duodenal end of the accessory duct may fail to expand; secretion is then diverted along the connecting channel into the main duct (Dawson & Langmann 1961).

Surface Anatomy



The head of the pancreas is in the duodenal curve. The neck lies in the transpyloric plane, behind the pylorus. The body passes obliquely up and left for about 10 cm, its left part lying a little above the transpyloric plane. The tail is a little above and to the left of the intersection of the transpyloric and left lateral planes.

PANCREATIC STRUCTURE



The pancreas is composed of two different types of glandular tissues in intimate association with each other. The main mass is *exocrine*, embedded in which are *pancreatic islets* of *endocrine cells*.

THE EXOCRINE PANCREAS

The exocrine pancreas is a branched acinar (acino-racemose) gland, surrounded and incompletely lobulated by delicate loose connective tissue (de Reuck & Cameron 1962, Beck & Sinclair 1971). Its pyramidal, acinar, secretory cells are arranged in flask-shaped or tubular groups. A narrow intercalated (intralobular) duct lies in each secretory mass, the initial parts of its walls being lined by cuboidal *centro-acinar cells*, later replaced by taller cuboidal and eventually columnar cells more distally. Larger, interlobular ducts are surrounded by areolar tissue containing non-striated myocytes and autonomic nerve fibres. Argentaffin

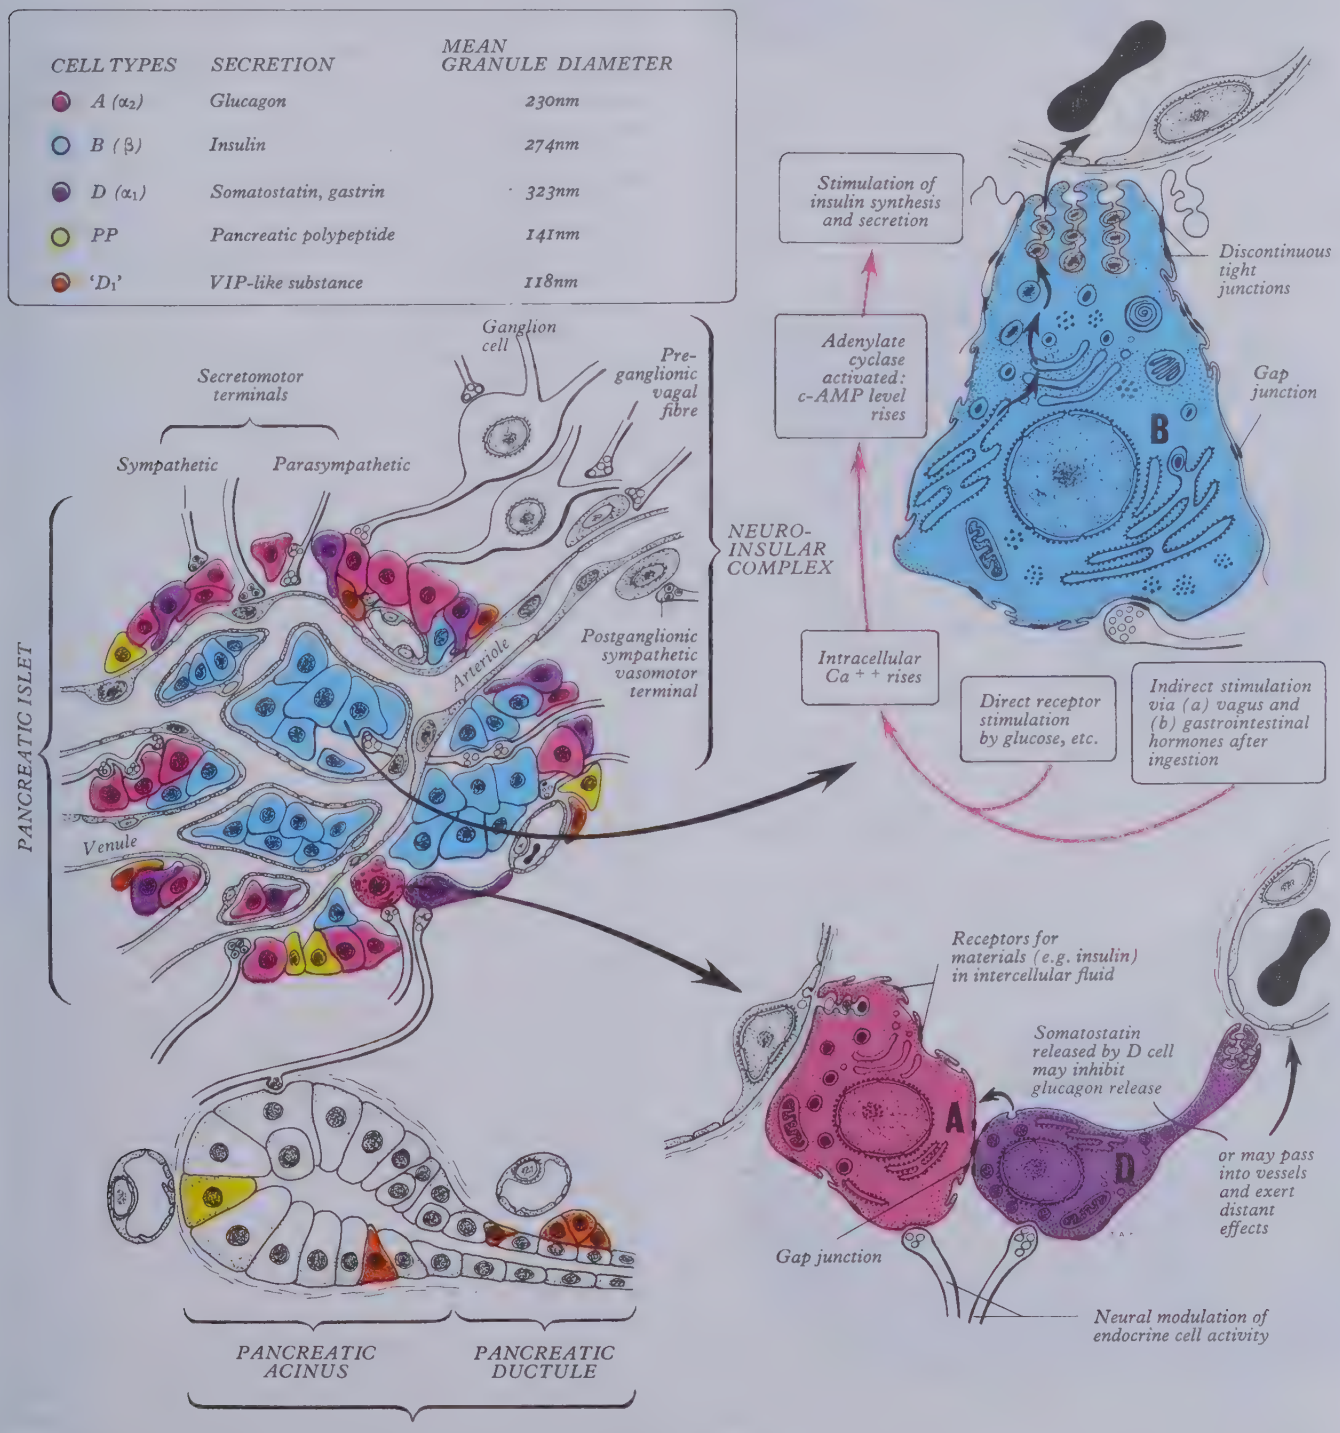
8.152 A low-power micrograph showing a cluster of autonomic ganglionic neurons with dendritic trees and axonal bundles, situated amongst pancreatic acinar cells of the goat. Palmgren silver impregnation. Provided by J Henderson, Department of Physiology, Guy's Hospital Medical School, London.



cells (p. 1376) are present amongst the undifferentiated columnar ductual cells; mast cells are numerous in the surrounding areolar tissue.

The acinar cells are typical zymogenic cells, with a basal nucleus and basophilic cytoplasm consisting of regular arrays of granular endoplasmic reticulum with mitochondria and dense secretory granules. A prominent supranuclear Golgi complex is surrounded by many larger, membranous granules containing enzymic constituents of pancreatic secretion, only active after release. The orderly contents of the acinar cells have provided a widely used model for investigation of routes of secretory synthesis and transport in protein-secreting cells at large (p. 25). After death, the action of pancreatic hydrolytic enzymes rapidly obscures cellular detail.

Ganglionic neurons (**8**.152) and cords of undifferentiated epitheliocytes also appear in the exocrine pancreas; the latter may provide stem cells for replacement of exocrine and perhaps endocrine cells. The structure of the exocrine pancreas and its control are summarized in **8**.150. For further details consult Webster et al (1977), Singh & Webster (1978), Case (1979) and Wormsley (1979).

THE ENDOCRINE PANCREAS

This consists of *pancreatic islets* or *insulae* (of Langerhans), consisting of spheroidal or ellipsoidal clusters of cells dispersed in the exocrine tissue (Laguesse 1906, Lane 1907), together with scattered, often solitary, endocrine cells (Heitz et al 1976).

8.153 Diagram of the histology, ultrastructure and mode of operation of the endocrine pancreas (VIP = vaso-active intestinal polypeptide).

The human pancreas may contain more than a million islets, usually most numerous in the tail (Findlay & Ashcroft 1975). Each is a mass of polyhedral cells pervaded by fenestrated capillaries (Goldstein & Davies 1968) and a rich autonomic innervation (Gerich & Lorenzi 1978). Staining procedures distinguish the major types of cell (Lane 1907, Bensley 1911, Bloom 1931, Kito & Hosoda 1977). Immunofluorescence microscopy and immuno-electron microscopy (Heitz et al 1976, Baetens et al 1977) have confirmed the identity of their secretory products and revealed other types of endocrine cell (**8**.153).

The most numerous cells, types A (alpha) and B (beta), respectively secrete glucagon (Baum et al 1962) and insulin (Lacy & Davies 1957). Though interspecific variation exists (Findlay & Ashcroft 1975), human A cells tend to be peripheral in islets and B cells more central (Orci 1976). Cytoplasmic storage granules of A cells are fixed by alcohol, are generally smaller than those of B cells, stain brilliant orange or red with Orange G and Mallory-Azan, and are aldehyde-fuchsin negative; in B cells they are alcohol-soluble and aldehyde-fuchsin positive. A third type, the D cell, discovered in human islets by Bloom (1931) and generally said to make gastrin, contains somatostatin or a similar peptide (Orci et al 1975). Human D cells are peripherally placed within the islets, like A cells. Orci & Unger (1975) suggested that islets may have two functional regions: a medulla mainly of B cells (where insulin is secreted at a constant rate in response, e.g., to the presence of glucose in the intercellular fluid) and a mixed cortex of A, B and D cells, rich in neurovascular elements (where secretory activity responds rapidly to various environmental changes). In the cortex somatostatin released by D cells may inhibit secretory activity in adjacent A or B cells (Orci 1976). In many mammals, including humans, D cells more often contact A cells than B, suggesting that pancreatic somatostatin may chiefly inhibit glucagon release. Organ culture studies by Barden et al (1977) corroborate this; when antisomatostatin serum was incubated with rat islets, glucagon release increased tenfold with no significant change in the release of insulin. How somatostatin inhibits the release of glucagon and possibly insulin is not clear; it may act intracellularly, passing through gap junctions from adjacent cells (Gerich & Lorenzi 1978). Another suggested hormonal modifier of islet activity is gastric inhibitory peptide, which appears to potentiate insulin secretory response to glucose (Dupre et al 1973). The autonomic 'neurohormones', acetylcholine and noradrenalin, also affect secretion, acetylcholine augmenting insulin and glucagon release, noradrenalin inhibiting glucose-induced insulin release; they may also affect somatostatin and pancreatic polypeptide secretion. The roles of the circulating noradrenalin and adrenalin or of neurogenous noradrenalin acting locally on islet cell secretion remain obscure. Control of islet activity is summarized in **8**.153.

Peptide-secreting cells, with smaller granules than those in A, B and D cells, occur in human pancreas, in at least two forms: one contains pancreatic polypeptide (PP cell); another has an ultrastructure like that of D_1 cells of the gastric mucosa (p. 1377). Pancreatic 'D_1' cells differ from PP cells in their granules; those of the former do not react with antibovine pancreatic polypeptide serum, those of the latter do (Baetens et al 1977). Although the product of gastro-enteric D_1 cells is uncertain, it may be related to vaso-active intestinal polypeptide (Buffa et al 1977); the product of pancreatic 'D_1' cells is still uncertain.

'D_1' and PP cells are not restricted to islets, being also scattered throughout the predominantly exocrine tissue (**8**.153).

Islet Vessels and Nerves

Pancreatic *arteries* are rami of the splenic and pancreaticoduodenal arteries (pp. 769, 772 and **6**.109). *Venous drainage* is into the portal, splenic and superior mesenteric veins. *Lymph drainage* is described elsewhere (p. 853). Larger blood and lymph vessels travel with the exocrine ducts and nerves in the interlobular connective tissue, supplying lobular branches. Bunnag et al (1963) have shown that in mice one to three afferent arterioles arise from arterial rami to supply each islet, before which they may supply the acini. In each islet they feed a capillary network almost as dense as in a renal glomerulus; the network is drained by one to six venules which join to enter an intralobular vein. McCuskey & Chapman (1969) reported an intermittent flow in islet capillaries, local interruption being due to luminal bulging of the endothelial cells. The capillaries are fenestrated.

The pancreatic *nerve supply*, from the coeliac plexus, enters along with the arteries of supply. Little is known of the afferent nerves; the efferents consist of sympathetic postganglionic fibres from the coeliac ganglion and parasympathetic preganglionic from the right vagus. The fibres, mainly nonmyelinated (Benscome 1959), are vasomotor (sympathetic) and parenchymal (sympathetic and parasympathetic) in their distribution. Fine branches ramify among the cells, from peri-insular plexuses (Findlay & Ashcroft 1975). Fibres frequently synapse with acinar cells before innervating the islets, suggesting a close linkage between neural control of exocrine and endocrine components. Many fibres enter the islets with the arterioles (Coupland 1958).

Parasympathetic ganglia lie in the inter- and intralobular connective tissue, and in the latter case are frequently associated with insular cells, forming *neuro-insular complexes*, first described by van Campenhout (1925) as 'complexes sympathico-insulaires', revised to 'complexes neuro-insulaires' by Simard (1937). They were classified by Fujita (1959) in two groups: one of neurons and insular cells (**8**.153), one of nerve fibres and insular cells, the latter being described in detail by Kobayashi & Fujita (1969). Both A and B cells are involved in the neuro-insular complexes. Their roles remain speculative; but if they are from the neural crest (Pearse 1969, Weichert 1970), the adjacency of insular and neural cells is not surprising, nor an autonomic involvement in the control of islet secretion.

Three types of nerve terminal are noted in islets (Smith & Porte 1976): cholinergic (with 30–50 nm diameter agranular vesicles), adrenergic (with 30–50 nm dense-cored vesicles) and a third, uncharacterized, type (with 60–200 nm dense-cored vesicles). No selective link with any one type of insular cell has been found; sometimes more than one type of terminal contacts a single cell (Esterhuizen et al 1968). Some of the chemical synapses between axon terminal and islet cell show narrow areas in the synaptic clefts suggesting an electrical synapse or gap junction (Orci et al 1973); such junctions also occur between islet cells (Orci 1974) and electrical coupling of nerve supply to a functional network of islet cells has been mooted. Some terminals appear remote from the surfaces of islet cells (Kobayashi & Fujita 1969); neuro-transmitters released from them could diffuse through intercellular spaces to affect numerous islet cells.

Applied Anatomy

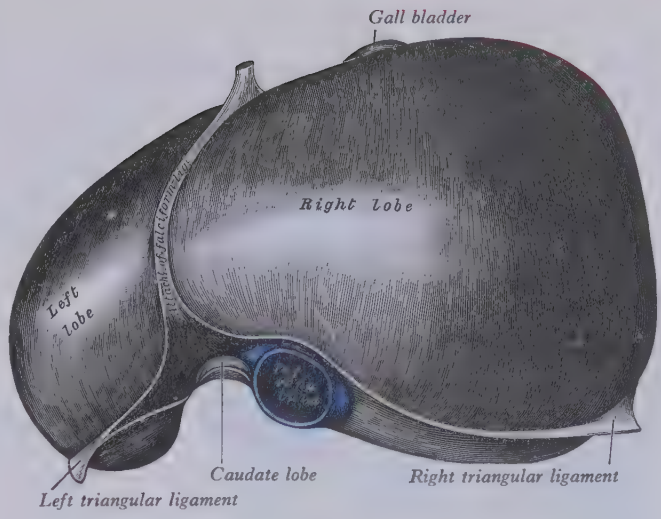
Pancreatic cysts may become very large, pressing on the stomach, diaphragm or bile duct. They usually push forwards between the stomach and transverse colon, becoming palpable in the upper abdomen as a median tumour, immobile even during respiration. Carcinoma usually affects the head, speedily involving the bile duct, leading to jaundice; or it may press on the portal vein, causing ascites, or obstruct the pylorus. The descending part of the duodenum is occasionally encircled by the pancreatic head (annular pancreas); neoplasm or infection may then cause duodenal obstruction. (Kasai et al 1974 have surveyed the literature on this occurrence.) If the bile duct is embedded in the pancreatic head (p. 1394), chronic pancreatitis may obstruct it and produce jaundice. Accessory nodules of pancreatic tissue may exist in the wall of the duodenum (most commonly), jejunum, ileum or ileal diverticulum (p. 1356). They may be associated with duodenal diverticula, as small protrusions of the whole wall or only of the mucosa and submucosa, usually adjacent to the pancreas and the opening of the bile duct.

The Liver

The liver (hepar), the largest gland, lies in the upper right part of the abdominal cavity, occupying most of the right hypochondrium and epigastrium and extending into the left hypochondrium as far as the left lateral line (Rouiller 1964). In males it generally weighs 1.4–1.8 kg, and in females 1.2–1.4 kg, with a range of 1.0–2.5 kg. It is somewhat cuneiform, is reddish brown in colour in the fresh state and, though firm and pliant, is easily

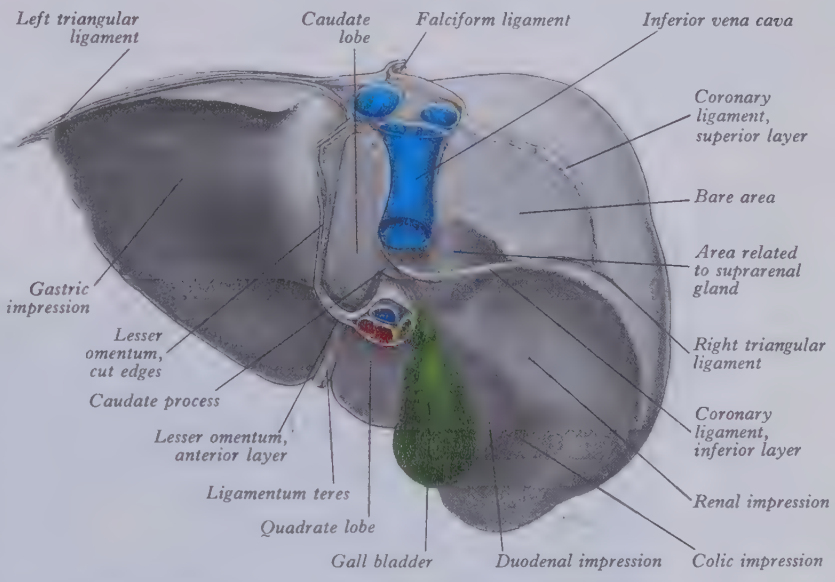
lacerated. Wound cannot be tightly sutured and bleeding may be severe, due to the organ's great vascularity. Despite its weight, it is widely believed that, like various other viscera, its position is not maintained by peritoneal (p. 1388) or fibrous attachments, but mainly by intra-abdominal pressure due to tonus in the abdominal muscles. The continuity of hepatic veins with the inferior vena cava may provide some support. However, such dogma should be viewed with caution. Without systematic studies of intra-abdominal pressure gradients and their variations with posture, respiration, gastrointestinal dilatation and so forth, and studies of the statics and dynamics of the peritoneal folds, connective tissues, adjacent viscera and vascular pedicles, any theories as to the mechanisms maintaining the position of the liver (or any other abdominal organ) remain highly speculative.

THE BORDERS OF THE LIVER



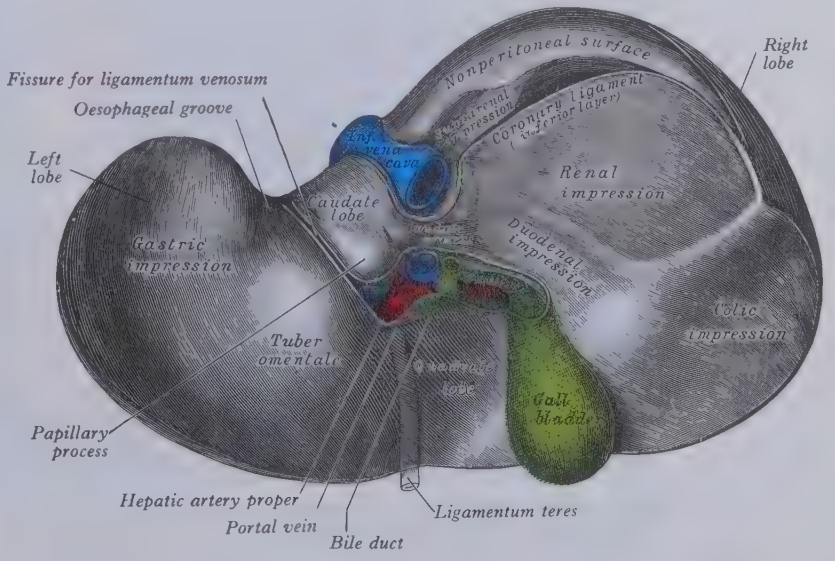
The superior, anterior and right surfaces are continuous at rounded 'borders', but a sharp *inferior border* (**8**.154) separates the right and anterior surfaces from the inferior surface. This border is rounded between the right and inferior surfaces, but becomes thin and angular at the lower limit of the anterior surface and is notched along this edge by the *ligamentum teres*, to the right of the midline. Lateral to the fundus of the gallbladder, which often corresponds to a second notch 4–5 cm to the right of the midline, the inferior border largely follows the costal margin. Left of the fundus it ascends less obliquely than the costal margin, crossing the infrasternal angle to pass behind the left costal margin near the tip of the eighth costal cartilage. It then ascends sharply to merge with the thin margin of the left lobe. At the infrasternal angle the inferior border adjoins the anterior abdominal wall and is accessible to examination by percussion, but is not usually palpable; in the midline the inferior border is near the transpyloric plane, about a hand's breadth below the xiphisternal joint (**8**.139). In women and children the border often projects a little below the right costal margin.

THE HEPATIC LOBES

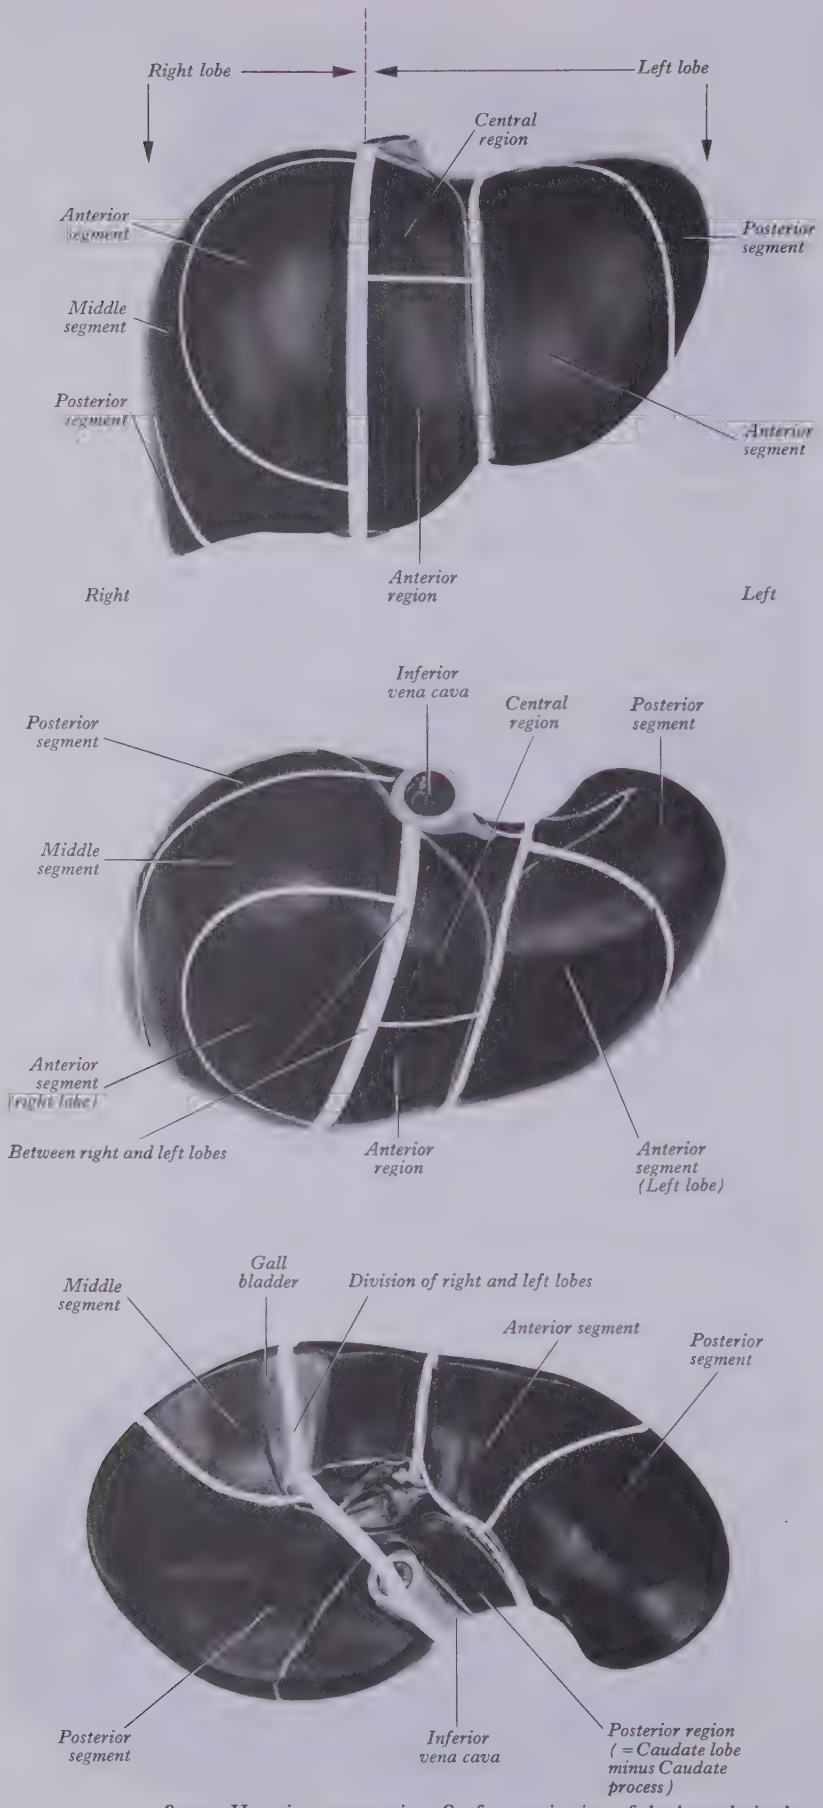


The liver is divisible into a right and a much smaller left lobe. The original basis for demarcation was a concatenation of superficial features (attachment of the falciform fold, the position of fissures for ligamenta teres et venosum, etc.) and such descriptions persist in many texts. However, classic studies by Hjortsjö (1948, 1951, 1956) on the intrahepatic segmental branching of the bile ducts, hepatic artery and portal vein, have emphasized that primary anatomical and functional lobation are better defined as the territories of the right and left hepatic ducts. Despite individual variation and some interdigitation between the smaller tributaries of the right and left ducts, the approximate dividing zone between the two lobes is a plane considerably to the right of the traditional demarcation (**8**.156). Inferiorly and posteriorly the division extends from the fossa for the gallbladder towards the inferior vena cava, making the quadrate and caudate lobes (vide infra) part of the *left* lobe, *not* the right, except for the processus caudatus which is served by the *right* hepatic duct. The plane of division is not quite sagittal, being tilted in the horizontal and vertical planes.

Other workers have confirmed Hjortsjö's classification and have made further subdivisions of lobes into segments, as described below (e.g. Healey & Schroy 1953, Goldsmith & Woodburne 1957, Stucke 1959), by corrosion cast techniques, dissection and radiology. In such investigations, particularly those involving examination of casts of ducts or vessels, so-called 'fissures' are visible (**8**.155A) between the territories of the right and left branches, and less clearly between lobar subdivisions (segments). These fissures, even in the main interlobar zone, do not produce reliable surface indications of use in lobectomy.



The right lobe, much the greater in volume, contributes to all surfaces, as described later, including the entire costal aspect. Its arbitrarily described surfaces (anterior, superior, inferior and posterior) all pass uninterruptedly on to the *left lobe*, except where shallow grooves partially demarcate the quadrate and caudate 'lobes', really parts of the left lobe, as already mentioned.

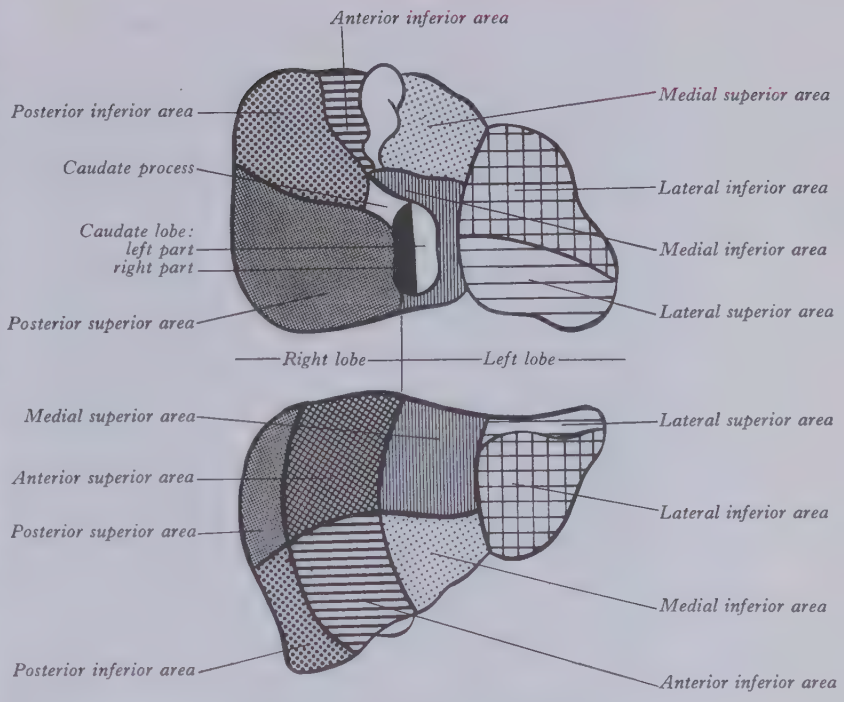


8.154A The superior, anterior and right lateral surfaces of the liver.

8.154B Posterior aspect of the liver, showing its peritoneal connections divided close to its surfaces.

8.154C The inferior surface of the liver.

8.155A Hepatic segmentation. Surface projection of the boundaries between hepatic segments based on the researches of Professor Carl-Herman Hjortsö, University of Lund, Sweden. See text for comment and references. Top: anterior view; middle: anterosuperior view; bottom: inferior visceral view.



The *quadrate lobe*, visible on the inferior surface, appears somewhat rectangular and is bounded in front by the inferior border, on the left by the fissure for ligamentum teres, behind by the porta hepatis and on the right by the fossa for the gallbladder.

The caudate lobe is visible on the posterior surface, bounded on the left by the fissure for the ligamentum venosum, below by the porta hepatis and on the right by the groove for the inferior vena cava. Above, it continues into the superior surface on the right of the upper end of the fissure for the ligamentum venosum. Below and to the right, it is connected to the right lobe by a narrow *caudate process*, which is immediately behind the porta hepatis and above the epiploic foramen. Below and to the left, the caudate lobe has a small rounded *papillary process*. Due to the depth of the fissure for the ligamentum venosum, the caudate lobe has an anterior surface, which forms the posterior wall of the fissure and is in contact with the lesser omentum (hepatic part).

HEPATIC SEGMENTATION

As in other organs with a group of hilar structures (e.g. the lungs), investigations of the branching patterns of blood supply and biliary drainage in the liver has revealed a system of lobes and further subdivisions (sectors or segments). The mode of growth of such organs, with the branching and rebranching of their vessels and ducts, makes it inevitable that territories are associated, in the liver, with individual rami of the *portal triad* of tubes (i.e. branches of the portal vein, hepatic artery and hepatic ducts). The size and number of such territories depends on the size of the tube designated as 'segmental', i.e. upon the level in the arborization arbitrarily selected. The hepatic artery, portal vein and common bile duct divide and subdivide with a common pattern, as implied in the classic observations of Glisson (1654) and confirmed by many subsequent workers. No evidence of significant intrahepatic anastomosis in these dendriform systems has been recorded. For example, despite variation in origin (and occurrence of accessory vessels), the hepatic arterial system consists of end-arteries (Michels 1966), a feature typical in any organ developed from a single vascularized blastema of dichotomizing potential. The implications of this pattern were not followed up until the late nineteenth century, apart from the recognition of right and left hepatic lobes (see McIndoe & Counsellor 1927, Hjortsö 1948 for earlier literature). Division into two lobes, based on the primary divisions of the triadic system (hepatic arteries, portal veins and biliary tree) rather than on surface features, is generally accepted but confusing descriptions persist in many texts. Inevitably, further divisions have been suggested, if only in the interests of effective partial hepatectomy. The pioneer in this field was Hjortsö (1948, 1951, 1956, 1975), who was the first to propose a complete segmental model (8.155A), based on dissections, injections and radiography, particularly applied to the biliary ducts and portal vein. Many have subsequently modified his scheme of segmentation, subdividing some segments, redefining and renaming others, (Elias & Petty 1952, Healey & Schroy 1953, Couinaud 1954, Goldsmith & Woodburne 1957, Bilbey & Rappaport 1960.) The main extension of Hjortsö's scheme is the division of his segments into superior and inferior parts, chiefly by Healey & Schroy 1953 (8.155B) and Couinaud 1954. Apart from this and minor differences in delineating the major segments, there is general consensus on the division of the right lobe into approximately 'anterior', intermediate and 'posterior' segments; and the left into lateral and medial parts. Most reports have been based on injections and casts, principally upon corrosion casts of one or more of the components of the triad's ramifications. In such casts is an easily discernible (8.156) sagittal zone between the lobes, the *fissura principalis*, picturesquely described by Hjortsö (1956) as lying in the plane of the left tympanic membrane. All other 'fissures' described (with some variation) by different workers are intersegmental. The term '*spatium*' was suggested for 'fissure', and Hjortsö recognized several of these (8.155A). Such 'spaces' in corrosion casts are due to the absence of all but the smallest rami of the portal triad, usually too fragile to preserve. These demarcations do *not* correspond to substantial zones of connective tissue, which might provide superficial or internal indications for purposes of subtotal resection (cf.

bronchopulmonary segments). Surface projections of segmental fissures are shown in 8.155A and B, according to Hjortsö (1948) and Healey & Schroy (1953), the chief difference being that the latters' scheme shows superior and inferior regions in each major segment (as also recognized by Elias & Petty 1952, Couinaud 1954, and Platzer & Maurer 1966). More recently Gupta et al (1978) have put forward a similar scheme (9 segments); in 1981 further observations by Gupta et al on hepatovenous segmentation in the human liver were published in which they recognized five segments: left, middle, right, paracaval and caudate. To equate the segments described, with their differing names and delimitations, by all the investigators quoted would not improve the reliability of this information in practical application. As Gupta et al (1978) stated, segmental pattern is in itself variable; of 41 corrosion casts more than half showed marked variation in the volume of one segment or another, as noted by others. Although most regard segments as functionally independent and uncomplicated by, e.g. intrahepatic arterial anastomosis, occasionally this has been noted. Surgical opinion is divided upon the usefulness of such patterns in hepatic resections. Dawson (1974) and others consider resection of less than a lobe to be hazardous; others, such as Ryncki (1974), have recorded successful segmental resections. Individual variation requires portal venography and cholangiography to define segmental patterns before operation, wherever feasible. It should be noted that the disposition of the *hepatic veins* and their tributaries is not a reliable guide; these veins, also studied by corrosion casts (Goldsmith & Woodburne 1957), do not follow the pattern of the hepatic triads; they drain parts of adjoining segments. It is therefore difficult to plan a resection plane which is optimal in respect of both triadic structures and hepatic veins.

8.155B The segmentation of the liver, based upon the principal divisions of the hepatic artery and accompanying hepatic ducts. The upper drawing is of the visceral surface of the liver, the lower drawing is of the diaphragmatic surface. See text for further description.

8.156 A resin corrosion cast of the blood vessels and duct systems of the liver of a woman: bile duct, cystic duct, gallbladder and their tributaries (yellow); the hepatic artery and its branches (red); the portal vein and its tributaries (light blue); the inferior vena cava, hepatic veins and their tributaries (dark blue). The photograph is of the visceral surface of the organ and was taken before the finer blood vessels and ducts were removed by trimming. The posterior aspect is above. Prepared by D H Tompsett of the Royal College of Surgeons of England.

PERITONEAL CONNECTIONS OF THE LIVER

Except for a triangular area on its posterior surface, the liver is almost completely covered by peritoneum, which connects it to the stomach, duodenum, diaphragm and anterior abdominal wall by several folds, their lines of attachment, of course, being devoid of peritoneum. These folds include the falciform ligament, right and left triangular and coronary ligaments and the lesser omentum.

The *falciform ligament* (**8**.108), a crescentic fold, consists of two applied layers of peritoneum, connecting the liver to the diaphragm and the supra-umbilical part of the anterior abdominal wall. Its convex base is fixed to the inferior diaphragmatic surface and to the posterior surface of the anterior abdominal wall, down to the umbilicus; as it ascends from this it inclines slightly right. It is attached to the notch for the ligamentum teres on the inferior hepatic border and to the anterior and superior hepatic surfaces. Its concave, free edge, from the umbilicus to the notch for the ligamentum teres, contains the latter and the small para-umbilical veins and is anterior to the pyloric region of the stomach. At its diaphragmatic end its layers separate to expose a triangular area on the superior hepatic surface devoid of peritoneum. The left layer continues into the anterior layer of the left triangular ligament, the right into the upper layer of the coronary ligament.

The *coronary ligament* (**8**.154), a reflexion of the peritoneum from the diaphragm to the right lobe's superior and posterior surfaces, has upper and lower layers, continuous with the right triangular ligament and diverging left to enclose posteriorly a triangular 'bare' area of the right lobe devoid of peritoneum. Its upper layer merges into the right falciform layer, skirts anteriorly the upper end of the caval groove and descends from the upper to the posterior surface, continuing into the anterior layer of the right triangular ligament. The lower coronary layer becomes the posterior layer of the right triangular ligament, following almost horizontally the lower limit of the right posterior hepatic surface. Here peritoneum may be reflected to the anterosuperior aspect of the right kidney (*hepatorenal ligament*) instead of to the diaphragm. The left end of the lower layer passes in front of the caval groove's lower end into the line of peritoneal reflexion from the right caudate border, i.e. the right margin of the upper omental recess.

The *left triangular ligament* ascends back from the left lobar superior surface to the diaphragm. Its closely applied layers become fused at the left edge of the ligament. To the right the anterior layer merges with the left falciform layer, the posterior with the anterior lesser omental layer at the upper end of the fissure for the ligamentum venosum. The left triangular ligament lies in front of the abdominal part of the oesophagus, the upper end of the lesser omentum and part of the fundus of the stomach. It varies much and may contain large blood vessels (Outrequin et al 1967).

The *right triangular ligament* is a short V-shaped fold connecting the lateral and posterior aspects of the right lobe to the diaphragm. At its right margin its two layers are continuous. The ligament is really the right extremity of the coronary ligament.

The *lesser omentum* has been described (p. 1341); at the upper end of the fissure for the ligamentum venosum, its anterior layer merges with the posterior layer of the left triangular ligament and its posterior layer with the line of reflexion of the peritoneum from the upper end of the right caudate lobe and so, indirectly, with the lower coronary layer (**8**.154B).

HEPATIC SURFACES

The superior surface (**8**.154A) includes parts of the right and left lobes. It fits closely under the diaphragm, separated from it by peritoneum except for a small triangular area where the two layers of the falciform ligament diverge. Right and left it is convex, but centrally it presents a shallow *cardiac impression* corresponding with the position of the heart above the diaphragm. It is related to the right diaphragmatic pleura and right pulmonary base, to the pericardium and ventricular part of the heart and to part of the left diaphragmatic pleura and left pulmonary base. It should be noted that the superior surface curves directly into the so-called anterior surface and the peritonealized part of the posterior surface of the right lobe. No definable border separates superior, anterior, right lateral and right posterior *aspects* of the liver and it would be more appropriate to group these as the *diaphragmatic surface*, mostly separated from the *visceral surface* by a narrow edge or border.

The anterior surface, which is triangular and convex, is covered by peritoneum except at the attachment of the falciform ligament. Much of it is in contact with the diaphragm, which separates it on the right from the pleura and sixth to tenth ribs and cartilages and on the left from the seventh and eighth costal cartilages. The thin margins of the base of the lungs are thus quite close to the upper part of this surface, more extensively so on the right. The median area of the anterior hepatic surface lies behind the xiphoid process and the anterior abdominal wall in the infracostal angle (**8**.107).

The hepatic profile is superficially projected as follows (**8**.139): its upper limit corresponds to a line through the xiphisternal joint, ascending to a point below the right nipple (fourth intercostal space) and to the left to a point inferomedial to the left nipple; its right border corresponds to a curved line, convex to the right, running from the right end of the upper border to a point 1 cm below the costal margin at the tip of the tenth costal cartilage; its lower limit is the line completing this triangle (**8**.139), crossing the midline at the transpyloric plane (slightly concave near the right linea semilunaris).

The right surface, covered by peritoneum, adjoins the right dome of the diaphragm which separates it from the right lung and pleura and the seventh to eleventh ribs. Above its upper third, both lung and pleura are inserted between the diaphragm and ribs; over its middle third only the costodiaphragmatic pleura is interposed; over its lower third the diaphragm and thoracic wall are in contact.

The posterior surface is convex and wide on the right but narrow on the left, with a deep median concavity corresponding to the forward convexity of the vertebral column (**8**.154A). Much of this surface is devoid of peritoneum, being attached to the diaphragm by loose connective tissue, forming the so-called 'bare area', triangular and limited above and below by the layers of the coronary ligament. The base of the posterior hepatic surface to the left is the caval groove; its apex, directed down and right, corresponds to the right triangular ligament. The *groove for the inferior vena cava* (caval groove), which is deep and occasionally a tunnel, lies at the posterior surface and is bare of peritoneum and adapted to the upper part of the vessel it contains; its floor is pierced by the hepatic veins (p. 818). Infero-anteriorly the caudate process separates it from the porta hepatis. Lateral to its lower end the 'bare area' adjoins the upper pole of the left suprarenal gland. Left of the groove the *caudate lobe* forms the posterior surface in the superior omental recess; the peritoneum on its posterior aspect curves round its left border to its anterior aspect, which is the posterior wall of the fissure for the ligamentum venosum (**8**.154). The caudate lobe projects into the superior omental recess from the right; its posterior surface is related to the diaphragmatic crura (above the aortic opening) and the right inferior phrenic artery, separated by them from the descending thoracic aorta. The *papillary process* often descends in front of the origin of the coeliac artery.

The *fissure for the ligamentum venosum* (**8**.154) separates the posterior aspect of the caudate from the main part of the left lobe. The fissure cuts deeply in front of the caudate lobe and contains the two layers of the lesser omentum. Below, it curves laterally in front of the papillary process to the left end of the porta hepatis. The *ligamentum venosum*, the fibrous remnant of the ductus venosus (p. 724), is attached below to the left branch of the portal vein's posterior aspect; ascending in the floor of the fissure and passing laterally at the upper end of the caudate lobe it joins the left hepatic vein near its entry into the inferior vena cava, or sometimes the vena cava itself.

The left lobe's posterior aspect has a shallow *oesophageal impression* near the upper end of the fissure for the ligamentum venosum, occupied by the abdominal part of the oesophagus. Left of this the left lobe is related to part of the fundus of the stomach.

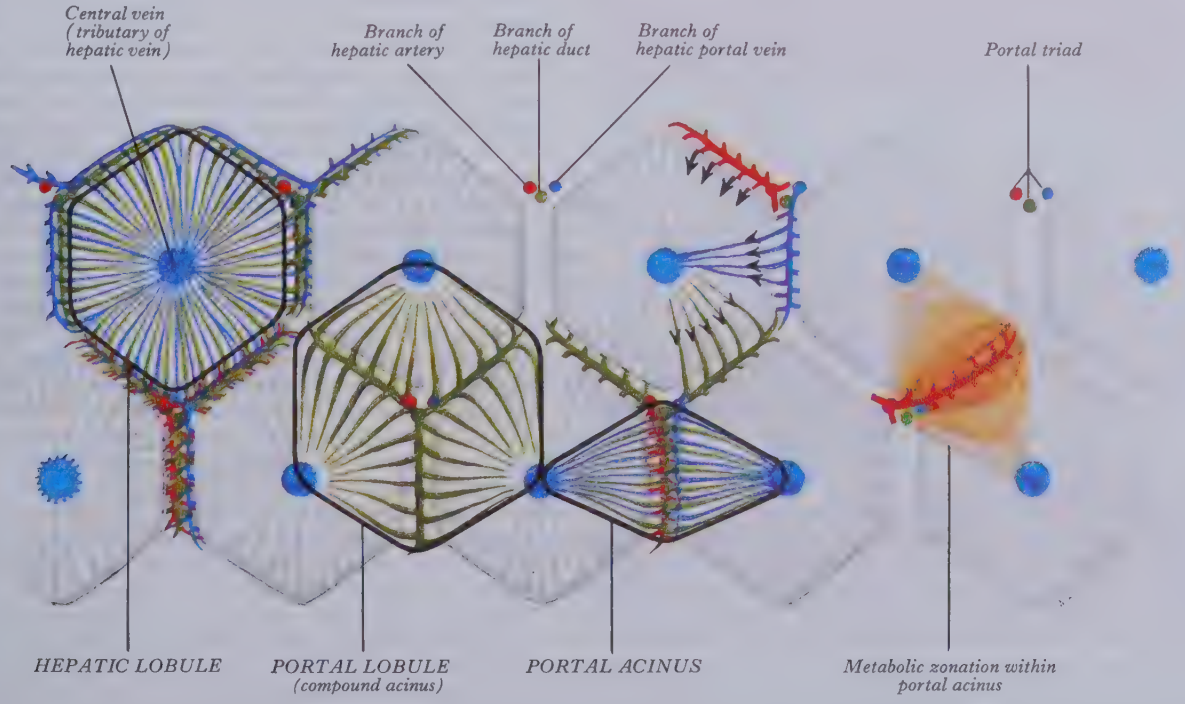
The inferior or visceral surface (8.154), facing down, back and to the left, bears the imprint, when preserved in situ, of the adjacent viscera. It is covered by visceral peritoneum except at the porta hepatis, the fissure for the ligamentum teres and the fossa for the gallbladder. On the left lobe, continuous with the oesophageal groove, is a *gastric impression*. To the right of this the rounded *omental tuberosity*, in the concavity of the lesser curvature, is in contact with the lesser omentum. The *fissure for the ligamentum teres*, of variable depth, ascends backwards from its notch on the inferior hepatic border to the left end of the porta hepatis, meeting the lower end of the fissure for the ligamentum venosum. It is the left boundary of the quadrate lobe and may be, partially or wholly, bridged by a band of liver. In its floor is the *ligamentum teres*, the obliterated vestige of the left umbilical vein (p. 724). From the umbilicus this ligament ascends in the edge of the falciform ligament to the inferior hepatic border, where it traverses the fissure to join the left branch of the portal vein at the left end of the porta hepatis, opposite the attachment of the ligamentum venosum.

The gastric impression may invade anteriorly the *quadrate lobe*, which is moulded to the pyloric region and the beginning of the duodenum. The posterior part of the quadrate lobe adjoins the right border of the lesser omentum and its contained structures. When the stomach is empty the quadrate lobe is related to the first (superior) part of the duodenum and part of the transverse colon.

The *porta hepatis*, situated between the quadrate lobe in front, and the caudate process behind, is a deep transverse fissure between the upper ends of the fissure for the ligamentum teres and the fossa for the gallbladder. At the porta hepatis the portal vein, hepatic artery and hepatic nervous plexus enter and the right and left hepatic ducts and some lymph vessels emerge. The hepatic ducts are anterior, the portal vein and its branches posterior and the hepatic artery proper and its branches lie intermediate in position.

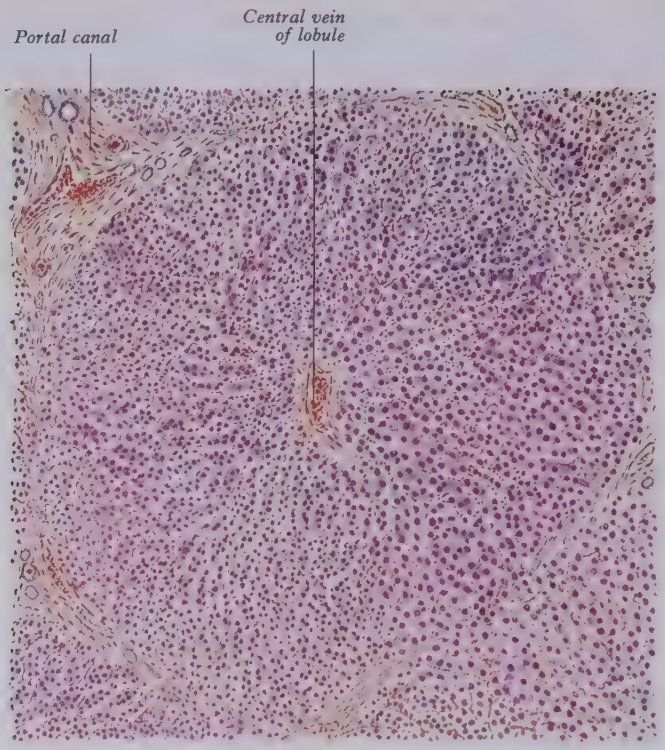
The *caudate process* connects the inferolateral part of the caudate lobe (left lobe) to the right lobe. It lies behind the porta hepatis, in front of the inferior vena cava, and roofs the epiploic foramen. It is often assigned to the right lobe but lies within the territory of the left hepatic duct, i.e. it forms part of the *left* lobe (vide supra).

The *fossa for the gallbladder*, forming the right limit of the quadrate lobe, extends from the inferior hepatic border to the right end of the porta hepatis. Usually shallow, it is variably bare of peritoneum. The inferior hepatic surface to the right of the fossa adjoins the colon, kidney and duodenum. A *colic impression* fits the right colic flexure near the inferior border. A *renal impression*, usually well marked, lies behind the colic and is separated from the neck and adjoining part of the gallbladder by a duodenal impression; it is related to the right upper renal pole and superomedially to the lower pole of the right suprarenal gland. When the lower coronary layer is reflected from the liver to the right kidney, the renal and suprarenal impressions extend to the lower part of the 'bare area'. The *duodenal impression* is lateral to the neck of the gallbladder and related to the junction of the first (superior) and second (descending) parts of the duodenum.



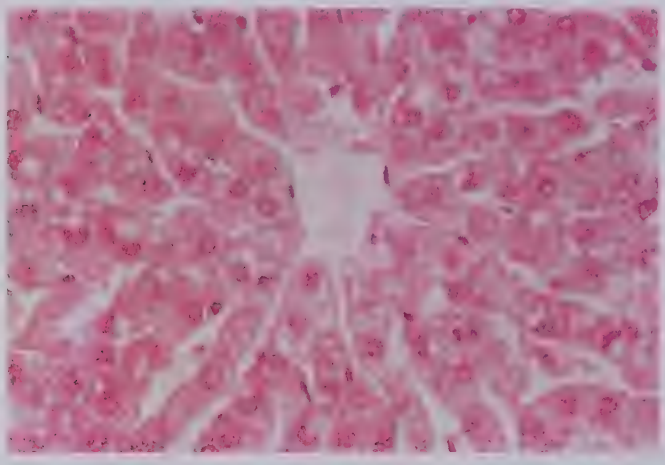
Hepatic relations vary with posture and respiration. In the above description the body is assumed to be supine.

The branches of the portal vein and tributaries of the hepatic veins are more numerous before birth, after which they are reduced by fusion or degeneration. The fetal portal vein joins the umbilical in a smooth right-hand curve, maintained after birth, with a sharp angle between the portal trunk and its left branch; the left vascular lobe may therefore be at a circulatory disadvantage and unable to keep pace in growth with the right. At the left end of the adult left lobe a fibrous band (*fibrous appendix of the liver*) may appear as an atrophied remnant of the more extensive left lobe in children; it contains atrophied bile ducts, the *hepatic vasa aberrantia*. Similar remnants may occur in the left lobe's edges and near the inferior vena cava. Occasionally the right lobe's lower border, to the right of the gallbladder, projects down as a broad linguiform process (*Riedel's lobe*).

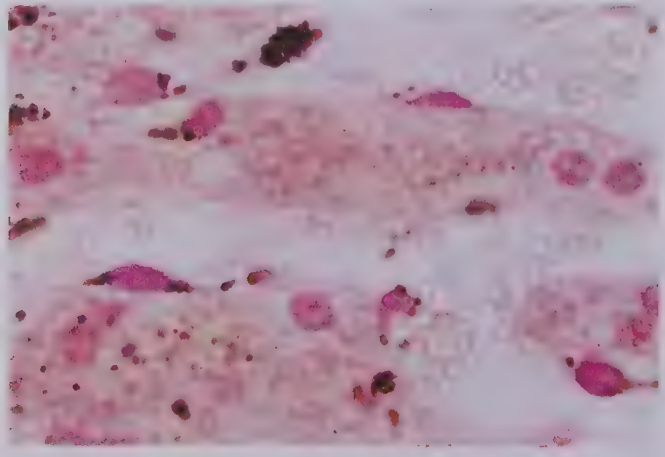


HEPATIC VESSELS AND NERVES

The vessels connected with the liver are the portal vein, hepatic artery proper and hepatic veins. The *portal vein* and *hepatic artery proper* ascend in the lesser omentum to the porta hepatis, where each dichotomizes; the *bile duct* and *lymphatic vessels* descend from the porta in the same omentum. All these structures are enveloped in the *perivascular fibrous capsule (hepatobiliary capsule of Glisson)*, a sheath of loose connective tissue, which also surrounds the vessels as they course through the portal canals in the liver. It is also continuous with the fibrous hepatic capsule.



The *hepatic artery* and its branches, after variable courses in the porta, divide and subdivide in the liver, their smaller rami being associated with those of the portal vein with which they are



8.157 Diagram of the histological organization of the liver, showing the principal types of subdivisions which have been proposed. For purposes of clarity, the territories of the classic hepatic lobules are shown as regular hexagons, unlike their real appearance which is highly variable (see text).

8.158A Section through a hepatic lobule (human) (after Sobotta). Stained with haematoxylin and eosin. Magnification × 70.

8.158B Section through a number of hepatic cords radiating from a central hepatic venule of the rabbit. The hepatocytes appear cuboidal and the Kupffer and endothelial cells, which line the sinusoids, have flattened, densely staining nuclei. Haematoxylin and eosin.

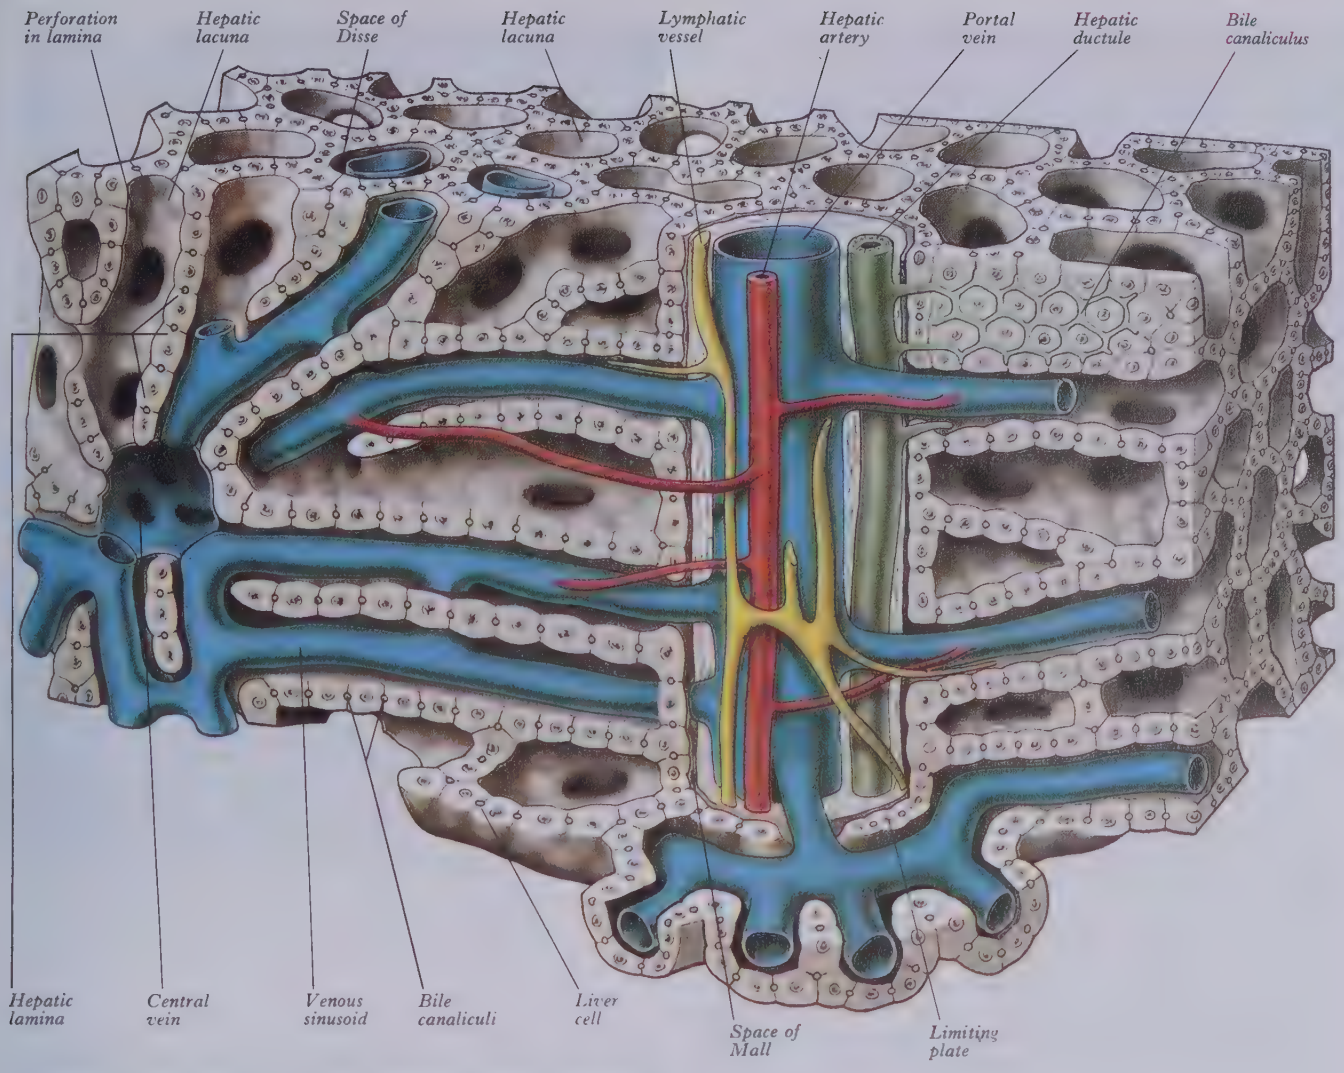
8.158C Section similar to that shown in (B), but taken from the liver of a rabbit previously injected intravenously with carbon particles. The Kupffer cell nuclei are outlined with phagocytosed particles which demonstrate the limits of the cell cytoplasm.

distributed. There are no (or very few) anastomoses between their territories; each is an end-artery (Glauser 1953).

The *hepatic veins* (**8**.156) convey blood from the liver to the inferior vena cava (p. 818). They have only a thin tunica adventitia, binding them to the walls of their canals; hence, in sections, they are widely open and solitary, and so easily distinguished from the branches of portal veins, which tend to collapse post mortem and are always accompanied by an artery and a biliary duct.

Hepatic *lymph vessels* are described on p. 851. Lymph from the liver has an abundant protein content. Obstruction of the hepatic venous drainage increases the flow of lymph in the thoracic duct. The importance of the transdiaphragmatic lymph drainage of the liver into internal mammary and diaphragmatic lymph nodes has been emphasized by Nidden et al (1973), who confirm that lymph reaches the right lymphatic duct, partly via the tracheobronchial lymph nodes.

Innervation is by an hepatic plexus (p. 1165) containing sympathetic and parasympathetic (vagal) fibres. These enter at the porta hepatis and largely accompany blood vessels and bile ducts; very few run amongst the liver cells and their terminations are uncertain. Both myelinated and non-myelinated fibres reach the liver from nerves in its various peritoneal folds (Sutherland 1965).



THE MICROSCOPIC STRUCTURE OF THE LIVER

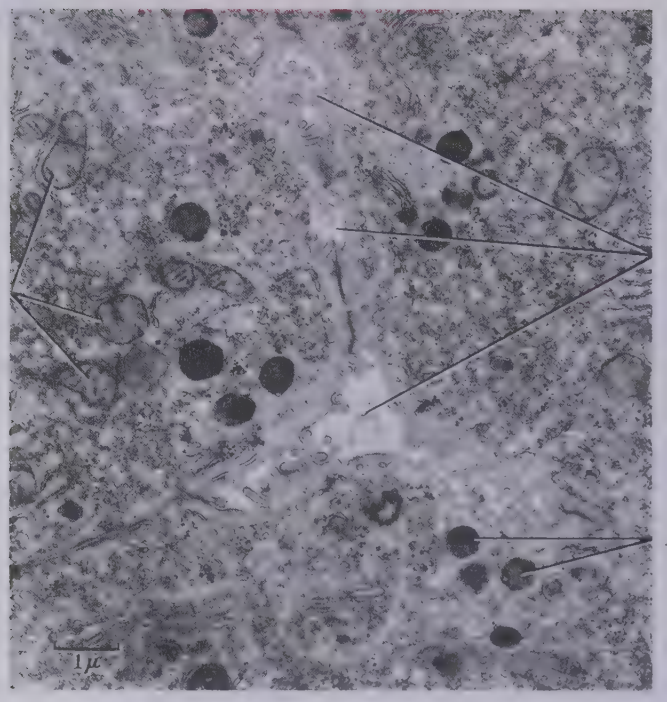
The liver consists of a connective tissue network of great complexity, in the meshes of which lie the great majority of its cells. These are epithelial in origin and carry out the major metabolic activities of this organ. Permeating the whole structure are great numbers of blood vessels of different types, perfusing and draining the liver with a rich flow of hepatic portal venous blood, and arterial blood derived from the hepatic arteries.

Lobulation of the liver

Under the peritoneal lining which covers most of the liver's surface, lies a thin layer of connective tissue (*'Glisson's capsule'*) from which extensions pass into the organ, branching and rebranching as connective tissue septa and trabeculae.

As classically described in the adult pig and some other mammals, this connective tissue component separates and encloses a multitude of polyhedral *hepatic lobules* (often hexagonal in histological sections), each about 1 mm in diameter with a small *central vein* (hepatic tributary) as its axis, surrounded by *portal triads* (**8**.157). Each triad contains a branch of the portal vein and hepatic artery and an interlobular biliary ductule, all ensheathed in connective tissue (the *portal canal* or *perivascular fibrous capsule*). In man (and many other mammals) hepatic lobules are not readily discernible as discrete entities and indeed three-dimensional reconstruction indicates that the concept of a lobule with definite geometrically-defined boundaries, surrounded by connective tissue and centred on an efferent vein, cannot be sustained. Instead, the more useful idea of a functional unit has been proposed, reflecting centres of biliary secretion and considerations of blood flow, oxygenation, metabolic gradients and, in pathology, hepatic degeneration. This is the *portal lobule*, consisting of the adjoining parts of (in pigs) at least three 'classic' lobules, bile from which drains into a biliary ductule in the portal canal between three such *hepatic* lobules; hence, in sections, a portal lobule is a polygonal territory centred on a portal triad, its boundary passing through adjacent central veins. A third unit, the *portal acinus*, is an even more useful concept in considerations of metabolic organization. It is centred on a preterminal branch of an hepatic arteriole and includes the hepatic tissue served by this, bounded by the territories of other acini and by two adjacent central veins (**8**.157). Because such phenomena as zones of anoxic damage, glycogen deposition and removal and toxic trauma are related to arterial flow, they tend to follow the acinar pattern. There are also real structural and physiological differences within the acinar lobules and they are customarily divided into three zones: zone 1 (periportal) i.e. nearest the portal radicles; zone 2 further away from these; and zone 3 around the central venous drainage (vide infra). Rappaport (1969) has proposed the concept of *compound portal acini*, which are more complex groups of

8.159 Diagram of hepatic structure (after H Elias, Department of Anatomy, Chicago Medical School). Note that in this picture, perisinusoidal endothelial cells and macrophages (Kupffer cells) are not shown.



hepatic units. Neither hepatic nor portal lobules are fixed anatomical entities; the '*hepatic lobular structure*' is usually evident but can be changed to a '*portal lobular structure*' by alteration in the relative blood pressures in the portal and hepatic veins (e.g. by raising hepatic venous or lowering portal pressure), these changes being reversible. Such alterations in venous pressures occur in pathological conditions.

The cells of the liver include hepatocytes (the main metabolic element), endotheliocytes, macrophages (Kupffer cells), lipocytes, the cells of the biliary tree (cuboidal to columnar epitheliocytes) and connective tissue cells of the capsule and portal tracts. For further details, see Phillips et al (1987), Jones & Spring-Mills (1983).

Hepatocytes. About 60% of cells in the liver (and 80% of its volume) are formed by *hepatocytes (parenchymal cells)*, derived from endoderm of the caudal part of the foregut, with which they retain connection by biliary ductules and hepatic ducts. Hepatocytes are polyhedral, with five to twelve sides and are from 12–25 μm across. Their nuclei are spheroidal and euchromatic and often polyploid or multiple (2 or more) in each cell (Doljansky 1960). Their cytoplasm typically displays much granular and agranular endoplasmic reticulum, many mitochondria, lysosomes and many well-developed Golgi bodies, features indicating a high metabolic activity. Glycogen granules and lipid vacuoles are usually prominent. Numerous, particularly large peroxisomes and vacuoles containing enzymes such as urease (uricosomes) in distinctive crystalline forms indicate the complex metabolism of these cells. Their role in iron metabolism is shown by storage vacuoles containing crystals of ferritin and haemosiderin. Where hepatocytes adjoin bile canaliculi they carry microvilli and numerous membrane-bound vesicles cluster near the lumen (**8**.160A). The borders of these canaliculi are marked by tight junctions where adjacent hepatocytes lie in contact, preventing their secretions from entering the general intercellular spaces of the liver and confining them to the canalicular system.

Their structure and metabolism varies within the portal acini, according to their distance from the portal inflow (vide supra); in zone 1, cells have more mitochondria and granular endoplasmic reticulum, whilst in zone 3 (nearest the central veins) the agranular endoplasmic reticulum is even more extensive, but mitochondria are fewer and more spheroidal. In zone 2, there is a gradient between the other two conditions.

Hepatocytes mediate many metabolic activities; they synthesize and release various plasma proteins such as albumins, clotting factors and complement components; they deaminate amino acids by the urea cycle, liberating urea for excretion; convert bilirubin to biliverdin for secretion into bile; synthesize bile salts, biliary secretions essential to the emulsification of fats in digestion; they eliminate many endogenous and exogenous toxic substances from the blood and convert tetra-iodothyronin to more active tri-iodothyronin. They also store carbohydrates as glycogen and triglycerides as lipid droplets, metabolizing these as required to release glucose and lipid into the blood. Most lipid thus secreted leaves the perisinusoidal surface of the cell in secretory vesicles, having been conjugated with protein in the endoplasmic reticulum and Golgi apparatus, to form the 'very low density

lipoprotein' moiety of blood plasma (Claude 1970). Some cholesterol also enters bile, apparently as an excretion. Iron is stored in the cells as ferritin. All these processes produce heat, important in the maintenance of body temperature.

The multitude of activities in hepatocytes is reflected in their structural complexity, which varies with metabolic demand; e.g. agranular endoplasmic reticulum proliferates during barbiturate detoxification (Jones & Fawcett 1966), while in starvation glycogen and lipid reserves disappear. Because of involvement in many such processes, hepatocytes are most vulnerable to anoxia, various toxins and carcinogens, which cause characteristic patterns of degeneration in the portal acini.

Hepatic laminae. The manner in which hepatocytes are arranged in the liver has been much debated. The most recent studies show that in the mature liver, hepatocytes are arranged mainly in plates of hepatocytes, one cell thick *(hepatic laminae)*, forming a continuous system or *muralium* which may branch or anastomose, as interlaminar bridges of cells connect adjacent laminae. Between the laminae lie *hepatic lacunae* containing venous sinusoids, which anastomose via perforations in the hepatic laminae. Where hepatocytes adjoin portal canals or hepatic venous tributaries they form a *limiting plate*, surrounding the vessels and perforated by their radicles and by rami of the hepatic artery and biliary ductules; a similar limiting plate composed of a single layer of liver cells underlies the hepatic capsule.

In histological sections (**8.158**) rows of liver cells seen radiating from the central vein to the lobular periphery are really sections through hepatic laminae. These rows, with intervening sinusoids, do not pass straight to the periphery like the spokes of a wheel but run irregularly, because the laminae themselves are irregular and branched. Some rows of cells (and sinusoids) arrive at the periphery of lobules between adjacent portal canals; others pursue indirect routes between the central vein and portal canals.

Perisinusoidal cells. Intralobular venous sinusoids are wider than blood capillaries and are lined by a thin but highly fenestrated endothelium. The fenestrae are grouped in clusters ('sieve plates'), the endothelium elsewhere being continuous. Attached to the luminal side of the endothelium are the *hepatic macrophages (stellate cells of von Kupffer* or *Kupffer cells*); the latter form a major part of the mononuclear phagocyte system (p. 668), responsible for removing from the circulation much debris, cellular and microbial. These activities are shared with the spleen and circulating leucocytes (Wisse 1970). In the liver they also remove aged and damaged red cells from the circulation (as in the spleen). Sinusoids are fed at one end with blood from fine branches of the hepatic portal venules (*inlet venules*) and hepatic arterioles, which pass through the limiting plate of hepatocytes to enter a hepatic lobule. Blood from these sources percolates between the walls of the sinusoids to the central veins and is exposed to the activities of the cells around the sinusoids. The endothelial linings of the sinusoids are separated from hepatocytes of the hepatic laminae by a narrow gap, the *perisinusoidal space of Disse* (**8.160B**) which is normally about 0.2–0.5 μm wide, but distends in

anoxic conditions: it contains reticulin fibres, and the irregular microvilli of adjacent hepatocytes; this space is continuous at the lobular periphery with a *space of Mall* surrounding the vessels and ductules in portal canals. In the latter space lymph vessels begin as cul-de-sac capillaries, as elsewhere; only a very few reach the periphery of the lobule. *Hepatic adipocytes* (Ito cells) are also present in small numbers in the space of Disse. *Central veins* from adjacent lobules form *interlobular veins*, which unite as *hepatic veins*, draining blood to the inferior vena cava.

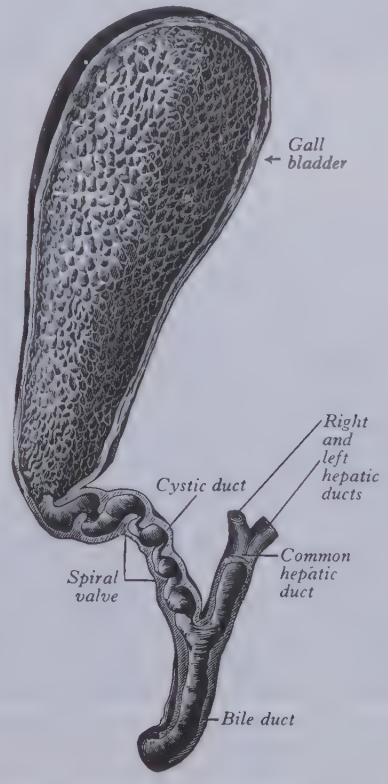
Minute *bile canaliculi* (**8**.159, 160A,C) form nets with polygonal meshes in the hepatic lobules; each hepatocyte is surrounded by canaliculi except on its juxtasinusoidal sides. Hepatic laminae thus enclose a network of canaliculi which pass to the lobular periphery where they join to form narrow intralobular ductules (*terminal ductules* or the *canals of Hering*) lined by cuboidal epithelium; these exit through the terminal laminae to enter interlobular hepatic ductules in the portal canals. Intralobular ductules differ from the other biliary canals in their structure and reaction to injury; e.g. they proliferate when the flow of bile is obstructed outside the liver (Biava 1964, Jones et al 1975). Hepatic ductules in portal canals are lined by cuboidal or columnar cells which may contain cholesterol crystals and lipid droplets.

The permeability barriers between blood, hepatocytes and canaliculi are demonstrable with colloidal tracers, e.g. injected horseradish peroxidase diffuses freely from the sinusoids through the large gaps between hepatic endothelial cells into the intercellular spaces between hepatocytes, which are held together largely by gap (communicating) junctions; but diffusion is halted at the perimeters of the canaliculi by tight junctions between hepatocytes. It is inferred that materials have free access from the bloodstream to hepatocytes but can only enter the canaliculi through their *cytoplasm*; they therefore resemble exocrine cells secreting into a duct system.

Preterminal hepatic arterioles in the portal canals branch to convey arterial blood to the sinusoids by several routes, the chief being via a fine capillary plexus around the interlobular ductules and ducts which drains to branches of the portal veins, inlet venules and hepatic sinusoids. Some arterial blood passes directly to the hepatic sinusoids, bypassing these capillary plexuses; but this is apparently only a small part of the total flow (Burkel 1970, Healey 1970, Jones & Spring-Mills 1977). Sinusoids thus contain mixed venous and arterial blood to sustain their cells. The composition, volume and velocity of blood through any local region may be regulated according to changing needs by the sphincters around the entry points of inlet venules and hepatic arterioles, and by the contractile walls of the sinusoids. Each portal triad supplies a distinct territory; normally there are no anastomoses between territories. Hepatic veins run quite separately with respect to the triadic system, freely crossing the boundaries of triadic territories.

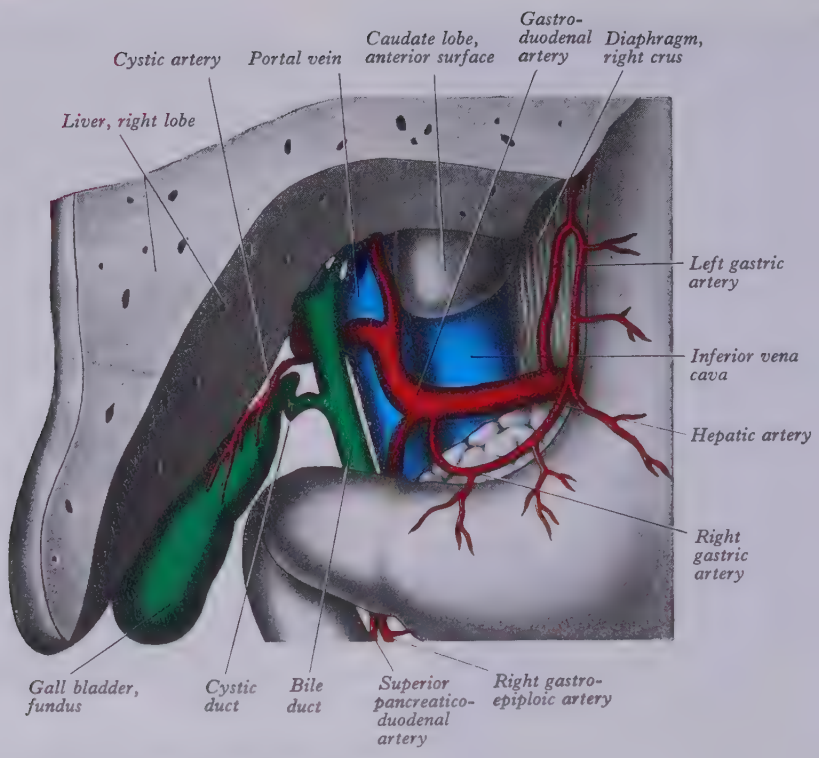
The fetal liver is a major haemopoietic organ, erythrocytes, leucocytes and platelets developing from the mesenchyme covering the sinusoidal endothelium (p. 678).

Biliary Ducts and the Gallbladder



The hepatic ductual apparatus consists of: (1) the *common hepatic duct*, formed by the junction of the *right* and *left hepatic ducts*; (2) the *gallbladder*, a reservoir for bile; (3) the *cystic duct* of the gallbladder; (4) the *bile duct*, formed by the junction of the common hepatic and cystic ducts.

THE COMMON HEPATIC DUCT



The main right and left hepatic ducts issue from the liver and unite near the right end of the porta hepatis as the common hepatic duct, which descends about 3 cm before being joined on its right at an acute angle by the cystic duct to form the main bile duct (**8**.161). The common hepatic duct lies to the right of the hepatic artery and anterior to the portal vein.

THE GALLBLADDER

The gallbladder (**8**.154C, 161, 162) is a slate-blue, piriform sac partly sunk in a fossa in the right hepatic lobe's inferior surface. It

8.161 Interior of the gallbladder and bile ducts.

8.162 Dissection to show the relations of the hepatic artery, bile duct and portal vein to each other in the lesser omentum: anterior aspect.

extends forwards from a point near the right end of the porta hepatis to the inferior hepatic border. Its upper surface is attached to the liver by connective tissue; elsewhere it is completely covered by peritoneum continued from the hepatic surface. Occasionally it is completely invested by peritoneum and even connected to the liver by a short mesentery. It is 7–10 cm long, 3 cm broad at its widest and 30–50 ml in capacity. It is described as having a fundus, body and neck. The *fundus*, the expanded end, projects down, forwards and to the right, extending beyond the inferior border to contact the anterior abdominal wall behind the ninth right costal cartilage, where the lateral edge of the right rectus abdominis crosses the costal margin. Posteriorly it is related to the transverse colon, near its commencement. (These relations change when the gallbladder is lower, as it often is in slender females, see Fleischner & Sayegh 1958.) the *body* is directed up, back and to the left; near the right end of the porta it is continuous with the neck. It is related above to the liver, below to the transverse colon and, further back, to the first and upper end of the second segments of the duodenum. The *neck* (cervix) is narrow, curving up and forwards and then abruptly back and downwards, to become the cystic duct, at which transition there is a constriction. The neck is attached to the liver by areolar tissue containing the cystic artery. The mucosa of the neck is obliquely ridged, forming a spiral valve; when the neck is distended, this gives its surface a spiral groove. From the right side of the neck a small recess may project down and back towards the duodenum. Often termed Hartmann's pouch (but originally described by Broca), it has been widely regarded as a constant feature, but Davies & Harding (1942) have shown that it is always a sequela of pathological states, especially dilatation; when it is large the cystic duct arises from its upper left aspect and not from what appears to be the gallbladder's apex.

THE CYSTIC DUCT

The cystic duct (**8.161, 162**) is 3–4 cm long; it passes back, down and to the left from the neck of the gallbladder, joining the common hepatic duct to form the bile duct. It is adherent to the common hepatic duct for a short distance before joining it, usually near the porta hepatis but sometimes lower, in which case the cystic duct lies along the lesser omentum's right edge. Its mucosa bears five to 12 crescentic folds, like those in the gallbladder's neck. They project obliquely in regular succession, appearing like a *spiral valve* (**8.161**). When the duct is distended, the spaces between the folds dilate and externally it appears twisted like the neck of the gallbladder.

THE BILE DUCT

The bile duct is formed near the porta hepatis, by the junction of the cystic and common hepatic ducts; it is usually about 7.5 cm long and 6 mm in diameter (vide infra). It descends posteriorly and slightly to the left, anterior to the epiploic foramen, at the right border of the lesser omentum, in front and to the right of the portal vein and to the right of the hepatic artery proper (**8.162**). It passes behind the first (superior) part of the duodenum, with the gastro-duodenal artery on its left, and then runs in a groove on the superolateral part of the posterior surface of the head of the pancreas (**8.149**), anterior to the inferior vena cava and sometimes embedded in pancreatic tissue (pp. 1382, 1384). Lytle (1959) has shown that the duct may be close to the left aspect of the second (descending) part of the duodenum or as much as 2 cm from it and that, even when it is embedded in pancreas, a superficial groove marking its position can be palpated behind the descending part of the duodenum, stones in the duct being thus detected. Left of the descending part of the duodenum the bile duct reaches the pancreatic duct; together they enter the duodenal wall where they usually unite to form the *hepatopancreatic ampulla* (p. 1382), the distal, constricted end of which opens into the descending part of the duodenum on the summit of the major duodenal papilla (**8.150**), about 8–10 cm from the pylorus (p. 1394). The position of the bile duct is indicated on the anterior abdominal surface by a line starting 5 cm above the transpyloric plane and 2 cm right of the median plane and descending vertically for 7.5 cm.

Vessels and Nerves

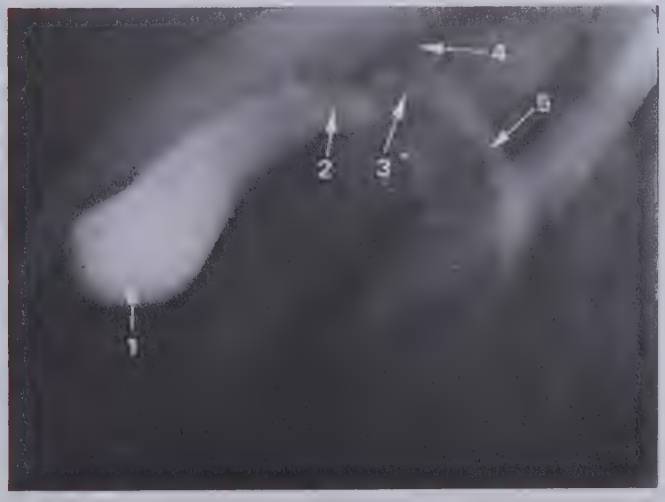
The *cystic artery* is described on p. 769 and the *cystic veins* on p. 820. The lower part of the bile duct receives rami from the *posterior superior pancreaticoduodenal artery* (p. 769), while its upper part and the hepatic ducts receive rami from the *cystic artery*. The *right hepatic artery* supplies its intermediate part through very small rami, the main supply being from the *cystic* and *posterior*

superior pancreaticoduodenal arteries. These supplies vary (Shapiro & Robillard 1948, Michels 1962). The posterior superior pancreatico-duodenal artery anastomoses with the posterior branch of the inferior pancreaticoduodenal near the hepatopancreatic ampulla; where this anastomosis is poor, ligation of the posterior superior pancreaticoduodenal artery may result in gangrene or stricture of the bile duct (Henley 1955). *Veins* from the upper part of the bile duct and hepatic ducts and from the gallbladder and cystic duct usually enter the liver, while those from the lower part of the bile duct enter the portal vein. *Lymph vessels* of the gallbladder and bile ducts are described on p. 852. Sympathetic and parasympathetic *innervation* is from the coeliac plexus along the hepatic artery and its branches. Autonomic plexuses exist in the muscular and submucous layers and ganglion cells, presumably parasympathetic, have been demonstrated in these plexuses in monkeys (Sutherland 1966, 1967). Fibres from the right phrenic nerve, through communications between the phrenic and coeliac plexuses, appear to reach the gallbladder via the hepatic plexus, thus explaining referred 'shoulder pain' in gallbladder pathology.

VARIATIONS IN GALLBLADDER AND BILE DUCTS

The gallbladder varies in size and shape; in rare cases it is duplicated (Mincsev 1967), with two or combined cystic ducts, or is absent, though its duct may be present. The junction of the cystic and common hepatic ducts varies in its level from the porta hepatis to behind or even below the duodenum's first (superior) part; when the junction is low, the two ducts may be connected by fibrous tissue and in cholecystectomy clamping the cystic duct without injuring the common hepatic (or main bile) duct is difficult. Occasionally the cystic duct joins the right hepatic duct; it may pass behind or in front of the common hepatic duct, joining it on its left surface. Accessory hepatic ducts may emerge, more often from the right lobe, to join the main hepatic ducts or, rarely, the gallbladder itself. Failure of canalization of bile ducts during development leads to a rare congenital atresia or stenosis with rapidly fatal results. The bile and pancreatic ducts may open separately into the duodenum or join even before entering its wall. Variations of the ductual arteries are much more common (p. 768). For further information consult Santulli & Blanc (1961), Boyden et al (1967).

MICROSCOPIC STRUCTURE OF THE GALLBLADDER AND BILIARY DUCTS



The gallbladder's wall has serous, fibromuscular and mucous layers. The *serosa* completely covers the fundus but only coats the inferior surfaces and sides of the body and neck of the gallbladder; beneath it is subserous loose connective and adipose peritoneal tissue. The *fibromuscular layer* is composed of fibrous tissue mixed with non-striated myocytes arranged loosely in longitudinal, circular and oblique bundles. Internally, the *mucosa* is loosely connected with the fibrous layer, is generally yellowish-brown and elevated into minute rugae with a honeycomb appearance

(8.161, 163). Its epithelium is a single layer of columnar cells which vary with species. Electron microscopy (Chapman et al 1966) in dogs shows microvilli on their apical surface, irregularly arranged, with endocytic or pinocytotic vesicles between their bases. Basally, spaces between epithelial cells are dilated and many capillaries adjoin the basement membrane. These features indicate active absorption of water and solutes from the bile to concentrate it. Basal spaces are large during absorption of water (Kaye et al 1966). Biliary concentration appears to involve the active transport of sodium and calcium, making an osmotic gradient from the lumen of the gallbladder to the capillaries of the lamina propria. In the apical parts of some cells, particularly those near the ducts, mucous granules appear; they are secreted into the lumen (Johnson et al 1962, Mueller et al 1972).

The large biliary ducts have external fibrous and internal mucous layers. The former is fibro-areolar tissue with a few longitudinal, oblique and circular non-striated myocytes. (Myocytes appeared in only 12 of 100 human common bile ducts examined by Mahour et al 1967.) The mucosa is continuous with that of the hepatic ducts, gallbladder and duodenum; like theirs, its epithelium is columnar; many lobulated mucous glands occur in the wall of these ducts. In the bile duct are many tubulo-alveolar glands arranged in clusters, secreting mucin, some at least of which is sulphated (McMinn & Kugler 1961). Electron microscopy of the bile duct epithelium in guinea-pigs showed microvilli on its luminal surfaces. Secretory granules, some of mucinogen, appear in the apical cytoplasm. Epithelial cells in rats, which lack a gall bladder, are termed either light or dark according to their electron density; light cells have longer, more regular microvilli but the basal intercellular spaces between adjacent dark cells are larger; the mucosa appears to modify bile, compensating for the absent gallbladder (Riches & Palfrey 1966).

Circular muscle around the lower part of the main bile duct, including the ampulla and terminal pancreatic duct, forms the *sphincter of the hepatopancreatic ampulla (sphincter of Oddi)*, comprising muscle at three levels: (1) at the end of the bile duct *(sphincter ductus choledoci)*; (2) at the end of the pancreatic duct *(sphincter ductus pancreatici)*; and (3) around the ampulla. Only (1) is constant. Expulsion of gallbladder contents appears to be under hormonal control. Fat or acid in the duodenum probably causes the liberation of cholecystokinin, stimulating the gallbladder to contract. Myocytes in its wall have surface-borne receptors for this hormone, which can therefore stimulate them to contract directly. In any case, when storage pressure exceeds 100 mm of bile, the gallbladder contracts, the sphincter of Oddi relaxes and bile enters the duodenum. Kirk (1944) denied the presence of sphincteric musculature around the openings of the bile and pancreatic ducts, describing the sphincter of Oddi as submucosal and continuous with the circular muscle of the duodenum. However, subsequent studies suggest that in man and other primates a common sphincter surrounds both ducts and that the common bile duct has a second sphincter as described above (Boyden 1957, 1966). The termination of the united bile and pancreatic ducts is packed with villous, valvular folds of mucosa and myocytes enter their connective tissue cores. This suggests that contraction results in retraction and clumping of the folds, preventing reflux of duodenal contents and controlling the exit of bile. In cats stimulation of vagal rami to this region relaxes the biliary opening; the human *myenteric (Auerbach's) plexus* is well developed at the ends of the ducts. Inflammatory swelling of villous folds may obstruct them.

Applied Anatomy. On account of its large size, fixed position, and friability, the liver is sometimes ruptured; haemorrhage may be severe, because the hepatic veins lie in rigid canals and are unable to contract. The organ may be torn by a broken rib, perforating the diaphragm. Clinical evidence suggests that the bloodstreams of the superior mesenteric and splenic veins remain largely separate in the portal vein, passing respectively along the right and left portal branches to the right and left physiological (vascular) lobes (p. 1385); thus malignant or infective emboli may be more pronounced in the right lobe if the primary disease is in the territory drained by the superior mesenteric vein, or in the left if it is in the splenic or inferior mesenteric territory. This correlation is also supported in experiments in living animals. Vascular hepatic segmentation (p. 1385) is a vital factor in *partial hepatectomy*.

The gallbladder may be distended by calculi or by obstruction of the cystic duct and may project down and forwards towards the umbilicus. It moves with respiration. Obstruction of the bile duct, apart from lithiasis, is often due to pressure of malignant tumours, especially in the pylorus or pancreas. It also follows cicatricial contraction after ulceration in the duct. Enormous distension of the bile duct and its radicles may also occur.

Cholecystography (8.164). The gallbladder is not radio-opaque, but radio-opaque substances introduced into the bloodstream are excreted by the liver into bile, and concentration in the gallbladder renders it much more strongly radio-opaque. The form, position and emptying of the gallbladder can be demonstrated by X-rays; its position and form vary with the general build of the body (or somatotype) (Davies 1927); in broad (hypersthenic) types it is broad, high up and far laterally (at the level of the first lumbar vertebra), whereas in narrow (asthenic) types it is narrow, more medial and may reach as low as the fourth lumbar vertebral level.

THE UROGENITAL SYSTEM

Introduction

So customary has it become to link the organs of urinary excretion and reproduction as a *urogenital system* that the suitability of this concept is rarely even questioned. Yet functionally the two have nothing in common and to associate them in description may seem at first absurd (Romer 1970). In mature human organs the structural overlap is little more than a shared use of the male urethra as a urinary *and* seminal duct. Of course, in development, gonadal ducts have a *nephric* origin; but in human females even the *oviduct* ('female', paramesonephric or Müllerian duct) is no longer formed from nephric tissue. Indeed, no adequate reason remains to continue defining a 'urogenital' system in female mammals. Even in males, where the duct systems of the testes (as in other mammals) are derived from nephric tubules and the *mesonephric duct*, these are not excretory structures. The reptilian functional kidney is no longer a mesonephros, and the intromittent *penis*, developed from cloacal tissues, has bilateral parts enclosing a purely seminal groove when erected for copulation, urine entering the cloaca. Apart from development, therefore, the genital system is already completely separated from the urinary organs in both sexes in reptiles. Birds, like amphibians, generally have no intromittent organ, though this is probably a secondary loss in the former, some more primitive birds possessing a rudimentary penis of a reptilian type.

In all vertebrates (excluding elementary chordates) nephric excretory tubules and gonads develop from coelomic epithelium, together with their collecting ducts as these evolve. Both develop in dorsal sites flanking the major vessels; and perhaps this propinquity, combined with the more medial location of gonads, has led to the adoption of urinary ducts and tubules to serve the gonads, especially in males. In primitive *Chordata*, such as *Amphioxus*, excretory tubules, or *nephridia*, have capillary *glomeruli* close to them and secrete from the adjoining bloodstream and coelom into a peribranchial atrium. These excretory organs are ectodermal and unrelated to the mesodermal nephric tubules of vertebrates. The evolutionary relation of *Amphioxus* to early vertebrates is, in any case, uncertain; it has even been suggested that this chordate is a paedomorphic form of a primitive vertebrate (Grassé 1948, Young 1962), matters beyond this discussion.

In vertebrates living in water, saline or fresh, the problems of preserving internal osmotic constants in blood and body fluids, despite variable and sometimes very large intakes of water and salts, have led to the continuous evolution of more efficient and elaborate excretory tubules, derived from mesoderm intermediate between the somites and the lateral plate in embryos, forming *nephrotomes* (p. 248). Though originally segmental, their large numbers overshadow this and in most lower vertebrates they form elongated masses or cords of nephrogenic tissue projecting into the coelom from a dorsolateral position. Gonads develop *medial* to these *nephrogenic cords* (p. 248); and since *primary excretory ducts* (p. 248), carrying urine to the exterior, evolve *lateral* to the nephros, gonadal access to them is effected by adaptation of the nephric tubules. The degree of development and functional status of different parts of this elongate kidney or vertebrate *holonephros*, extending through many body segments, has varied much. The cranial part generally tends to disappear, except where it functions in embryos or in larval forms, as in some cyclostomes (e.g. *Petromyzon*, the lamprey). In anamniotic gnathostomes (fish and amphibia) an intermediate nephrogenic region becomes a functional kidney and, while still elongate, this occupies a comparatively small number of segments, with which its vessels approximately correspond. In reptiles and mammals the most caudal mass of nephrotomes differentiates into a definitive kidney, which becomes more localized and rounded, of familiar reniform shape particularly in mammals, losing almost all indications of plurisegmental origin when fully developed.

This progressive caudal shift of the functioning nephros has prompted the division of the holonephros into pro-, meso-, and meta-nephros, and has given rise to some misleading concepts; e.g. amphibian kidneys are often termed mesonephric and mammalian organs metanephric. Nevertheless, the formation of nephric tubules is substantially alike at all levels and it cannot be assumed that these regional terms are applicable over large and diverse vertebrate groups with anything more than approximate segmental uniformity. The terms are more of a descriptive convenience than vehicles of biological precision. (For a discussion of problems in the development of the urogenital organs, consult Fraser 1950.) Distinctions between the three regional levels of the nephrogenic ridge depend more upon their functional status and ducts than their intrinsic morphology. In cyclostomes, excretory tubules discharge, as do gonads, into the coelom, from which their products escape through the *abdominal pores* or through short ducts situated caudally. In gnathostomes, *nephric tubules* lose continuity with the coelom, each developing a saccular end, with which *glomeruli* are closely related. The tubules join a longitudinal *archinephric duct (primary excretory duct)*, which first serves the pronephros but is taken over by the more caudal mesonephros. Through mesonephric tubules testes find outlets via the urinary ducts, an arrangement typical of amphibians, both urine and spermatozoa reaching the cloaca by such *mesonephric (Wolffian) ducts*. Ovaries also acquire ducts, in some forms from the mesonephric duct; but this *paramesonephric, female* or *Müllerian duct* becomes a separate entity and does not transmit urine. Moreover, oviducts never establish direct continuity with the ovaries, which retain a primitive habit of shedding ova into the coelom, though very close to the open, coelomic beginnings of the oviducts. This relation is constant and occurs in human females. Oviducts of mammals and of tetrapods in general appear to develop independently by evagination from the coelomic lining.

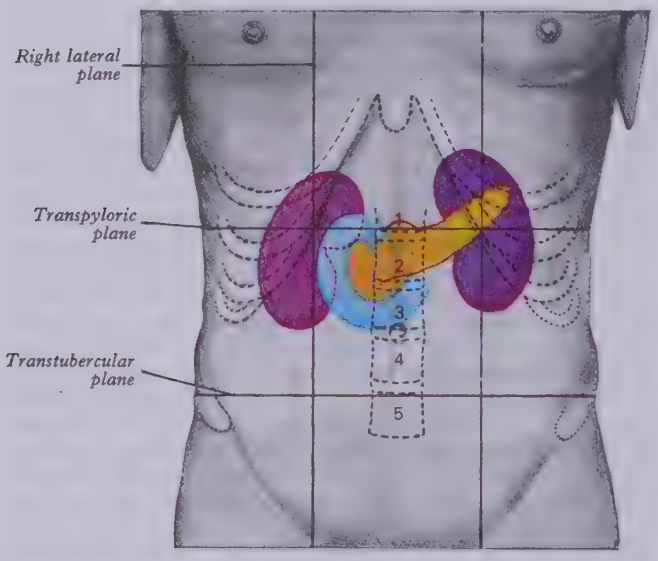
In reptiles, birds and mammals, the functioning kidney is a *metanephros*, developing caudal to the mesonephros. Its main distinction is its *dissociation from genital function*; though in part an outgrowth of the caudal end of the mesonephric duct, it ultimately opens separately into the bladder by its own duct, the *ureter*. The mesonephros is thus relieved of all excretory function, its tubules and ducts persisting only in modified form as testicular *vasa efferentia, epididymis* and *ductus deferens*.

To summarize: the pronephros is an embryonic or larval excretory organ with a purely excretory duct. The mesonephros, which takes over this duct and excretion, also provides a route for spermatozoa and, by the division of its duct in some vertebrates, is a separate exit for the ova. The metanephros is again purely excretory, male genital ducts continuing as mesonephric derivatives and the oviduct as an increasingly independent development.

The complete segregation of urinary and genital organs in reptiles (apart from their embryonic development and the opening of their separate ducts in a common cloaca) becomes modified again by the evolution of a male intromittent organ for internal fertilization, necessitated by full emancipation from reproduction in water. Production of eggs, or rather embryos, protected from desiccation in a terrestrial environment by shells impervious to water (though not to respiratory gases), requires fusion of gametes in the oviduct proximal to specializations of its wall to produce such coverings. Similarly, production of offspring at a sufficient stage of development for life exposed to the external environment also entails internal fertilization. Apart from monotremes, all mammals have this viviparous habit. Internal fertilization is accomplished without an intromittent organ in most birds, but an erectile *penis* is universal in marsupials and eutherian mammals. Since this is traversed by the urethra, used to void both urine and semen, male mammals, including the human, exhibit to this extent an association of the excretory and reproductive organs. Both systems display many adaptations and specializations, concerned in mammals with a much improved ability to preserve a steady internal environment in terms of total body water volume and concentrations of ions and other dissolved substances. This entails an increasing complexity in glomeruli and renal tubules, forming *nephrons* or kidney units, capable not only of removing variable and sometimes large volumes of water, but also of selective reabsorption of substances such as glucose and salts and retention of others, such as urea, in the urine.

The renal ducts open into various forms of reservoir in many vertebrates and in mammals into a cloacal derivative, the *bladder*. In mammalian reproductive organs, accessory structures have evolved in connection with intromission and the retention and nurture of developing embryos; these include seminal vesicles and the prostate, uterus and vagina. All have already been considered in embryological development (p. 248); they must now be studied in their mature primate morphology. The customary association of the two groups of organs has been partially retained, since even in description of completely differentiated urinary and genital systems reference to ontogeny and phylogeny is occasionally necessary. It is, nevertheless, worthy of repetition that their association in the postnatal human being is wholly limited to the dual function of the penile urethra.

THE URINARY ORGANS



The urinary organs are: (1) two *kidneys* (renes) producing urine, (2) *ureters*, conveying it to (3) the *urinary bladder* (vesica urinaria) for temporary storage, and (4) the *urethra* by which the bladder empties. The female urethra is purely urinary; the male is urinary and reproductive, the latter essential, the former merely the use of a tube almost entirely genital. Loss of the penile urethra affects urination little, whereas genital function is abolished. Almost the whole male urethra is therefore genital (p. 1421) but for the sake of completeness it is described in this section.

The Kidneys

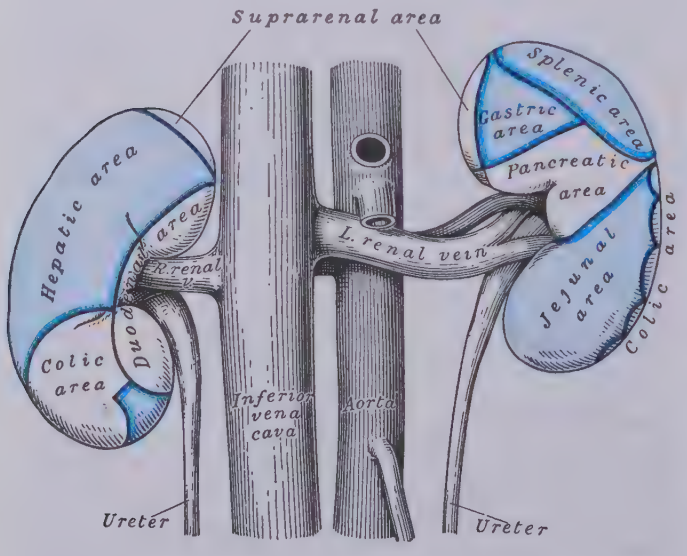
The kidneys excrete the final products of metabolic activities and excess water, both of these actions being essential to the control of concentrations of various substances in the body fluids, e.g. maintaining electrolyte and water balance approximately constant in tissue fluids. They also have endocrine functions producing and releasing *erythropoietin* which affects blood formation, *renin* influencing blood pressure and *1,25-hydroxycholecalciferol*,

involved in the control of calcium metabolism and a derivative of vitamin D, perhaps modifying the action of the parathyroid hormone (O'Riordan 1978), and various other soluble factors with metabolic actions. The kidneys in the fresh state are reddish-brown, are situated posteriorly behind the peritoneum on each side of the vertebral column and are surrounded by adipose connective tissue. Superiorly they are level with the upper border of the twelfth thoracic vertebra, inferiorly with the third lumbar. The right is usually slightly inferior, probably due to the volume of the liver on this side; the left is a little longer and narrower and lies nearer the median plane. The long axis of each is directed inferolaterally and the transverse axis posterolaterally. Hence the anterior and posterior aspects usually described are in fact *anterolateral* and *posteromedial*. The transpyloric plane (p. 1334) passes through the superior part of the right renal hilum and the inferior part of the left.

Each kidney is about 11 cm in length, 6 cm in breadth and 3 cm in anteroposterior dimension. In adult males the average weight is about 150 g, in adult females 135 g. In thin individuals with a lax abdominal wall the lower pole may just be felt in full inspiration by bimanual lumbar examination; usually it is impalpable.

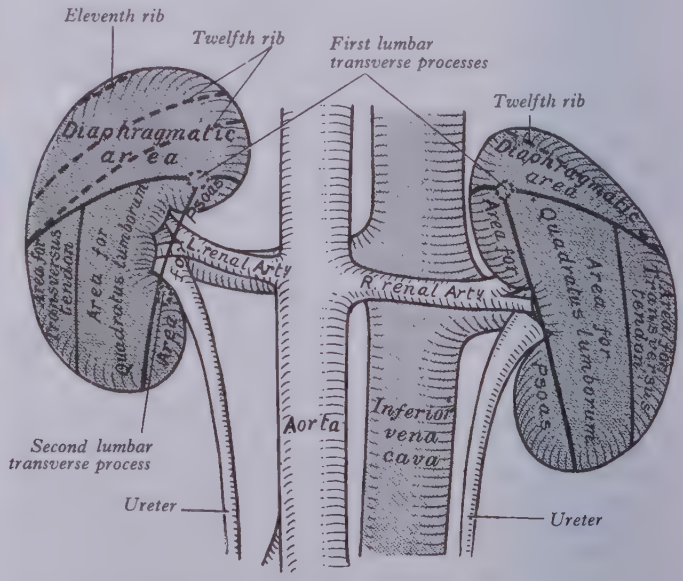
8.165 Surface projections of the duodenum, pancreas and kidneys. The lower ribs and the lumbar vertebrae are also indicated, the latter being numbered.

Renal Surface Projections



In a recumbent posture, each renal profile can be projected to the anterior or posterior surface of the body as follows, the right kidney being about 1.25 cm lower: (1) *Anterior surface*. The hilar centre is at the transpyloric plane, about 5 cm from the midline and slightly medial to the apex of the ninth costal cartilage. The left hilum is just above the plane, the right just below it (8.165). In relation to the position of the hilum, a reniform profile can be drawn 11 cm long and 4.5 cm broad, the upper pole being about 2.5 cm and the lower 7.5 cm from the midline. Since the transverse axis is oblique, the width thus shown is 1.5 cm less than the actual width. (2) *Posterior surface*. The hilar centre is opposite the first lumbar spine's lower edge, and about 5 cm from the midline. In relation to this point, a reniform profile can be similarly traced, the lower pole being usually about 2.5 cm above the summit of the iliac crest. The kidneys are about 2.5 cm lower in the standing position; they ascend and descend a little with respiration.

Renal Relations



The convex *anterior surface* (8.125, 166) in reality faces anterolaterally. Its relations differ on the two sides of the body.

(1) *Right anterior surface*. A small area at the superior pole contacts the right suprarenal gland, which may overlap it or the upper medial border. A large area below this (about three-quarters of the surface) adjoins the renal impression on the right lobe of the liver and a narrow medial area is related to the descending duodenum. Inferiorly the anterior surface is related laterally to the right colic flexure and medially to the small intestine. The areas related to the small intestine and almost all those in contact with the liver are covered by peritoneum (with the renal fascia subjacent); the suprarenal, duodenal and colic areas are devoid of peritoneum.

(2) *Left anterior surface*. A small medial area at the superior pole is related to the left suprarenal gland and approximately the upper two-thirds of the lateral half of the anterior surface is related to the spleen. A central quadrilateral area lies in contact with the pancreatic body and splenic vessels. Above this a small variable triangular region, between the suprarenal and splenic areas, is in contact with the stomach. Below the pancreatic and splenic areas the lateral region is related to the left colic flexure and the beginning of the descending colon, while the medial region adjoins the coils of the jejunum. The latter region is extensive but the colic area is an irregular, narrow strip adjoining the lateral border of the kidney. The gastric area is covered with the peritoneum of the

8.166 The anterior surfaces of the kidneys, showing the areas related to neighbouring viscera. Areas coloured pale blue are separated from adjacent viscera by the peritoneum.

8.167 The posterior surfaces of the kidneys, showing the areas of relation to the posterior abdominal wall.

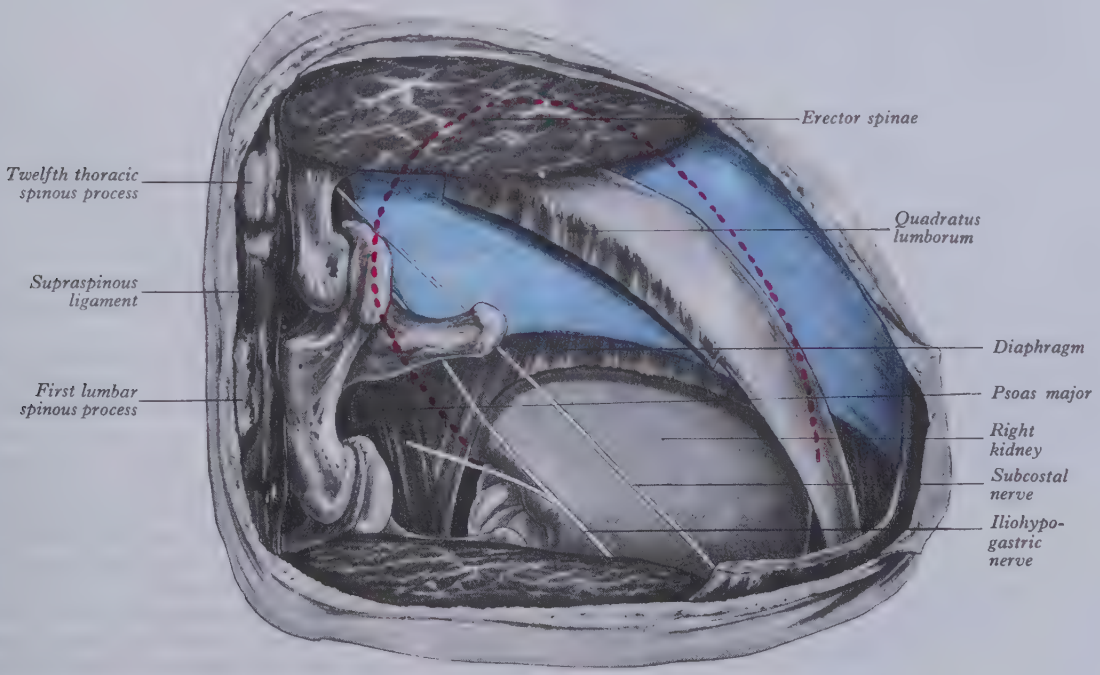
omental bursa and the splenic and jejunal areas are covered by the peritoneum of the greater sac; behind the jejunal area's peritoneum, branches of the left colic vessels are related to the kidney. Suprarenal, pancreatic and colic areas are devoid of peritoneum, there being no mutual movement of organs here.

The *posterior surface* (**8**.167, 168, 170), in reality posteromedial, is embedded in fat and devoid of peritoneum. It is anterior to the diaphragm and to the medial and lateral arcuate ligaments, psoas major, quadratus lumborum and the aponeurotic tendon of transversus abdominis, to the subcostal vessels and subcostal, iliohypogastric and ilio-inguinal nerves. The right upper pole is level with the twelfth rib, the left with the eleventh and twelfth. The diaphragm separates the kidney from the pleura descending in the costodiaphragmatic recess (**8**.168); sometimes its muscle is defective or absent in a triangle immediately above the lateral arcuate ligament, allowing perirenal adipose tissue to contact the diaphragmatic pleura.

The *superior poles* are thick, round and nearer the midline, each related to its suprarenal gland. The *inferior poles*, smaller and thinner, extend to within 2.5 cm of the iliac crests. The *lateral borders* are convex, the left covered superiorly by greater sac peritoneum, so separating it from the spleen, and below this is in contact with the descending colon; the right lateral border is separated by the peritoneum of the greater sac from the liver (right lobe). The *medial borders* are convex adjacent to the poles, concave between them and slope inferolaterally. In each a deep vertical fissure opens anteromedially as the *hilum*, bounded by anterior and posterior lips and containing the renal vessels and nerves and the *renal pelvis* of the ureter. The relative positions of the main hilar structures are: the renal vein anterior, the renal artery intermediate and the pelvis posterior. Commonly an arterial branch enters behind the renal pelvis and a renal venous tributary often leaves the hilum in the same plane. Above the hilum the medial border is related to the suprarenal gland and below to the commencement of the ureter.

The hilum leads into a central *renal sinus*, lined by the renal capsule and almost filled by the renal pelvis and vessels; numerous *renal papillae* project on the wall of the sinus. The collecting tubules open onto the summits of the renal papillae and drain into the funnel-shaped expansions of the upper urinary tract, named the minor calices (**8**.169B, 172). The minor calices terminate in two or three major calices which in turn open into the renal pelvis. The renal calices and pelvis are described in detail on p. 1411.

The kidney and its vessels are embedded in *perirenal (perinephric) fat*, which is thickest at the renal borders and prolonged at the hilum into the renal sinus. Fibrous connective tissue surrounding this fat is condensed as *renal fascia* (**8**.170).



The Renal Fascia

At the lateral renal borders the two layers of renal fascia fuse; the anterior extends medially in front of the kidney and its vessels to merge with connective tissue enclosing the aorta and inferior vena cava, but it is thin and does not ascend above the superior mesenteric artery. The posterior layer passes medially between the kidney and the fascia on quadratus lumborum and psoas major, attaching to this fascia at the lateral and medial borders of the psoas and to the vertebrae and intervertebral discs. A deeper stratum (not shown in **8**.170) unites the anterior and posterior layers at the medial renal border and is pierced by renal vessels (Martin 1942); this may account for the failure of perirenal effusions to cross the midline (although injected air *does* diffuse along this route, Grossman 1954). Above the suprarenal gland the two layers of renal fascia fuse and blend with the diaphragmatic fascia; it is generally agreed that below the kidney they are separate, enclosing the ureter, the anterior fading into the extraperitoneal tissue of the iliac fossa, the posterior blending with the iliac fascia (although this has also been denied, Mitchell 1950). Renal fascia joins the renal capsule by numerous trabeculae traversing the perirenal fat and strongest near the lower pole. Behind the renal fascia is a mass of fat, the *pararenal (paranephric) body*. The kidney is held in position partly by renal fascia but principally by the apposition of neighbouring viscera.

The fetal kidney has about 12 lobules (**8**.171), but these are fused in adults to present a smooth surface, though traces of lobulation may remain.

General Renal Structure (8.172)

The kidney has a thin capsule, easily removed, composed of collagen-rich tissue with some elastic and non-striated muscle

8.168 The right kidney (posterior exposure). The blue area represents the pleura, the broken red line the upper part of the kidney. The subcostal nerve has been displaced downwards. Parts of the diaphragm and the quadratus lumborum have been resected.

fibres. In renal disease it may become adherent. The kidney itself has an internal *medulla* and external *cortex*.

The *renal medulla* consists of pale, striated, conical *renal pyramids*, their bases peripheral, their apices converging to the renal sinus where they project into calices as papillae, each minor calix receiving from one to three of these structures. Each pyramid is capped by cortical tissue to form a renal *lobe*. Estimates of papillae, and hence of pyramids or renal lobes, are variable. Counts in 375 human kidneys (Lake et al 1966) ranged from 5–11 in 89% with a most frequent value of 8 (in 26%). Total numbers of terminal uriniferous ducts (of Bellini) opening on papillae varied (in 208 kidneys) from 116 to 776; no peak of frequency was observed, but 23% of kidneys displayed about 275 such openings. In another series of 54 kidneys (Arvis 1969) the number of papillae was 6 to 14.

8.169A An intravenous pyelogram. Both ureters can be visualized throughout much of their length, except where peristalsis has temporarily displaced the excreted contrast medium, which also fills the urinary bladder. Compare with the retrograde pyelogram illustrated in **8.169B**.

The *renal cortex* (**8.172A**) is subcapsular, arching over the bases of pyramids and extending between them towards the renal sinus as *renal columns* (**8.172C**); the peripheral regions are *cortical arches* and are traversed by radial, lighter-coloured *medullary rays* (**8.172C**), separated by darker tissue, the *convoluted part*. The rays taper towards the renal capsule and are peripheral prolongations from the bases of renal pyramids. The cortex is also histologically divisible into *outer* and *inner zones*; the inner is demarcated from the medulla by tangential blood vessels (arcuate arteries and veins) which lie at the junction of the two, but a thin layer of cortical tissue ('*subcortex*') appears on the medullary side of this zone. The cortex close to the medulla is sometimes termed *juxtamedullary*.

Renal Histology

The kidney is composed of many tortuous, closely packed *uriniferous tubules*, bound by a little connective tissue in which run blood vessels, lymphatics and nerves. Each tubule consists of two embryologically distinct parts (p. 248): (1) the secreting *nephron* which elaborates urine and (2) a *collecting tubule*. The *nephron* comprises *(a) a renal corpuscle*, concerned with filtration from the plasma and *(b) a renal tubule*, concerned with selective resorption from the glomerular filtrate to form the urine. *Collecting tubules* carry fluid from several renal tubules to a terminal *papillary duct (of Bellini)*, opening into a minor calix at the apex of a renal papilla. Papillary surfaces (vide supra) show numerous minute orifices of these ducts and pressure on a fresh kidney expresses urine from them.

The Renal Corpuscle (8.172D, 173A, 175B)

Renal (Malpighian) corpuscles, small rounded masses averaging about 0.2 mm in diameter, are visible in the renal cortex and columns except from a narrow peripheral cortical zone (*cortex corticis*). There are one to two million renal corpuscles in each kidney, decreasing with age (Dunnil & Halley 1973). Each has a central *glomerulus* of vessels and a membranous *glomerular capsule*, the commencement of a renal tubule.

A glomerulus is a lobulated collection of convoluted, capillary blood vessels, united by scant connective tissue etc., and fed by an *afferent arteriole* which usually enters the capsule opposite the exit into the tubule; an *efferent arteriole* emerges from the same *vascular pole (mesangium)* of the capsule. Glomeruli are simple until late prenatal life, some remain so for about six months after birth, the majority maturing by six years and all by 12 (Macdonald & Emery 1959). In the fetal rabbit, guinea-pig and sheep, the glomerular precursor is a solid sphere of mesodermal cells in which vessels canalize until the glomerulus is a compact anastomosing plexus, not showing independent capillary loops (Lewis 1958).

The glomerular capsule (of Bowman), the expanded end of a renal tubule, deeply invaginated by the glomerulus, is lined by simple squamous epithelium on its outer (parietal) wall; its glomerular, juxtacapillary (visceral) wall is composed of specialized epithelial *podocytes* (Latta 1973, Spinelli 1974, Arakawa & Tokunaga 1974). Thus, between glomerulus and external capsular layer, is a flattened *urinary space*, varied in size by secretory activity (vide infra) and continuous with the proximal convoluted tubule. The basal lamina of the capsular cells fuses with that of glomerular endothelium.

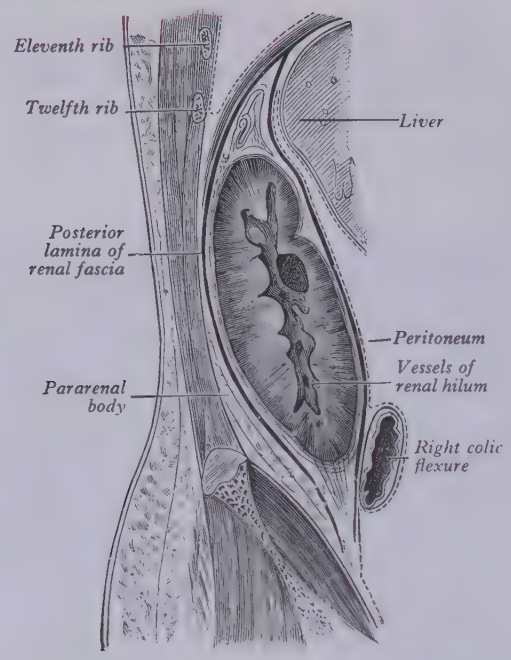
Podocytes surrounding the capillary loops are flat, stellate cells, their major processes curved around capillaries, interdigitating tightly with each other and attached to the basal lamina by numerous pedicles; narrow gaps lie between these cellular extensions. Podocytes contain many mitochondria, microtubules, microfilaments and vesicles of various types, all of these being signs of active metabolism. The glomerular *endothelium* is finely

fenestrated and the sole barriers to the passage of fluid from capillary lumen to urinary space are therefore the fused endothelial and podocytic basal laminae. This *glomerular basement membrane* is about 0.33 μm thick in man; it is finely fibrillar and shows three layers, the first and third pale-staining (*laminae rarae interna et externa*) and the middle dense and fibrous (*lamina densa*). Unlike many fenestrated endothelia, a regular dense lamina appears absent from the *fenestrae* of glomerular endothelial cells; but at the distal aspect of glomerular membrane areas between adjacent pedicles are covered by a clear dense *glomerular slit diaphragm*, through which filtrate must pass to enter the urinary space. This diaphragm is composed of fine filaments arranged in two regular rows like a zip-fastener (Rodewald & Karnovsky 1974) which may form an important part of the glomerular filter. The glomerular basement membrane certainly acts as a selective filter, allowing the passage from blood, under pressure, of water and various small molecules and ions in the circulation. Haemoglobin may pass, but larger molecules are held back. Selectivity appears related to the physicochemical nature of the filter. Tracer experiments show that some materials withheld from urine by the glomerulus traverses all but the outer surface of the filter, which is therefore more complex than a simple physical filter (Rennke et al 1975). The glomerular filter has chemical features similar to those of basal laminae elsewhere, including type IV collagen in the lamina densa and negatively charged proteoglycans elsewhere (see Farquhar 1981). The presence of fixed negative charges tends to inhibit the filtration of charged macromolecules from the blood, particularly in the laminae rarae. Irregular *mesangial cells*, with phagocytic and contractile capacities, have been demonstrated, particularly around bases of glomerular capillary tufts; these may help to clear the glomerular filter of enmeshed substances which might clog it, e.g. immune complexes, cellular debris, etc (Caulfield & Farquhar 1974; see also Brenner & Rector 1981, Bulger & Dobyan 1982).

The Renal Tubule

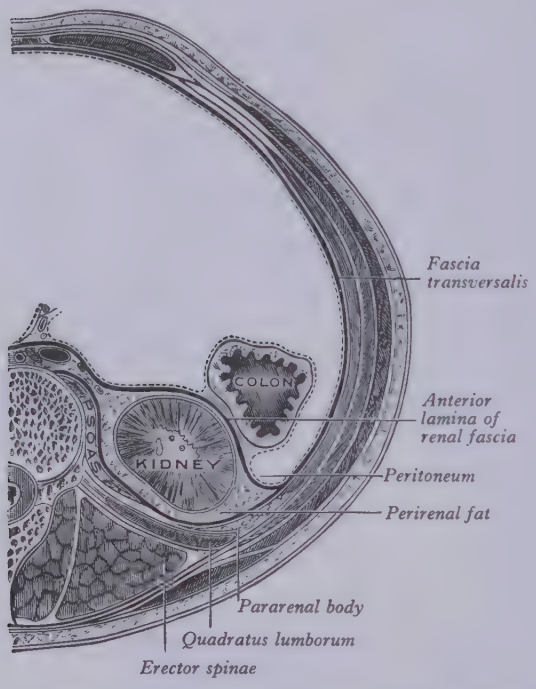
A renal tubule (**8**.172D) consists of: (1) a *glomerular capsule*, already described, (2) a *proximal (first) convoluted tubule*, connected to the capsule by a short *neck* (in humans a little narrower than the tubule) leading to a first sinuous or partially coiled *convoluted part*, then to a terminally straight or slightly spiral *straight part*; this approaches the medulla to become (3) the *descending limb* of the *loop of Henle* connected by (4) a 'U' turn to (5) the *ascending limb*. The limbs of Henle's loop are for some distance narrower and thin-walled, forming the *thin segment*; but the upper part of the ascending limb (*thick segment*) has the same diameter as the proximal convoluted tubule. The ascending limb continues into (6) the *distal (second) convoluted tubule*, divisible into *straight* and *convoluted sections* with an intermediate thickened *macula densa* where the tubule comes close to a glomerulus. The nephron finally straightens as (7) the *junctional (connecting) tubule*, which ends in (8) a *collecting (straight) duct*. Between the distal convoluted and junctional tubules, there is often a short angular *zigzag* (or *irregular*) *tubule*.

Collecting ducts (**8**.172) commence in the cortical medullary rays and unite at short intervals, finally opening into wider *papillary ducts* (*of Bellini*), which end on a papillary summit, their numerous orifices forming an *area cribrosa*.



STRUCTURE OF THE RENAL TUBULE (**8**.172D, 173A)

Renal tubules are lined by a simple epithelium with a basal lamina of varying thickness (Maunsbach 1973). The type of epithelial cell varies according to the functional roles of the different regions, being concerned mainly with active transport and passive diffusion of various ions and water into and out of tubules, with reabsorption of organic substances such as glucose and amino acids and with the uptake of any proteins which may leak through the glomerular filter (Bulger 1977).



Proximal tubules are lined by cuboidal epithelium with a brush border of tall microvilli on their luminal aspect. The shape of the cells depends on tubular fluid pressure, which in life distends the lumen and stretches cells to a slightly flattened shape, becoming taller when glomerular blood pressure falls at death or at biopsy. The cytoplasm of these cells is strongly eosinophilic and their nuclei euchromatic and central. By light microscopy their bases show faint striae, which by electron microscopy appear as a complex series of pleats between which numerous mitochondria are

8.169B A left retrograde pyelogram. The contrast medium has been introduced into the calices, pelvis and upper ureter via a ureteric catheter, which is still in position and can be clearly identified. There is considerably greater density of the shadows of the calices than that achieved by the intravenous method. Note the relation of the ureter to the tips of the lumbar transverse processes and the characteristic 'cupping' or 'champagne glass' profiles of the tips of the lesser calices where they surround the renal pyramids. 'Calix' means a cup and such 'cupping' of the minor calices is the normal appearance. (Note that the major calices are not cusps and are hence inappropriately named.)

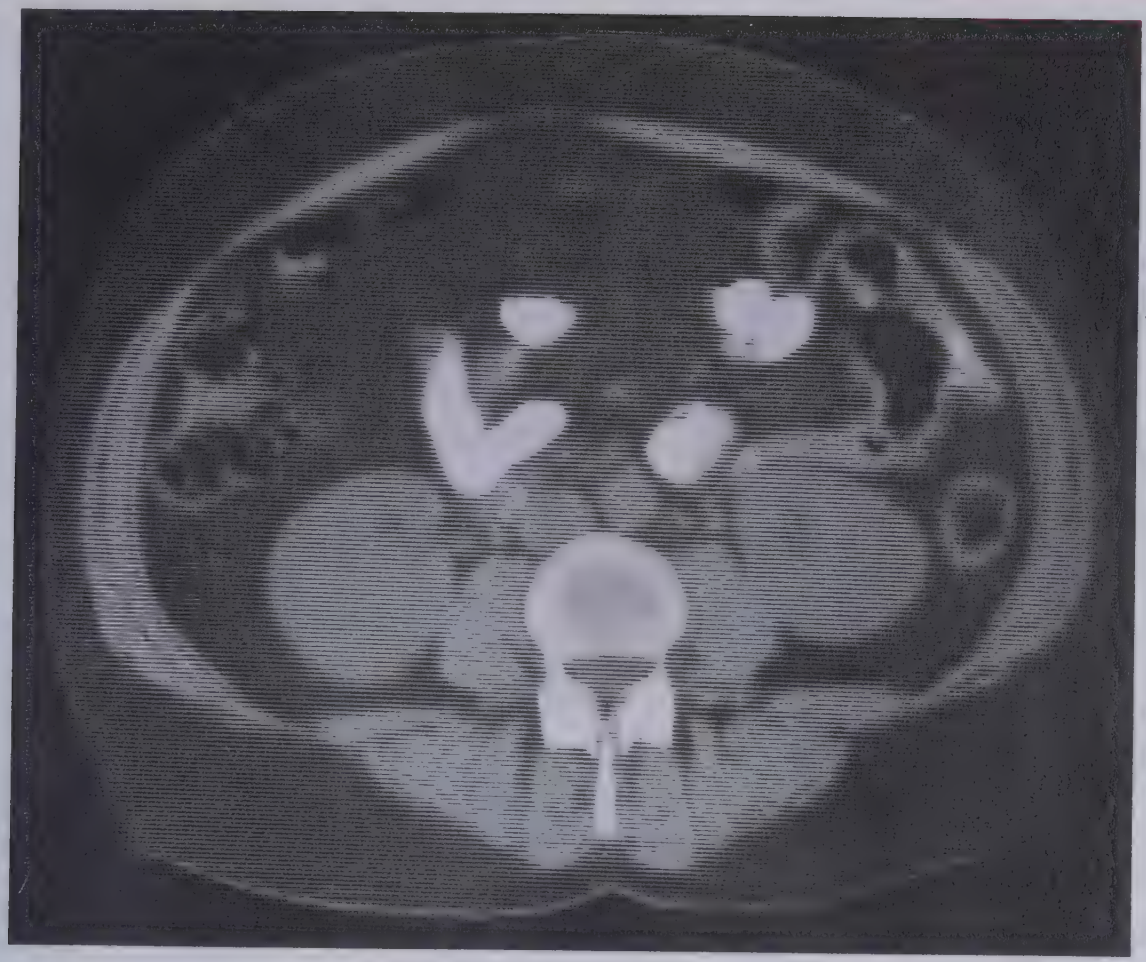
orientated perpendicular to the basal lamina. Reconstruction has shown this complex to consist of processes inter-digitating between the lateral aspects of adjacent epithelial cells, creating a labyrinth of cytoplasmic pedicles in the outer part of the tubular wall (Bulger 1965, 1977). Taking into account also the microvilli on the luminal surface, such cells provide relatively vast areas of plasma membrane in contact with tubular fluid and the extratubular space, an arrangement facilitating the transport of ions and small molecules against steep concentration gradients and energized by abundant mitochondria. Sodium/potassium-stimulated adenosine triphosphatase (Na/K ATPase) is located in apical and basal membranes (Wachstein & Bradshaw 1965), with numerous other cytoplasmic enzymes associated with ionic transport. Apart from such ionic transport through epithelial cells, water and other ions may pass between cells passively along osmotic and electrical gradients, probably through 'leaky' tight junctions at their apices (Fromter 1979). These cells also contain extensive invaginations of their plasma membranes, channels and lysosomes engaged in the uptake and hydrolysis of proteins which escape in small amounts into the glomerular filtrate (Caulfield & Farquhar 1975). Peroxisomes and lipid droplets are also frequent and basal microfilaments assist to maintain the shape of the tubule. Among many cytoplasmic enzymes demonstrable by histochemistry are cytochrome oxidase, succinic dehydrogenase and other respiratory enzymes, acid phosphatase in lysosomes and glucose-6-phosphatase and leucine aminopeptidase, reflecting the highly energetic nature of these cells (vide infra).

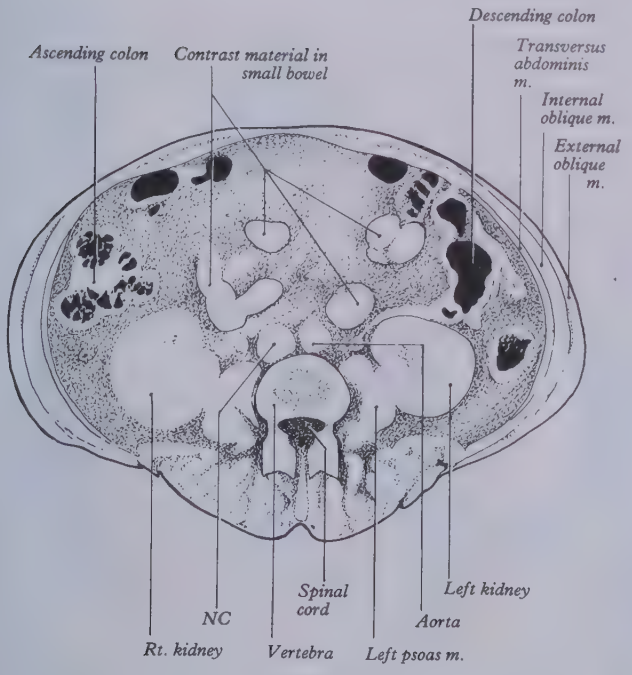
Variations occur in cell structure, enzyme content and functions along the proximal tubules. The short, initial *neck* is the simple squamous epithelial extension of the outer wall of the renal corpuscle; the rest of the proximal tubule is divided into three (sometimes four) regions: the first typified by long microvilli, the second by microvilli of medium length, the third (in man) again by long microvilli (Moffat 1975). Patterns of lysosomal and transport activities appear to follow these divisions, too, but the functional significance of this distribution is not clear.

The *ansa nephroni* (renal loop of Henle) consists of the *thin segment* (about 30 μm in diameter), lined by low cuboidal to squamous cells, and the *thick segment* (about 60 μm across) composed of cuboidal cells like those in the distal tubule, with which it is sometimes considered, as its *straight part*. The *thin segment* forms most of the loop in juxtamedullary and deep cortical nephrons which reach far into medulla; here, the descending limb of the thin segment has low cuboidal epithelial cells with complex interdigitations and narrow belts of tight junctions between cells, whereas the ascending limb is lined by squamous cells with wider junctional zones. These differences may be related to the different permeabilities to water and ions (Bulger 1971). Few organelles appear in either cell type, indicating a passive rather than an active role in ionic movements. The *thick segment* is composed of cuboidal epithelium with many mitochondria, deep basolateral folds and short apical microvilli, indicative of a more active metabolic state.



Cells of the *distal tubule* resemble those in the proximal, but microvilli are few, small and irregularly spaced; the basolateral folds containing mitochondria are so deep that they almost reach the luminal aspect (**8**.172D). Enzymes concerned in active transport of sodium, potassium and other ions are richly present and are known to be important in ionic regulation. At the junction of the straight and convoluted regions the distal tubule approaches the vascular pole of the renal corpuscle where tubular cells form a sensory structure, the *macula densa*, concerned in the regulation of blood flow and ionic exchange (vide infra). In the terminal part of the distal tubule, cells have fewer basal folds and mitochondria, constituting what is sometimes termed a *connecting duct*, in part like a distal collecting duct but formed from nephrogenic rather than ductual tissue during embryogenesis.

Collecting ducts are of simple cuboidal or columnar epithelium, increasing in height from the cortex, where they receive the contents of distal tubules, to the wide papillary ducts discharging at the area cribrosa. The cells have relatively few organelles or lateral interdigitations and only occasional microvilli; scattered among them are *dark cells* (also present in smaller numbers in the distal convoluted tubule) with longer microvilli and more mitochondria. The functions of these remain uncertain.



The Structure and Function of Nephrons

Three processes co-operate in nephrons to determine renal excretory and regulatory functions (**8**.172D): *filtration*, at the glomerular level, *selective resorption* from the filtrate passing along the renal tubules and *secretion* by the cells of the tubules into this filtrate. These processes have been intensively studied and can be generally correlated with structural variations along the nephron. For further details, see Brenner & Rector (1981).

Glomerular filtration is the passage of water containing various dissolved small molecules from the blood to the urinary

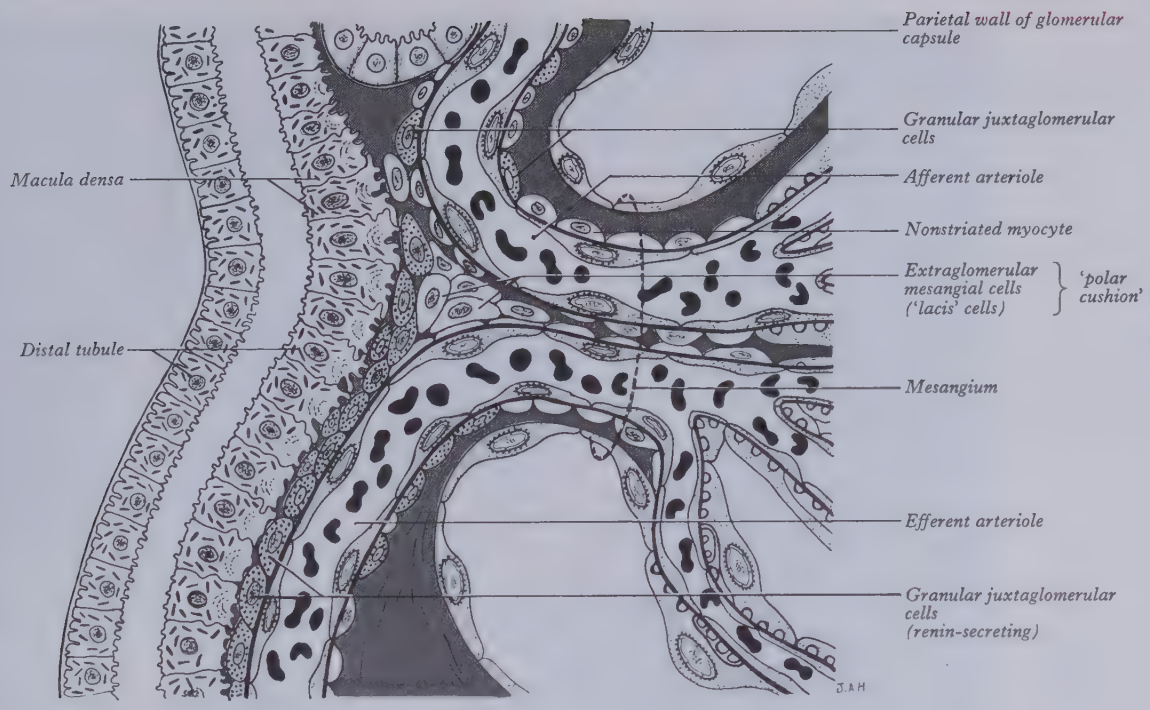
space in the glomerular capsule; larger molecules, e.g. plasma proteins, polysaccharides and lipids, are largely retained in blood by the selective permeability of the glomerular basement membrane.

Filtration occurs along a steep pressure gradient existing between the large glomerular capillaries and the urinary space, the only structure separating the two being the glomerular basement membrane. This gradient far exceeds the colloid osmotic pressure of blood which opposes the outward flow of filtrate. In the peripheral renal cortex the arteriolar pressure gradient is enhanced by an inequality in the calibres of afferent and efferent glomerular arterioles, the former having larger diameters (vide infra). In all glomeruli the rate of filtration can be altered by changes in the tonus of the glomerular arterioles. When first formed, the *glomerular filtrate* is isotonic with glomerular blood and has an identical concentration of ions and small molecules.

Selective resorption of many substances from the filtrate is an active process and occurs mainly in the proximal convoluted tubules, particularly the resorption of glucose, amino acids, phosphate, chloride, sodium, calcium and bicarbonate. Cells of the proximal tubules are permeable to water, which leaves the tubule along an osmotic gradient created by resorption of these solutes, particularly sodium and chloride ions, so that the filtrate remains locally isotonic with blood. Numerous microvilli, the folded lateral and basal surfaces and profuse mitochondria indicate that absorption by proximal tubular cells is an energy-dependent process. Further selective absorption, particularly of sodium ions, also occurs in distal convoluted tubules.



The rest of the tubule reabsorbs most of the filtrate's water (95%); when it reaches the calices, urine is thus much reduced in volume and is *hypertonic* to blood. Along the *descending* limb of the renal loop, sodium and water pass freely between the tubular lumen and adjacent extratubular spaces of the renal medulla, within which lie many loops. In part of the *ascending* limb (the thick segment), chloride ions are transported from the tubule lumen to interstitial spaces, sodium ions following passively; but the lining cells of the tubules do not allow water to follow sodium and chloride ions, some of which diffuse back into the descending limbs, adding to that already in filtrate passing along them; in ascending limbs, sodium is again extracted from this enriched solution, increasing intercellular ion concentrations and causing further diffusion of these into the descending limbs. Alternatively, sodium and chloride may not be recycled into the descending limb, water being merely withdrawn from the tubular loop because of the raised tonicity in the extratubular space, thus concentrating the filtrate. In either manner, high concentrations of sodium and chloride ions are built up in the renal medulla by this *countercurrent multipler system*. Rapid removal of ions from the renal medulla by the circulation of blood is minimized by another looped *countercurrent exchange system*, in which arterioles entering the medulla pass for long distances parallel to the venules leaving it before ending in capillary beds around tubules; this close apposition of oppositely flowing blood allows the direct diffusion of ions from outflowing to inflowing blood, so that these vessels (*vasa recta*) conserve a general high osmotic pressure in the medulla.

Because of the selective secretion of sodium and chloride ions by the cells of the ascending limbs and distal tubules (under aldosterone control), the filtrate at the distal end of the convoluted tubules is *hypotonic*; but, as it proceeds into the collecting ducts, descending again through the medulla, it re-enters a region of high osmotic pressure. Here, since ductual cells are, under the influence of the neurohypophysial antidiuretic hormone (ADH, vasopressin), variably permeable to water, the latter follows an osmotic gradient into the adjacent extratubular spaces (Gottschalk & Mylle 1959). Thus, along collecting ducts, the tonicity of the filtrate gradually rises until at the renal pyramids it is above that of blood. As much as 95% of water in the original glomerular filtrate is thus resorbed into blood. This complex system is highly flexible and the balance between the rate of filtration and absorption can be varied to accommodate to the current general physiological needs.

Secretion of various ions occurs at several sites, control of hydrogen and ammonium ion concentrations being essential to the regulation of acids and bases in the blood. Other secreted substances include various organic acids and antibiotics, these being passed into the filtrate especially in the proximal and distal tubules (**8.172D**).

The Juxtaglomerular Apparatus

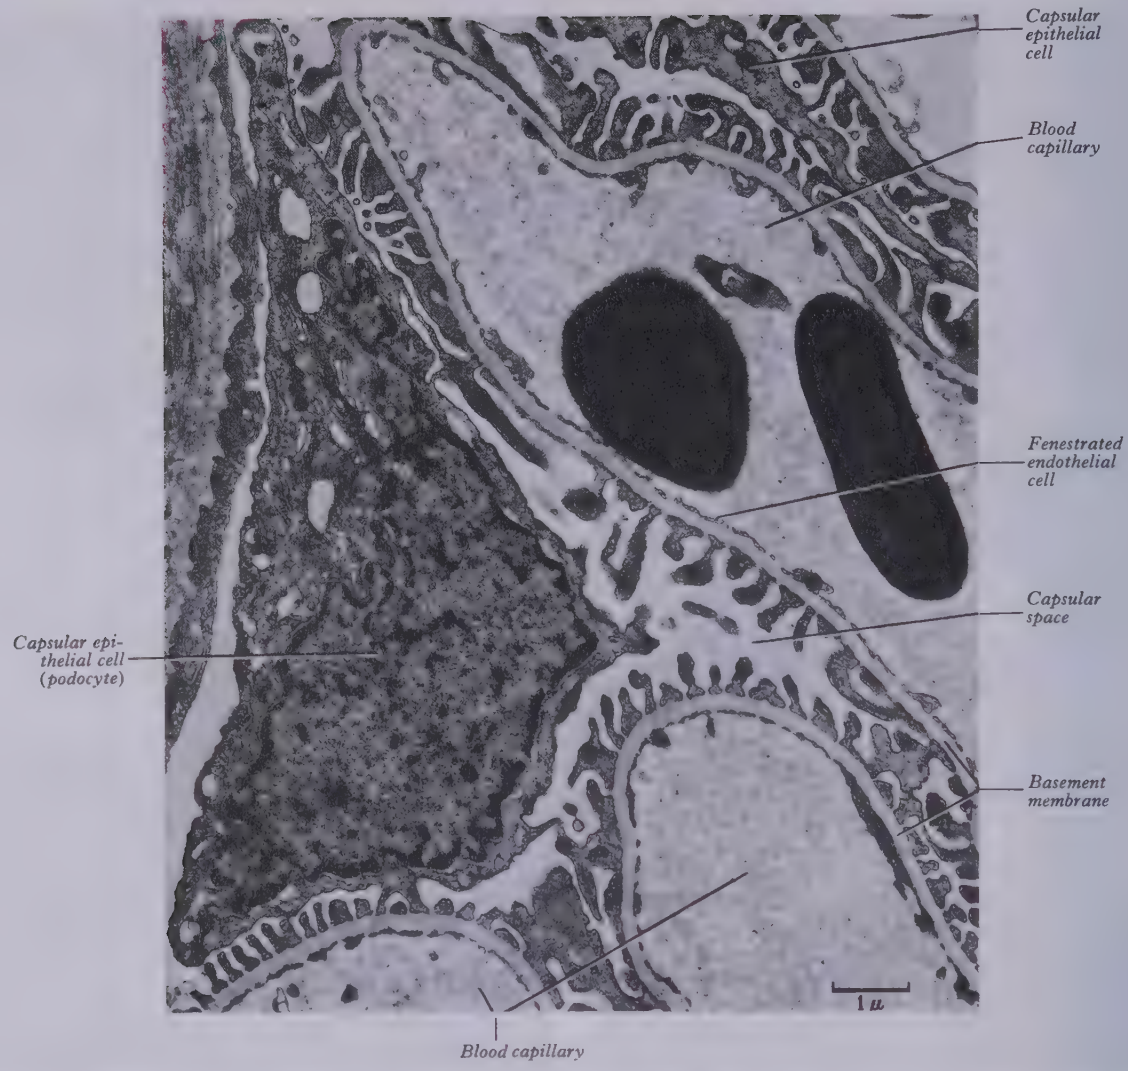
The afferent and efferent arterioles of a glomerulus pass through the mesangium (the vascular stalk of the glomerulus) nearly opposite the exit of the proximal tubule (**8.172D**). In each nephron, the ascending limb of its renal loop returns from the medulla towards its glomerulus and the distal tubule commences between the afferent and efferent vessels, in close contact with them. The cells of the tunica media of the afferent arteriole differ from non-striated myocytes elsewhere in being large, rounded and 'epitheloid' with large spherical nuclei; their cytoplasm contains dense vesicles, 10–40 nm in diameter, and also many mitochondria. These *juxtaglomerular cells* contact cells of the slightly dilated distal convoluted tubule, closely aggregated together here as the *macula densa*; the latter cells are clustered in a group of up to 40, with large, oval nuclei, each cell containing a concentration

8.174 Diagram showing the organization of the juxtaglomerular complex including the macula densa (left), granular juxtaglomerular cells (middle) and the vascular pole of the glomerular capsule (right).

of mitochondria apically (see Barajas 1971, Sikri & Foster 1981) and have a few short microvilli on their luminal surface. The two groups, with various mesangial elements, constitute the renal *juxta-glomerular apparatus* (Edelman & Hartroft 1961, Barajas 1970). In many animals, interspersed between the macula densa and mesangium are *'lacis cells'* (Polkissen cells, extraglomerular mesangial cells, see Spanidis et al 1982). These cells are stellate in form and their processes create an irregular network (lacis). Each cell has a surrounding basal lamina and internally contains occasional granules of a secretory type, but few organelles otherwise. Adrenergic nerve fibres occur in small numbers among these cells. Recently, another cell type, present as a minor component of this intermediate region, has been described. This is the *granular peripolar cell* reported in sheep (Ryan et al 1979) and humans (Gardiner et al 1986). Their main feature is the presence of dense membrane-bound vacuoles 0.4–2.1 μm in diameter. These cells are situated close to the epithelial cells of the renal corpuscle wall, near the mesangial root. Their functions are not yet known but they would appear to be secretory.

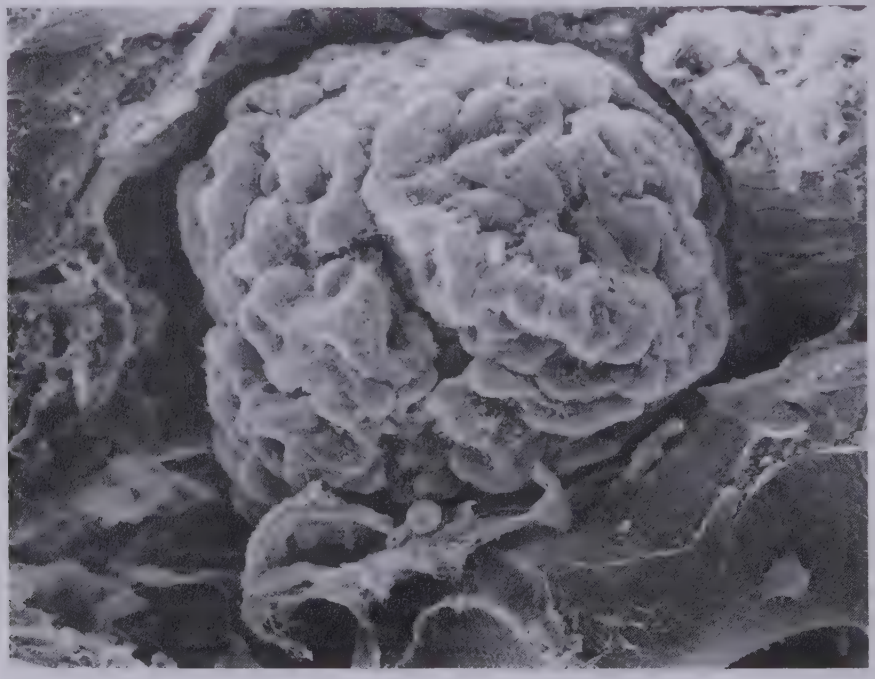
In experimental diminution in renal blood flow, with consequent increase of blood pressure and sometimes in hypertension associated with renal disease, juxtaglomerular cells hypertrophy; they contain *renin* (Cook 1971) within their granules, an enzyme converting a polypeptide in blood, *angiotensinogen*, to *angiotensin I*. This is converted by other enzymes (notably in the lungs) into *angiotensin II*, a polypeptide whose actions include the elevation of blood pressure and stimulation of aldosterone release from the adrenal cortex, increasing resorption of sodium ions from the distal convoluted tubules. Details of renin secretion and consequent changes in tubular activity are not yet clear but the juxtaglomerular apparatus appears to be a feedback device regulating flow of fluid through the glomerular filter and the ionic resorption in renal tubules, thus determining the final concentration of the urine. Renin secretion may be controlled by at least three factors (Davies & Freeman 1976): (1) the activity of the macula densa cells which react to changes in fluid passing them in the distal tubules; (2) pressure in glomerular arterioles affecting the secretory activity of their granule cells; (3) stimulation by sympathetic fibres ending near juxtaglomerular cells. These and other agents (perhaps including other cell types in this region) appear to assist the juxtaglomerular apparatus in correlating blood flow, filtration rate and osmoregulation and in mediating the appropriate actions needed for homeostasis.

Other Renal Cells



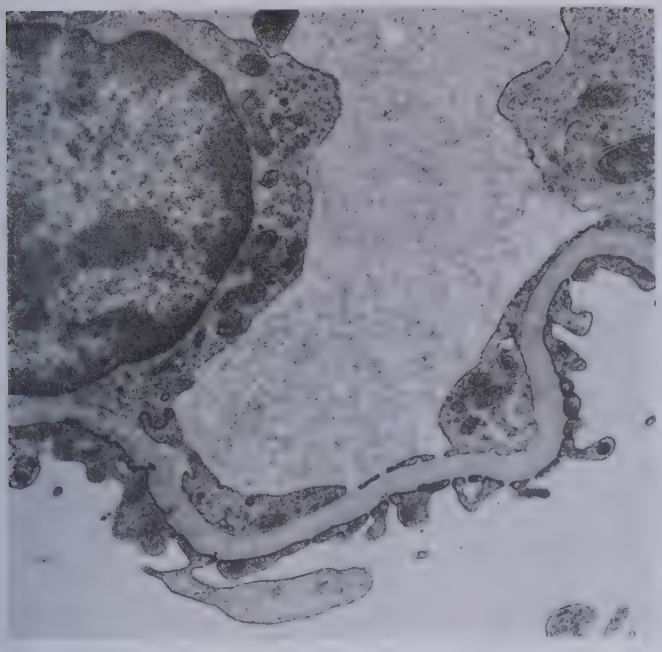
Between the renal tubules and blood vessels lie other cells essential to renal structure and function, such as connective tissue elements, inconspicuous in the cortex but prominent in the medulla, where they secrete the proteoglycans and collagen of the connective tissue matrix, particularly visible in the papillae. Medullary *interstitial cells*, some apparently modified fibroblasts, form vertical piles of tangentially orientated cells between the more distal collecting ducts, like the rungs of a ladder. These cells secrete prostaglandins (Muirhead et al 1972).

Renal Blood Vessels



The complex renal vascular patterns show regional specializations, closely adapted to the spatial organization and functions of renal corpuscles, tubules and ducts (**8**.172, 176, 178). The large literature concerning renal angioarchitecture, haemodynamics and controlling mechanisms cannot be analysed here, nor can variation between species, or minor human variations be considered. For these admirable reviews exist by Trueta et al (1947), Fourman & Moffat (1971) and Moffat (1975), among others.

Renal vasculature may be studied at various levels, commencing with the principal and accessory *renal arteries*. Their primary patterns of branching and areas of distribution suggest the presence of *vascular segmentation*. From the primary stems branch *lobar*, *interlobar*, *arcuate* and *interlobular* arteries, *afferent* and *efferent glomerular arterioles* and cortical *intertubular capillary plexuses*; cortical venous radicles drain them and also the *vasa recta* and associated capillary plexuses of the medulla to the renal vein **8**.172, 176).



A single renal artery to each kidney (p. 737), is present in about 70% of individuals but they vary in their level of origin (the *right* often being superior) and in their calibre, obliquity and precise relations. (For a review of these features in almost 11 000 kidneys, see Merklin & Michels 1958.) In its extrarenal course (Schneider

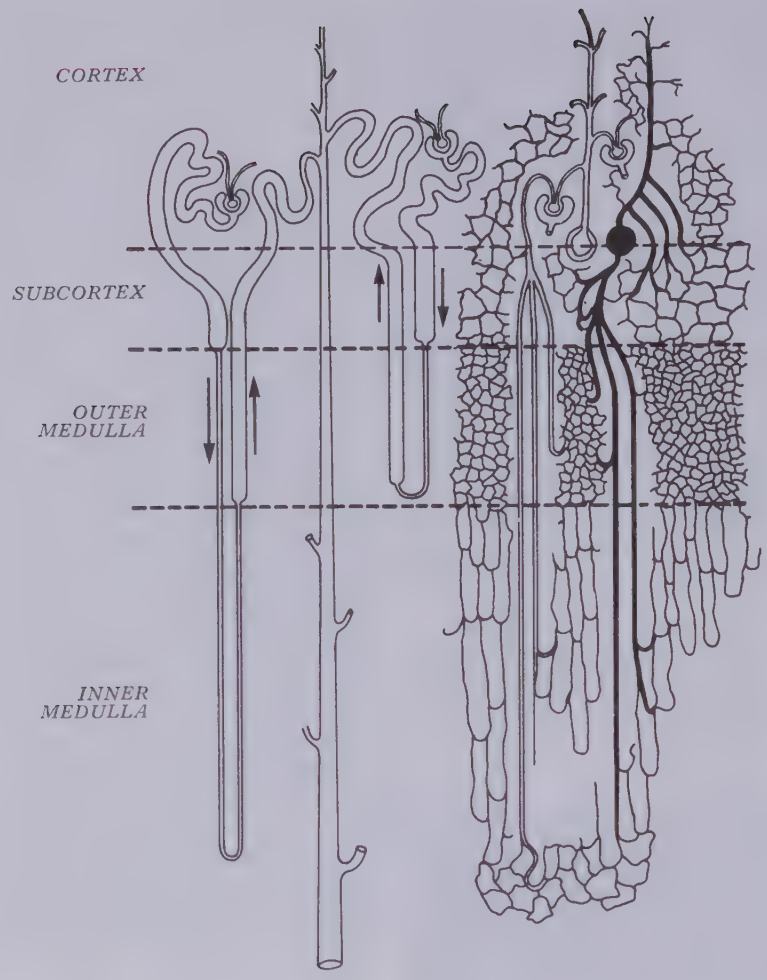
et al 1969) each renal artery gives off one or more inferior suprarenal arteries and branches which supply perinephric tissue, the renal capsule, pelvis and the proximal part of the ureter; near the renal hilum, each artery divides into an *anterior* and *posterior division*, the primary branches of which (*segmental arteries*) supply renal *vascular segments*. *Accessory renal arteries* are common (30% of individuals), usually arising from the aorta above or below the main renal artery and following it to the renal hilum. Higher or lower origins are not uncommon, an accessory artery or leash of arteries passing to the superior or inferior renal pole. They are regarded as persistent embryonic *lateral splanchnic* arteries. Accessory vessels to the inferior pole cross anterior to the ureter and may, by its obstruction, cause hydronephrosis. Rarely, accessory renal arteries arise from the coeliac or superior mesenteric arteries near the aortic bifurcation or from the common iliac arteries.

Renal vascular segmentation was originally recognized by John Hunter in 1794 but the first detailed account of the primary pattern was by Graves (1954, 1956a, b) from casts and radiograms of injected kidneys. He described five segments: (1) *apical*, occupying the anteromedial region of the superior pole, (2) *superior (anterior)*, including the rest of the superior pole and the central anterosuperior region, (3) *inferior*, encompassing the whole lower pole, (4) *middle (anterior)* between the anterior and inferior segments and (5) *posterior* including the whole posterior region between the apical and inferior segments. Graves' terminology has been adopted internationally and was used by some researchers (Smith 1963, Sykes 1963, 1964), but others have proposed more complex schemes, e.g. three posterior segments (Faller & Ungvary 1962); some have emphasized the great variability of the regions supplied by segmental arteries (Fine & Keen 1966). Whatever the divergences, it must be emphasized that vascular segments are supplied by virtual end-arteries. In contrast, larger *intrarenal veins* have no segmental organization and anastomose freely.



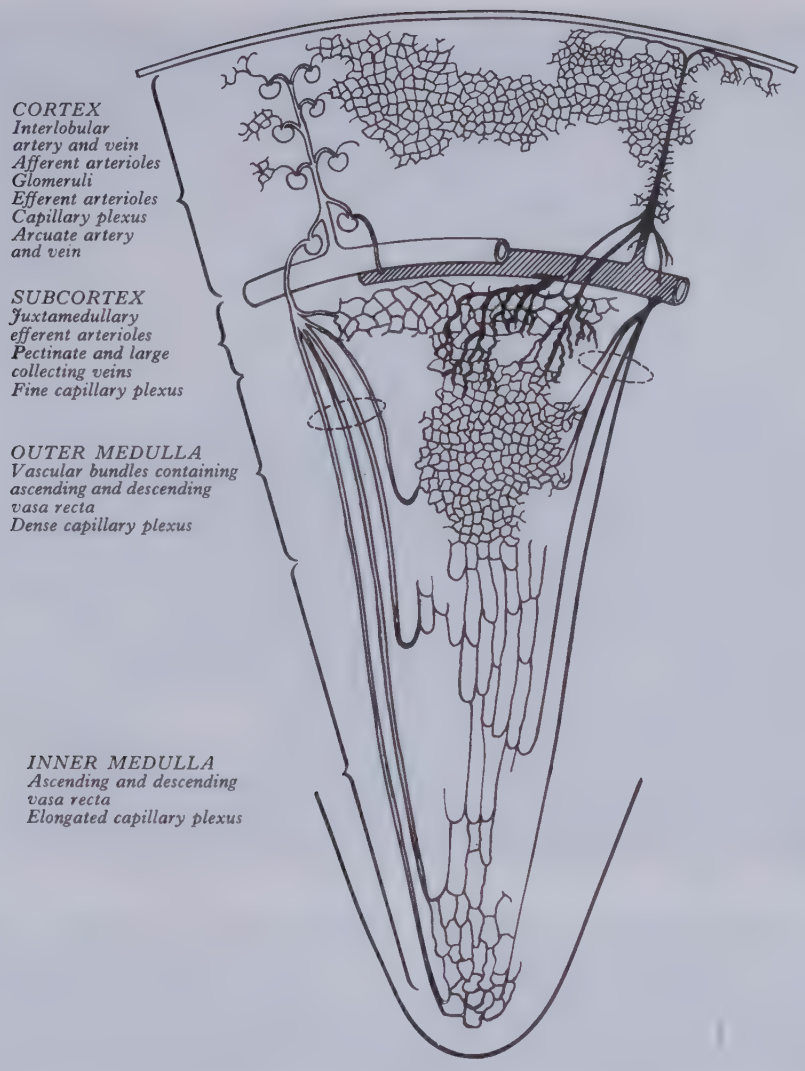
Brodel (1901) described a relatively avascular longitudinal zone (*the 'bloodless' line of Brodel*) along the convex renal border, proposed as the most suitable site for surgical incision. However, many vessels cross this zone, which is far from 'bloodless'; planned radial or intersegmental incisions are said to be preferable.

Initial branches of segmental arteries are *lobar*, usually one to each renal pyramid, but before entry they subdivide into two or three *interlobar arteries*, extending towards the cortex around each pyramid. At the junction of the cortex and medulla, interlobar arteries dichotomize into *arcuate arteries* which diverge at right angles; as they arch between cortex and medulla, each divides further and, from its branches, *interlobular arteries* diverge radially into the cortex. The terminations of adjacent arcuate arteries do not anastomose but end in the cortex as additional interlobular arteries. Though most interlobular arteries come from arcuate branches, some arise directly from arcuate or even terminal interlobar arteries (8.176B).

Interlobular arteries ascend towards the superficial cortex or may branch a few times en route (8.172C); some are more tortuous, recurving towards the medulla once or more before proceeding towards the renal surface. Some traverse the surface as *perforating arteries* (Hammersen & Staubesand 1961) to anastomose with the *capsular plexus* (also supplied from the *inferior suprarenal*, *renal* and *testicular* or *ovarian* arteries).

Afferent glomerular arterioles are mainly the lateral rami of interlobular arteries but a few arise from arcuate and interlobular arteries, when they vary their direction and angle of origin: deeper ones incline obliquely back towards the medulla, the intermediate pass out horizontally, while the more superficial approach the renal surface obliquely before ending in a glomerulus (8.176A,B).

From most glomeruli (excepting the juxtamedullary and a few at intermediate cortical levels) *efferent glomerular arterioles* soon divide to form a dense *peritubular capillary plexus* around the proximal and distal convoluted tubules. In the main renal cortical circulation there are thus *two* sets of *capillaries* in series, glomerular and peritubular, linked by efferent glomerular arterioles. From the venous ends of the peritubular plexuses fine radicles converge to join *interlobular veins*, one with each interlobular artery. Many interlobular veins commence beneath the fibrous renal capsule by convergence of several *stellate veins*, draining the most superficial zone of the renal cortex and so named from their surface appearance. Proceeding to the corticomedullary junction, interlobular veins also receive some ascending vasa recta (vide infra) and end in *arcuate veins* which accompany arcuate arteries but, unlike them, they anastomose with neighbouring veins. Arcuate veins drain into *interlobar veins*, which anastomose and converge to form the renal vein.



8.176A Diagram to illustrate the arrangement of the tubules (left) and blood vessels (right) in various structural zones of the kidney. Note the variations in the pattern of the tubules with either long or short medullary loops; tubules of intermediate length also occur. Compare the different structural and functional segments of the tubules which occur together in the cortical, subcortical and outer and inner medullary zones with their related vascular patterns. Arteries are black outlines; capillaries are single black lines; veins are full black. Compare with 8.176B. (From Fourman & Moffat 1971 with permission of the authors and Blackwell Scientific Publications.)

The vascular supply of the *renal medulla* is largely from efferent arterioles of juxtamedullary glomeruli, supplemented by some from more superficial glomeruli, and 'aglomerular' arterioles (probably from degenerated glomeruli). Efferent glomerular arterioles passing into the medulla are relatively long, wide vessels, contributing side branches to neighbouring capillary plexuses before entering the medulla, where each divides into 12–25 *descending vasa recta*; these, as their name suggests, run straight to varying depths in the renal medulla, contributing side branches to a radially elongated capillary plexus (8.176A) applied to the descending and ascending limbs of renal loops and to collecting ducts. The venous ends of capillaries converge to the *ascending vasa recta*, which drain into arcuate or interlobular veins. An essential feature of the vasa recta is that, particularly in outer medulla, both ascending and descending vessels are grouped into *vascular bundles*, within which the external aspects of both types are closely apposed, bringing them close to the limbs of renal loops and collecting ducts. As these bundles converge centrally into the renal medulla they contain fewer vessels, some terminating at successive levels in neighbouring capillary plexuses. This proximity of descending and ascending vessels with each other and adjacent ducts is the structural basis for the countercurrent exchange and multiplier phenomena previously mentioned (p. 1406, 8.172D, 177A,C).

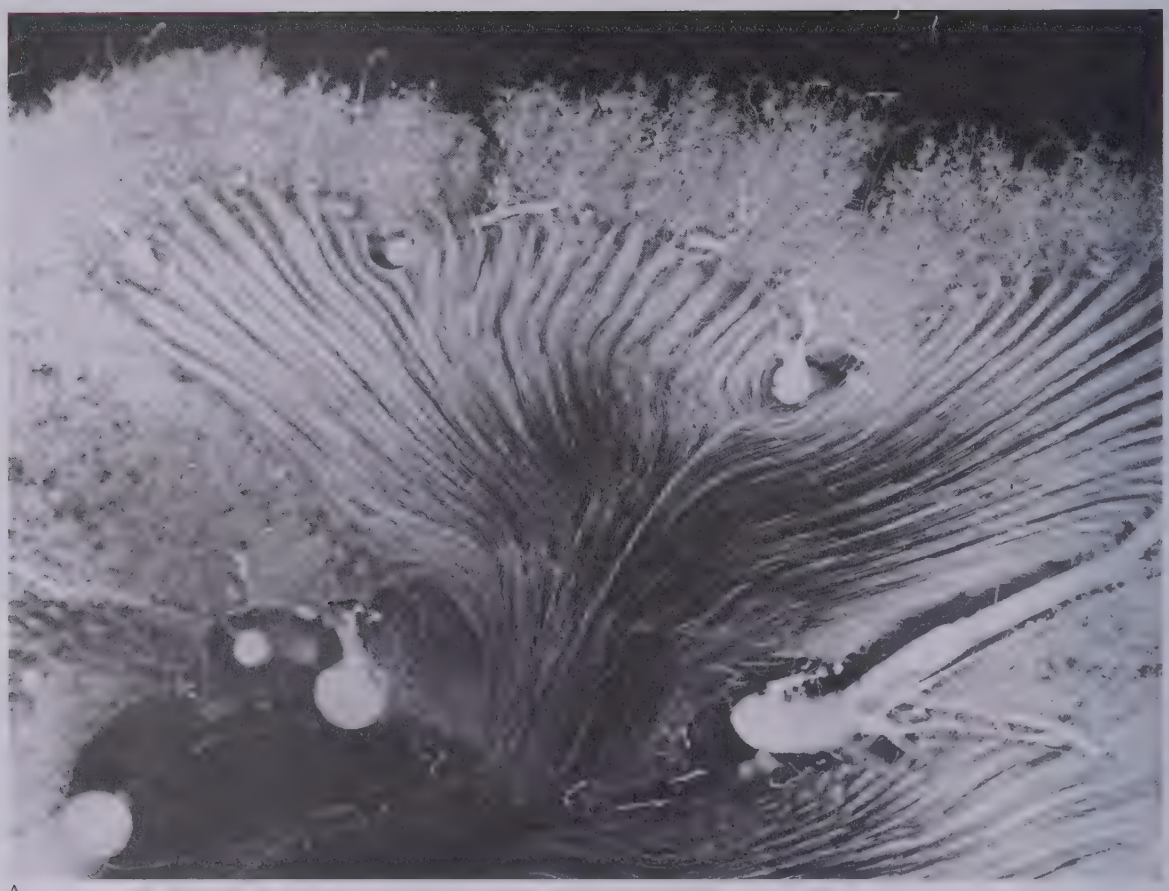
In *ultrastructure*, renal vessels show the regional features described elsewhere; renal, interlobar and arcuate arteries are typical 'large muscular arteries' (p. 686); the interlobular vessels are like 'small muscular arteries' and afferent glomerular vessels have typical arteriolar structure with a muscular coat two to three cells thick; this and the connective tissue components of the wall diminish near a glomerulus until a point 30–50 μm proximal to it where arteriolar cells begin to show modifications typical of the *juxtaglomerular apparatus* (p. 1406). The efferent arterioles from most cortical glomeruli have thicker walls and a narrower calibre than corresponding afferents. The peritubular and medullary capillaries possess a well-defined basal lamina and their endothelial cells have typically fenestrated cytoplasm (p. 689), as in ascending vasa recta; in contrast, the descending vasa recta have thicker, continuous endothelium. The structure of glomerular capillaries is considered above (p. 1409). For brief comments on the functional association between the regions of renal tubules and associated blood vessels see p. 1391 and Fourman & Moffat (1971). A detailed account of renal microvasculature has also recently been given for monkeys (Horacek et al 1986, 1987).

Renal innervation. The general sources of renal nerves are described on p. 1165. Direct nerve fibres from plexuses around arcuate arteries to innervate juxtamedullary efferent arterioles and vasa recta have been described (Munkacsi & Newstead 1971);

8.176B Diagram of the basic arrangements of the blood vessels in the mammalian kidney. Arteries are black outlines, capillaries are single black lines, veins are cross-hatched or full black. (From Fourman & Moffat 1971 with permission of the authors and Blackwell Scientific Publications.)

these might control blood flow between the cortex and medulla without affecting the glomerular circulation.

Lymph vessels are described on p. 855.

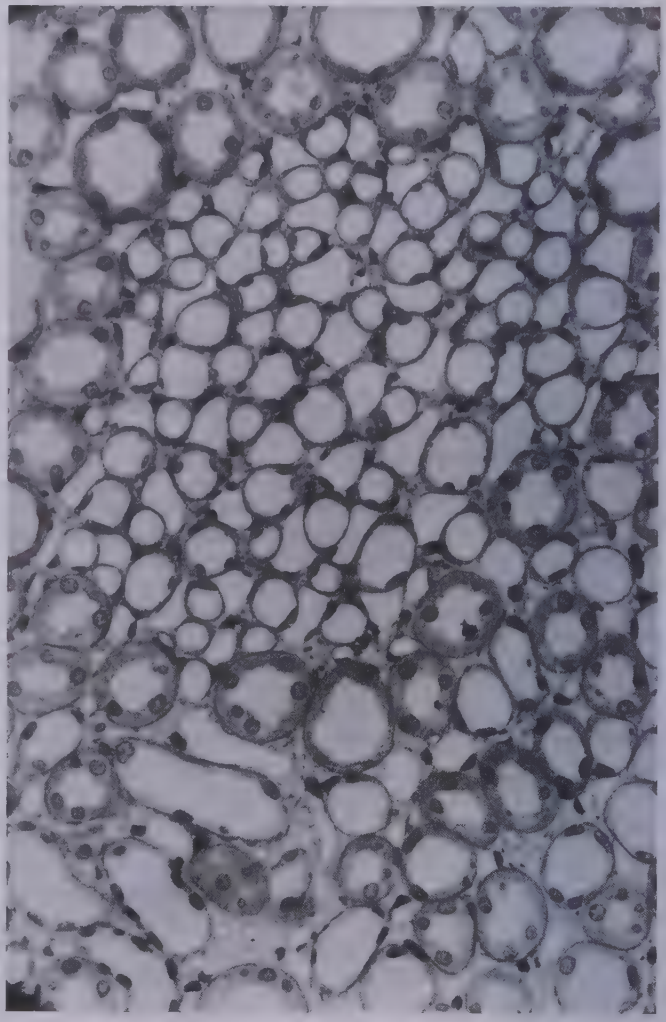


Renal anomalies. The early pelvic position of the kidneys (p. 250) may persist; they are then usually supplied from the common iliac arteries and the hila are anterior. Occasionally kidneys are connected by a transverse bridge of renal tissue, forming a 'horseshoe kidney', the commissure usually lying between the inferior poles and rarely the superior. The ureters curve anterior to the connection and may be here partially obstructed. A congenital absence or imperfect development of one kidney may be compensated by an enlargement of the opposite organ. Two kidneys may also occur on the same side. Single or multiple congenital renal cysts and widespread congenital polycystic disease may also be present.

The Upper Urinary Tract

This term is generally used as a collective name for the main urinary outflow conduits from the kidney (renal calices, renal pelvis and ureter), as distinct from the bladder and urethra, which constitute the *lower urinary tract*. This separation is of course arbitrary.

RENAL CALICES AND PELVIS



Within the renal sinus the proximal parts of the urinary tract consist of the minor and major calices and the renal pelvis. The minor calices are attached to the renal parenchyma around the bases of a variable number (7–14) of conical renal papillae which form the tips of the renal pyramids (p. 1400). The renal capsule covers the external surface of the kidney and continues through the hilus to line the sinus (p. 1399) and fuse with the adventitial coverings of the minor calices. Each minor calix is a trumpet-shaped structure which surrounds either a single papilla or, more rarely, groups of two or three papillae (**8**.169B, 172A,B). The minor calices unite with their neighbours to form two or possibly three larger chambers, the major calices. The latter usually fuse with each other to form a single funnel-shaped renal pelvis, which tapers as it passes inferomedially, traversing the renal hilus to become continuous with the ureter (**8**.169A,B, 172A). Normally it is not possible to determine precisely the position where the renal pelvis ceases and the ureter begins. Consequently the precision implied by the phrase 'pelviureteric junction' to describe this area is anatomically invalid and the term 'pelviureteric region' is preferable. This region is usually extrahilar in location and normally lies adjacent to the lower part of the medial border of the kidney. In some individuals, however, the entire renal pelvis has been found to lie

inside the sinus of the kidney and, as a consequence, the pelviureteric region is situated either in the vicinity of the renal hilus or completely within the renal sinus.

Structure of the Renal Calices and Pelvis

The wall of the proximal part of the urinary tract is composed of three histological layers, namely a connective tissue adventitia (fibrous coat), a coat of smooth muscle and an inner mucosa. (The mucosal lining of the renal calices and pelvis is identical in structure to that of the ureter (p. 1414) and will not be considered further here.) The adventitia forms the outermost layer and consists of loose fibro-elastic connective tissue which merges with retroperitoneal areolar tissue. Proximally the coat fuses with the fibrous capsule of the kidney lining the renal sinus. The muscle coat of the renal calices and pelvis is composed of two morphologically and histochemically distinct types of smooth muscle cell (Dixon & Gosling 1982). One type of muscle cell is identical to that described for the ureter and can be traced proximally through the pelviureteric region and renal pelvis as far as the minor calices. The other type possesses a number of unusual structural features; these cells form the muscle coat of each minor calix and continue into the major calices and pelvis where they form a distinct inner layer. The cells also form a thin sheet of muscle which covers each minor caliceal fornix and extends across the renal parenchyma between the attachments of neighbouring minor calices, thereby linking each minor calix to its neighbours. Further out in the wall of each minor calix, the muscle cells are arranged longitudinally and form a discrete layer confined to the inner aspect of the muscle coat, the remainder of which is formed of bundles of typical smooth muscle. Such a configuration continues throughout the wall of the major calices and renal pelvis but ceases in the pelviureteric region so that the proximal ureter is devoid of a morphologically distinct inner layer. Individually, these muscle cells are separated from one another by extensive amounts of connective tissue and differ histochemically from typical ureteric nonstriated muscle. In addition the muscle cells possess unusual fine structural features when examined by means of the electron microscope (Dixon & Gosling 1982). The functional significance of these structural features is considered on p. 1415.

The Ureters

Ureters are muscular tubes whose peristaltic contractions convey urine from the kidneys to the urinary bladder. Each measures 25–30 cm in length and is thick-walled, narrow and continuous superiorly with the funnel-shaped renal pelvis (p. 1411); a slight constriction may mark this junction (**8.172**A). Each descends slightly medially anterior to psoas major, entering the pelvic cavity to open into the base of the urinary bladder. Its surface projection is an almost vertical line from a point on the transpyloric plane, 5 cm from the midline to the pubic tubercle. Its diameter is about 3 mm but slightly less at its junction with the renal pelvis,

8.178 Resin corrosion cast of human kidneys prepared by D H Tompsett of the Royal College of Surgeons of England. Ureter, pelvis and calices are yellow; aorta, renal arteries and their branches are red. See text for a detailed description of the renal blood vessels.

the brim of the lesser pelvis near the medial border of psoas major, and where it traverses the vesical (bladder) wall (its narrowest part). The *renal pelvis* has already been described (p. 1411).

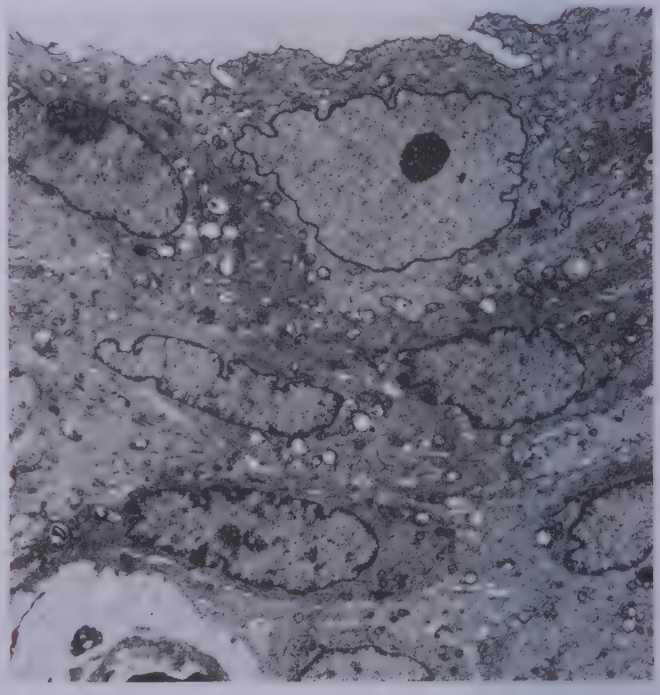
The ureter's *abdominal part* descends posterior to the peritoneum on the medial part of psoas major, which separates it from the tips of the lumbar transverse processes (**8**.169B). Anterior to the muscle it crosses in front of the genitofemoral nerve and is obliquely crossed by the gonadal vessels. It enters the lesser pelvis anterior to either the end of the common or the beginning of the external iliac vessels.

At its origin the *right* ureter is usually overlapped by the descending part of the duodenum; it descends lateral to the inferior vena cava, crossed anteriorly by the right colic and ileocolic vessels; near the superior aperture of the lesser pelvis it passes behind the lower part of the mesentery and terminal ileum. The *left ureter*, crossed by the left colic vessels, passes posterior to the sigmoid colon and its mesentery in the posterior wall of the intersigmoid recess. At operation, the abdominal part of the left ureter is hence easier to expose than the right.

The *pelvic part*, about the same length as the abdominal, lies in both sexes in extraperitoneal areolar tissue. At first it descends posterolaterally on the lateral wall of the lesser pelvis along the anterior border of the greater sciatic notch. Opposite the ischial spine it turns anteromedially into fibrous adipose tissue above the levator ani to reach the base of the bladder. On the pelvic wall it is anterior to the internal iliac artery and the beginning of its anterior trunk, posterior to which are the internal iliac vein, lumbosacral nerve and sacro-iliac joint. Laterally it lies on the fascia of obturator internus. It progressively crosses medial to the umbilical artery, the obturator nerve, artery and vein, the inferior vesical and middle rectal arteries. *In males*, in the anteromedial part of its descent, the pelvic ureter is crossed anterosuperiorly, from lateral to medial, by the ductus deferens. Then it passes in front of and slightly above the upper pole of the seminal vesicle to traverse the bladder wall obliquely before opening at the ipsilateral trigonal angle (**8**.184). Its terminal part is surrounded by tributaries of the vesical veins. *In females*, the pelvic part at first has the same relations as in males, but anterior to the internal iliac artery it is immediately behind the ovary, forming the posterior boundary of the ovarian fossa (p. 1435). In the anteromedial part of its course to the bladder it is related to the uterine artery, uterine cervix and vaginal fornices. It is in extraperitoneal connective tissue in the inferomedial part of the broad ligament of the uterus (parametrium, p. 1445); here the uterine artery is anterosuperior to the ureter for 2.5 cm and then crosses to its medial side to ascend alongside the uterus. The ureter turns forwards slightly above the lateral vaginal fornix and is here generally 2 cm lateral to the supravaginal uterine cervix (p. 1441). It then inclines medially to reach the bladder, with a variable relation to the front of the vagina. As the uterus is commonly deviated to one side, one ureter may be more extensively apposed to the vagina, usually the left, which may cross the midline; the reverse may occur and sometimes one ureter is not anterior to the vagina, a much longer part of the other then being in front of it.

In the distended bladder, in both sexes, the ureteric openings are about 5 cm apart, somewhat less in the empty viscus. In its oblique course through the vesical wall, the ureter is compressed and flattened as the bladder distends, perhaps preventing regurgitation, though ureteric peristalsis is also a factor.

Radiography



The ureter, renal pelvis and calices are easily demonstrated in the living by radiography (1) after intravenous injection of radiopaque substances excreted in urine (descending or *excretion pyelography*), or (2) after the introduction of similar solutions into the ureter by catheterization through an operating cystoscope (ascending or *retrograde pyelography*), the results being *pyelograms* (**8**.169B). Normal cupping of the minor calices by projecting renal papillae is clinically important; it may be obliterated by conditions such as hydronephrosis, associated with chronic distension of the ureter and renal pelvis due to urinary back pressure.

STRUCTURE OF THE URETERS

The wall of the human ureter is composed of three histological layers, namely an external adventitia, a non-striated muscle layer and an inner mucosal layer. The latter consists of two components: the transitional epithelium (or urothelium) and the underlying connective tissue (the lamina propria). The ureteric *adventitia* contains elongated fibrocytes and interlacing bundles of collagen and elastic fibrils, together with numerous blood vessels, lymphatics, nerves and occasional fat cells. The majority of the adventitial blood vessels and the connective tissue elements are orientated parallel to the long axis of the ureter.

8.179 Transverse section through the lower third of a human ureter. Note the great thickness of muscular wall. Stained with haematoxylin and eosin. Magnification × 30.

8.180 Transmission electron micrograph showing the transitional epithelium lining the ureter (rat). Prepared and photographed by Susan Smith, Department of Anatomy, Guy's Hospital Medical School, London. Magnification × 4000.

Throughout its length, the *muscle coat* of the ureter is fairly uniform in thickness and in cross-section measures about 750–800 μm in width. The muscle bundles which constitute this coat are frequently separated from one another by relatively large amounts of connective tissue. Branches which interconnect muscle bundles are common and result in frequent interchange of muscle fibres between adjacent bundles. Due to this extensive branching individual muscle bundles do not spiral around the ureter (Gosling 1970). Hence, the ureteric muscle coat consists of a complex meshwork of interweaving and interconnecting smooth muscle bundles. In addition, unlike the gut, the muscle bundles are so arranged that morphologically distinct longitudinal and circular layers cannot be distinguished. However, in the upper part of the ureter, the inner muscle bundles tend to lie longitudinally while those on the outer aspect have a circular or oblique orientation. In its middle and lower parts, additional outer longitudinally-orientated fibres can also be discerned. As the ureterovesical junction is approached, the muscle coat consists predominantly of longitudinally-orientated muscle bundles. However, there are distinct differences between ureteric and vesical muscles (Gilpin & Gosling 1983). Ureteric muscle bundles are composed of closely-packed spindle-shaped cells which are approximately 300–400 μm in length and 4–7 μm at their widest diameter. Each non-striated muscle cell is surrounded by a trilaminar plasma membrane on the outer aspect of which is a layer of amorphous electron-dense basal lamina material approximately 40 nm in thickness. The latter is separated from the underlying plasma membrane by an electron-lucent zone about 4 nm in width (the lamina lucida).

Within any one muscle bundle the plasma membranes of adjacent cells are frequently observed in mutual opposition. The most common form of junction between neighbouring ureteric muscle cells is the 'region of close approach' at which the apposed plasma membranes converge to within 10–20 nm of each other. Basal lamina material is reflected from one cell to the other at the margins of the junction and does not extend into the narrow intercellular cleft. However neither the plasma membranes nor the adjacent subsarcolemmal cytoplasm show any form of specialization. Intercellular junctions of this type often occur between the tips of narrow cytoplasmic protrusions from adjacent non-striated muscle cells. Another common type of association between ureteric non-striated muscle cells is the so-called 'peg and socket' junction. This type consists of an elongated or bulbous projection from one cell which fits snugly into a depression in an adjacent cell. At the interdigitation, basal lamina material is absent from the 10 nm gap separating the membranes of the two adjacent muscle cells. Occasionally, the apposing cell membranes are more closely related in the narrowed 'stalk' of the projection. It has been suggested that these interdigitations provide a mechanical linkage between neighbouring cells. Alternatively, they may represent a special type of 'close approach' and permit myogenic conduction.

The *mucosa* of the ureter consists of an epithelium (the urothelium) on the external aspect of which is a layer of subepithelial fibro-elastic connective tissue (the lamina propria). The latter varies in thickness from 350–700 μm and consists mainly of bundles of collagen and elastic fibres, fibrocytes and small blood vessels. Many of the latter are accompanied by bundles of non-myelinated nerve fibres. Occasional lymphocytes may be present in the lamina propria but their aggregation into definitive lymph nodules is rare. The urothelium is usually extensively folded, giving the ureteric lumen a stellate outline. Although the urothelium appears to consist of four to five separate layers of cells, it has been shown that all cells reach down to the base and as a consequence the urothelium is by definition a pseudostratified epithelium (Martin 1973).

The surface cells of the urothelium are large and polyhedral, the underlying intermediate cells are smaller and spindle-shaped, and the basal cells are mainly cuboidal in form. The luminal cells of the urothelium are characterized by the presence of a specialized apical membrane (Hicks 1965, Staehelin et al 1972) and are attached to one another near the ureteric lumen by a junctional complex composed of the three typical components (p. 25) of zonula occludens, zonula adherens and macula adherens. The lateral cell membranes of the luminal cells are often extensively interdigitated, although such infoldings presumably flatten out to enable the urothelium to accommodate distension of the ureteric lumen.

Vessels and Nerves

The arteries supplying the ureter (Daniel & Shackman 1952) are derived from the renal, abdominal aortic, testicular (or ovarian), common iliac, internal iliac, vesical and uterine vessels, their branches supplying the different parts of the ureter in its course and being subject to much variation. The longitudinal anastomosis between these branches on the wall of the ureter is good. The branches from the inferior vesical artery (p. 778) are constant in their occurrence and supply the lower part of the ureter as well as a large part of the trigone of the bladder.

The lymph vessels of the ureter are described on p. 855.

The ureteric nerves (pp. 1165, 1166) are derived from the renal, aortic and superior and inferior hypogastric plexuses; through these plexuses fibres are derived from the lower three thoracic and first lumbar and the second to fourth sacral segments of the spinal cord. In the adventitia the nerves consist of relatively large axon bundles which form an irregular plexus, from which numerous smaller branches penetrate the ureteric muscle coat. Some of the adventitial nerves accompany the blood vessels and branch with them as they extend into the muscle layer. Others are unrelated to the vascular supply and lie free in the adventitial connective tissue around the circumference of the ureter. Autonomic ganglion cells occur only at the extreme lower end of the ureter; such cells are absent from all other regions of the ureter. In the muscle coat of the upper urinary tract, nerve fibres can be identified both between and within the non-striated muscle bundles. However, regional differences in the density of these nerves result in a gradual increase in innervation from the renal pelvis and upper ureter (which has a sparse distribution of autonomic nerves) to a maximum in the juxtavesical segment. The non-striated muscle of the upper urinary tract is supplied with at least three different types of autonomic nerve. Some nerves are rich in acetylcholinesterase and the presence of this enzyme has been taken to be indirect evidence in support of a cholinergic innervation to ureteric non-striated muscle. Noradrenergic nerves also occur in the ureteric muscle coat where they are evident as finely beaded fibres, some of which run parallel to the muscle bundles. Others accompany the vascular supply and their branches occasionally penetrate the muscle bundles and course amongst the smooth muscle cells. A third type of nerve, characterized by its content of substance P, has been demonstrated in the muscle coat of the ureter (Alm et al 1978). The distribution of this so-called peptidergic innervation within the ureter appears to be similar to the other types of autonomic nerve. Other neurotransmitters also exist (see Burnstock 1986), so the control mechanisms are likely to be complex (see also p. 889). Using the electron microscope, occasional axon bundles, some containing up to 50 unmyelinated axons, can be seen in the connective tissue separating the ureteric muscle bundles and, very rarely, varicose vesicle-packed terminal axons run between individual smooth muscle cells. However, neuromuscular relationships suggestive of synaptic regions are exceedingly sparse by comparison with many other autonomically innervated smooth muscle systems (e.g. the urinary bladder and ductus deferens).

The functional significance of these different types of autonomic nerve in relation to ureteric non-striated muscle activity is not fully understood, particularly since nerves are not essential for the initiation and propagation of ureteric contraction waves (see p. 1416). However, the contractile response of the ureter has been shown to be modified by the use in vivo of exogenous transmitter substances. Thus, while nerves are not essential for the normal occurrence of ureteric peristaltic activity, they may exert a modulating influence upon the contractility of ureteric non-striated muscle cells.

A branching plexus of fine nerve fibres occurs within the lamina propria and extends from the inner aspect of the muscle coat towards the base of the urothelium. These nerves are acetylcholinesterase positive and, while some form perivascular plexuses, others lie in isolation from the vascular supply. A

similar distribution of noradrenergic and peptidergic nerves has been observed throughout the lamina propria. The functional significance of these nerves, which are not related to blood vessels, remains unclear. It seems unlikely that the urothelium receives a direct efferent innervation, particularly when most of the nerve fibres are more than 100 μm away from the basal urothelial cells and thus beyond the accepted range for effective synaptic transmission. It seems probable therefore that some of the nerves in the lamina propria are sensory in function.

Ureteric Peristalsis

Under normal conditions contraction waves originate in the proximal part of the upper urinary tract and propagate in an anterograde direction towards the bladder. However, the mechanism involved in the initiation of these contractile events has been the subject of much controversy in the past. One theory proposed that contraction of the non-striated muscle of the calices and pelvis was stimulated by stretching forces produced by the luminal contents. However, there is now a considerable body of experimental evidence to show that the urinary tract possesses spontaneously active regions which initiate the peristaltic activity of the ureter and exercise a controlling influence on ureteric contraction (Constantinou & Djurhuus 1981). From a morphological viewpoint the unusual non-striated muscle cells which occur in the wall of the proximal parts of the upper urinary tract (p. 1415) and which are structurally distinct from those elsewhere, may act collectively as one or more pacemaker sites. Since each minor calix possesses these cells (and is linked across the renal parenchyma to other calices by similar cells), the number of pacemaker sites within a given kidney will be related to the number of minor calices. It seems probable that the normal sequence of events begins with the initiation of a contraction wave at one (or possibly more) of the several minor caliceal pacemaker sites. Once initiated, the contraction is propagated through the wall of the adjacent major calix and activates the non-striated muscle of the renal pelvis. To what extent the inner layer of cells acts as pacemaker (or as a preferential conduction pathway) remains to be determined. The proximal pacemaker site for successive contractions may change from one minor calix to another, although it has been shown that a single minor calix can initiate several successive contraction waves. Functionally, the proximal location of these pacemaker sites ensures that, once initiated, contraction waves are propagated away from the kidney, thereby avoiding undesirable pressure rises directed against the renal parenchyma. In addition, since several potential pacemaker sites exist, the initiation of contraction waves is unimpaired by partial nephrectomy; the minor calices spared by the resection remain in situ to continue their pacemaking function.

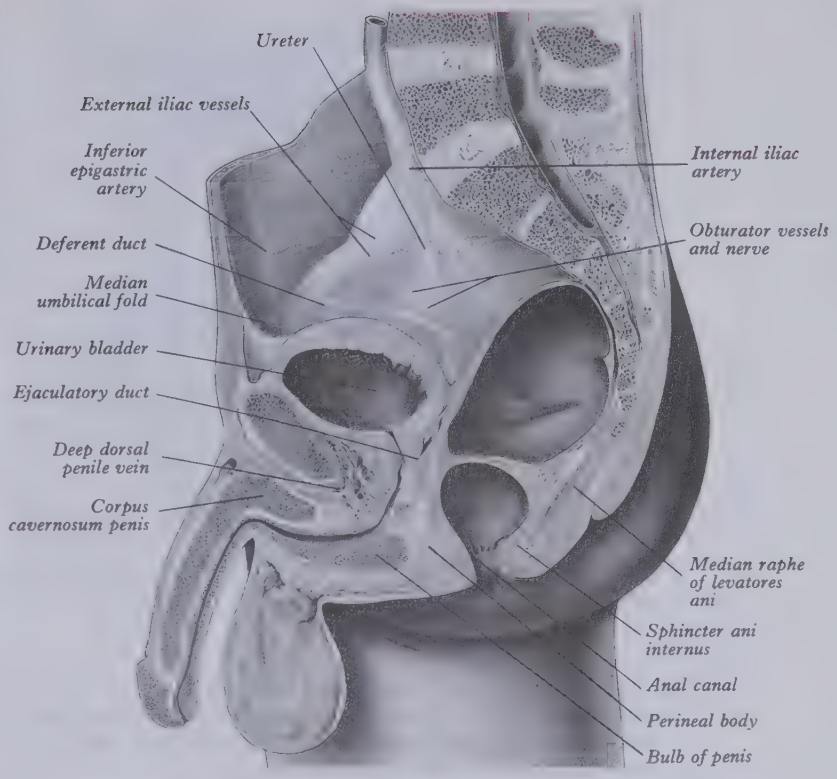
Concerning the means by which contractions are propagated across the renal pelvis and along the ureter, considerable experimental evidence indicates that autonomic nerves do not play a major part in the propagation of upper urinary tract peristalsis. It seems more likely that autonomic nerves may have only a modulatory role on the contractile events occurring in the musculature of the upper urinary tract. The most likely mechanism to account for impulse propagation is that of myogenic conduction resulting from electrotonic coupling of one muscle cell to its immediate neighbours. Regions of close approach are extremely numerous between ureteric non-striated muscle cells and also between both types of muscle cell in the renal pelvis and calices. Thus in the upper urinary tract this type of intercellular junction may be responsible for the conduction of excitation from one myocyte to the next.

To conclude, contraction waves arising from the upper end of the urinary tract are thought to be propagated from muscle cell to muscle cell by means of intercellular junctions. This process is essentially a property of non-striated muscle and does not require the direct involvement of autonomic nerves. The direction of the propagated contractile wave is normally from the renal calices and pelvis towards the bladder, as dictated by the pacemaker mechanism in these proximal regions. However, since electrotonic excitation can spread from one muscle cell to another in either direction, retrograde peristalsis can also occur.

Applied Anatomy

As in the case of the gut (p. 1347), excessive ureteric distension or spasm of its muscle provokes severe pain (renal colic), e.g. by a stone (calculus) causing incomplete and intermittent obstruction, particularly if it is gradually forced down by the muscle spasm. The pain, spasmodic and agonizing, is referred to cutaneous areas innervated from spinal segments which supply the ureter, mainly T11–L2 (p. 1168). It shoots down and forwards from the loin to the groin and scrotum or labium majus and may extend into the proximal anterior aspect of the thigh by projection to the genitofemoral nerve (L1,2); the cremaster (which has the same innervation) may reflexly retract the testis. A ureteric stone is liable to impact at one of the ureteric constrictions, namely its cranial end, where it crosses the brim of lesser pelvis or as it passes through the vesical wall; radiologically it would appear near the tip of the second lumbar transverse process, overlying the sacroiliac joint, or slightly medial to the ischial spine. Sometimes the ureter is duplicated on one or both sides even as far as the bladder; separate vesical openings are rare in such cases.

PELVIC VISCERA



The Urinary Bladder

The urinary bladder (**8**.181), is solely a reservoir and varies in size, shape, position and relations, according to its content and the state of neighbouring viscera. When empty it is entirely in the lesser pelvis but as it distends it expands anterosuperiorly into the abdominal cavity. When empty, it is somewhat tetrahedral and has a fundus, neck, apex, a superior and two inferolateral surfaces. The *fundus* or *base* is triangular and postero-inferior. In females (**8**.183) it is closely related to the anterior vaginal wall, in males to the rectum but its upper part is separated from the rectum by the rectovesical pouch and below that by the seminal vesicles and deferent ducts (**8**.182). In a triangular area between the deferent ducts, the bladder and rectum are separated only by rectovesical fascia (p. 1433); its inferior part may be obliterated by approximation of the deferent ducts above the prostate. Although the vesical fundus should be, by definition, the lowest region, the *neck* is in fact lowest and also the most fixed; it is 3–4 cm behind lower part of the symphysis pubis (i.e. a little above the plane of the inferior aperture of the lesser pelvis). It is pierced by the internal urethral orifice and alters little in position with varying conditions of the bladder and rectum. There is no special vesical constriction at its neck. In males the neck rests on its wall and is in direct continuity with, the base of the prostate; in females it is related to the pelvic fascia which surrounds the upper urethra. The vesical *apex* in both sexes faces towards the upper part of the symphysis pubis; from it the median umbilical ligament (urachus, p. 1417) ascends behind the anterior abdominal wall to the umbilicus, the peritoneum over it being the median umbilical fold. The triangular *superior surface* is bounded by lateral borders from the apex to the ureteric entrances and by a posterior border joining them. In males the superior surface is completely covered by peritoneum, extending slightly on to the base and continued posteriorly into the rectovesical pouch, laterally into the paravesical fossae and anteriorly into the median umbilical fold. It is in contact with the sigmoid colon and the terminal coils of the ileum. In females the superior surface is also largely covered by peritoneum but posteriorly this is reflected to the uterus at the level of the internal os (i.e. the junction of the uterine body and cervix), forming the vesico-uterine pouch. The posterior part of the superior

surface, devoid of peritoneum, is separated from the supravaginal cervix by fibro-areolar tissue. Each *inferolateral surface* in males is separated anteriorly from the pubis and puboprostatic ligaments by an adipose retropubic pad and posteriorly by fascia from levator ani and obturator internus. In females the relations are similar, but the puboprostatic are replaced by pubovesical ligaments. The inferolateral surfaces are not covered by peritoneum.

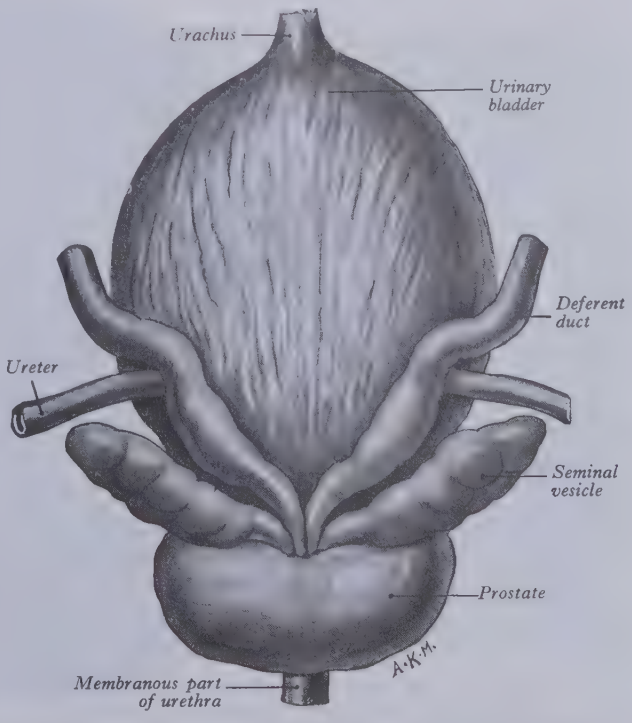
As the bladder fills it becomes ovoid. In front it displaces the parietal peritoneum from the suprapubic region of the abdominal wall, so that the surfaces become anterior and rest against it without intervening peritoneum for a distance above the symphysis pubis varying with the degree of distension and commonly about 5 cm; in excessive distension the bladder may reach the umbilicus or beyond. Thus a full bladder may be approached surgically through the anterior abdominal wall above the symphysis pubis without traversing the peritoneum. The full bladder's apex points up and forwards above the attachment of the median umbilical ligament, so that the peritoneum forms a supravesical recess of varying depth between the apex and the anterior abdominal wall; this recess often contains coils of small intestine.

At birth (**8**.183), the bladder is relatively higher than in the adult, the internal urethral orifice being level with the *upper* symphysial border; the bladder is abdominal rather than pelvic, extending about two-thirds towards the umbilicus. It progressively descends, reaching the adult position shortly after puberty.

8.181 Median sagittal section to show male internal and external genitalia, bladder etc. A number of structures (e.g. obturator vessels, ureter) are only faintly visible through the overlying peritoneum.

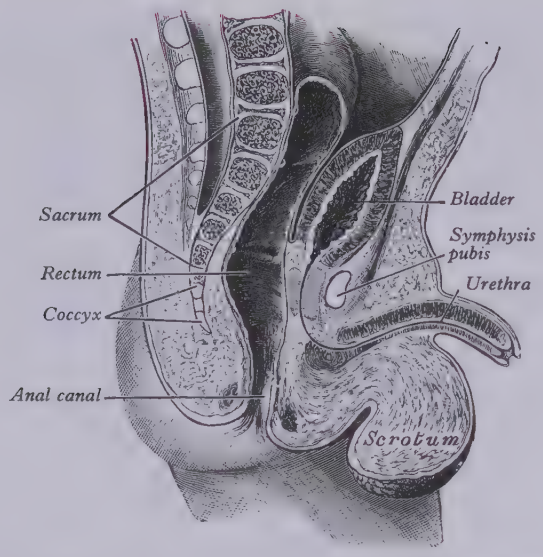
THE LIGAMENTS OF THE BLADDER

In both sexes stout bands of fibromuscular tissue extend from the bladder neck to the inferior aspect of the pubic bones. These structures are the pubovesical ligaments and constitute the superior extensions of the pubo-urethral ligaments in the female or the puboprostatic ligaments in the male. The two pubovesical ligaments lie one on each side of the median plane, leaving a midline hiatus through which pass numerous small veins. In addition to the pubovesical ligaments a number of other so-called ligaments have been described in relation to the base of the urinary bladder (Zacharin 1972). These are formed by condensation of connective tissue around neurovascular structures and as such do not merit the distinction of having specific names assigned to them.



The apex of the bladder is joined to the umbilicus by the remains of the urachus, which forms the median umbilical ligament. The lumen of the lower part of the urachus may persist throughout life and communicate with the cavity of the bladder (Begg 1930). From the superior surface of the bladder the peritoneum is carried off in a series of folds which are termed the 'false' ligaments of the bladder. Anteriorly there are three folds: the median umbilical fold over the median umbilical ligament and two medial umbilical folds over the obliterated umbilical arteries (**8**.109). The reflexions of the peritoneum from the bladder to the side walls of the pelvis form the lateral false ligaments while the sacrogenital folds (p. 1338) constitute the posterior false ligaments.

THE VESICAL INTERIOR



The vesical mucosa (**8**.185, 186), attached only loosely to subjacent muscle for the most part, folds when the bladder empties, the folds being effaced as it fills. Over the *trigone* (**8**.184), immediately above and behind the internal urethral orifice, it is adherent to the subjacent muscle layer and always smooth. The trigone's anteroinferior angle is formed by the internal urethral orifice, its posterolateral angles by the ureteric orifices. The superior trigonal boundary is a slightly curved *interureteric crest*, connecting the two ureteric orifices and produced by the continuation into the vesical wall of the ureteric internal longitudinal muscle. (For details of trigonal musculature, consult Uhlenhuth et al 1952, Woodburne 1965, 1968.) Laterally this ridge extends beyond the ureteric openings as *ureteric folds*, produced by the terminal parts of the ureters running obliquely through the bladder wall. At cystoscopy the interureteric crest appears as a pale band and is a guide to the ureteric orifices in catheterization.

The ureteric orifices, placed at the posterolateral trigonal angles (**8**.184), are usually slit-like. In empty bladders they are about 2.5 cm apart and about the same from the internal urethral orifice; in distension these measurements may be doubled.

The internal urethral orifice, at the trigonal apex, the lowest part of the bladder, is usually somewhat crescentic in

8.182 Posterosuperior aspect of the male internal urogenital organs.

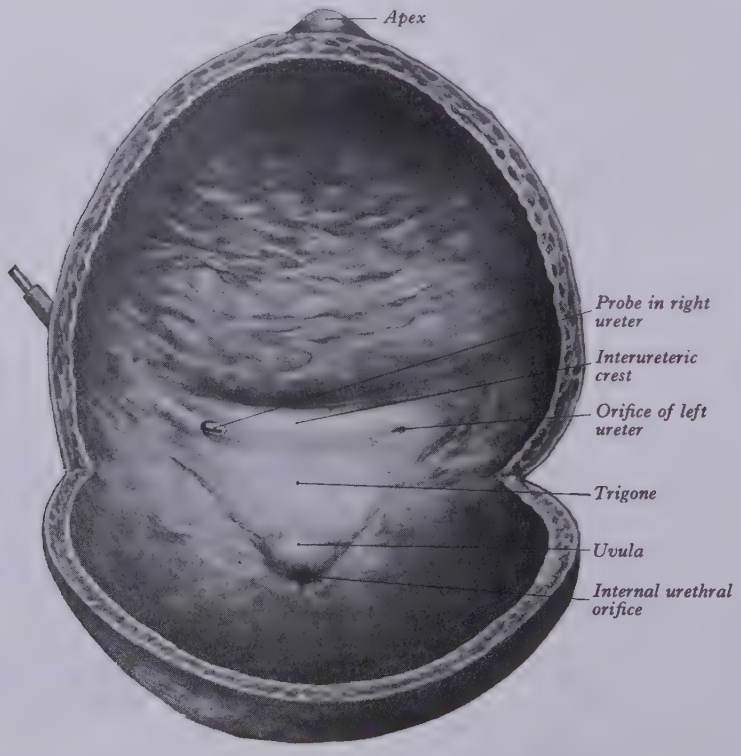
8.183 Sagittal section of the pelvis of a newborn male infant. Note the abdominal position of the urinary bladder.

section; in adult males, particularly past middle age, immediately behind it is a slight elevation caused by the median prostatic lobe, the *uvula* of the bladder.

Bladder Capacity

Mean vesical capacity in male adults varies from 120–320 ml (Thompson 1919); micturition commonly occurs at about 280 ml. Filling to about 500 ml may be tolerated but beyond this pain is caused by tension in the wall, leading to reflex contractions and the urgent desire to micturate. Pain is referred to the cutaneous areas supplied by spinal segments supplying the bladder (T11–L2, S2–4), including the lower anterior abdominal wall, perineum and penis.

BLADDER STRUCTURE



Histologically the wall of the urinary bladder consists of three layers (8.185): an outer adventitial layer of connective tissue which in some regions possesses a serosal covering of peritoneum, a non-striated muscle coat (the detrusor muscle) and an inner layer of mucous membrane which lines the interior of the bladder.

The Serous Layer

This is restricted to the superior and in males part of the posterior surfaces of the bladder, the rest being devoid of peritoneum (p. 1417). It consists of mesothelium and underlying connective tissue as elsewhere in the peritoneum.

The Muscular Layer

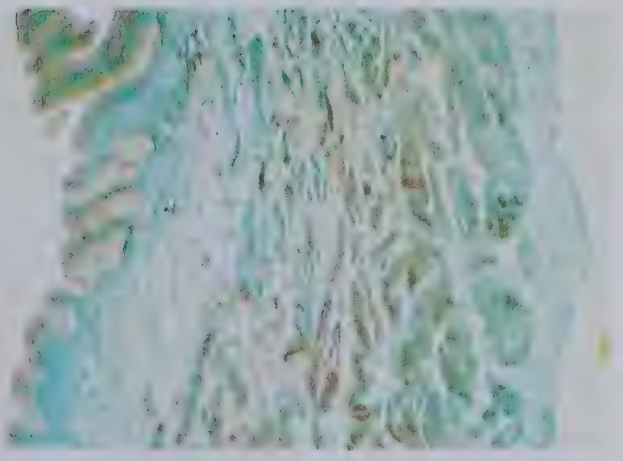
This is composed of relatively large (in diameter) interlacing bundles of non-striated muscle cells arranged as a complex meshwork. Three ill-defined layers are present and arranged in such a way that longidutinally orientated muscle bundles predominate on the inner and outer aspects of a substantial middle circular layer. Posteriorly some of the outer longitudinal bundles pass over the bladder base and fuse with the capsule of the prostate or with the anterior vaginal wall. Other bundles are carried on to the anterior aspect of the rectum and named the rectovesical muscle. Anteriorly some of the outer longitudinal bundles continue into the pubovesical ligaments and contribute to the muscular component of these structures. As in the muscle coat of the ureter, exchange of fibres between adjacent muscle bundles within the bladder wall frequently occurs so that from a functional viewpoint, the detrusor comprises a single unit of interlacing smooth muscle. An electron-dense basal lamina surrounds each bladder non-striated myocyte except at certain junctional regions. The most frequently observed type of junction between muscle cells is the region of close approach at which an intercellular separation of 10–20 nm occurs over distances occasionally in excess of 1 μm in length. Junctions of the 'peg and socket' and 'intermediate' types are observed occasionally but gap junctions (nexuses) have not been reported in the detrusor. Since electrotonic spread excitation occurs in the non-striated muscle of the bladder wall, the

8.184 Anterior aspect of the interior of the urinary bladder.

regions of close approach may represent the morphological feature which enables this physiological event to take place, although it is more likely that gap junctions exist, albeit few of them. Within muscle bundles, the smooth muscle cells are closely packed together such that the basal lamina of one cell very often becomes confluent with that of its neighbours.

Trigone. The smooth muscle of this region consists of two distinct layers, sometimes termed the superficial and deep trigonal muscles. The latter is composed of muscle cells which are indistinguishable from the muscle cells of the detrusor. Hence this deep trigonal muscle is simply the postero-inferior portion of the detrusor muscle proper and confusion might be avoided if the term deep trigonal muscle was abandoned in favour of the more accurate definition as trigonal detrusor muscle. The superficial trigonal muscle represents a morphologically distinct component of the trigone which, unlike the detrusor, is composed of relatively small diameter muscle bundles continuous proximally with those of the intramural ureters. The muscle layer comprising the superficial trigone is relatively thin but becomes thickened along its superior border to form the interureteric crest. Similar thickenings occur along the lateral edges of the superficial trigone (Bell 1812). In both sexes the superficial trigone muscle become continuous with the smooth muscle of the proximal urethra, extending in the male along the urethral crest as far as the openings of the ejaculatory ducts.

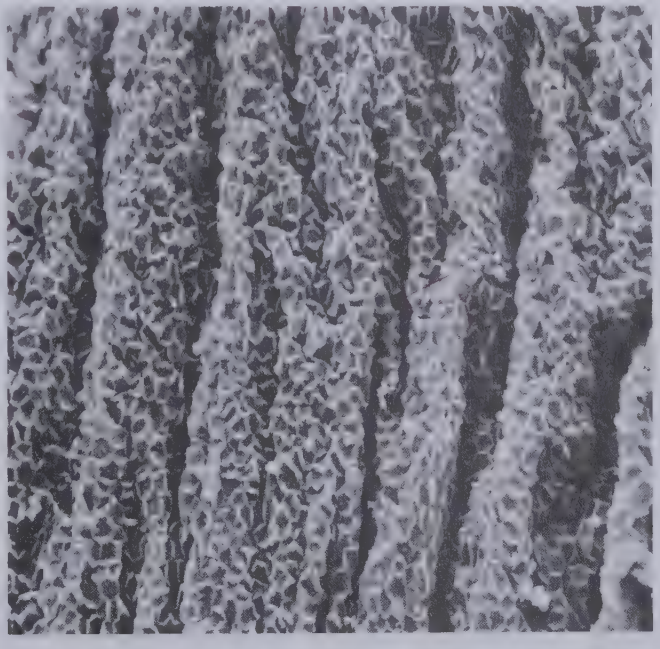
Ureterovesical junction. The distal 1–2 cm of each ureter is surrounded by an incomplete collar of the detrusor non-striated muscle which forms a sheath (of Waldeyer) separated from the ureteric muscle coat by a connective tissue sleeve. The ureters pierce the posterior aspect of the bladder and run obliquely through its wall for a distance of 1.5–2.0 cm before terminating at the ureteric orifices. This arrangement is believed to assist in the prevention of reflux of urine into the ureter, since the intramural ureters are thought to be occluded during increases in bladder pressure. The longitudinally orientated muscle bundles of the terminal ureter continue into the bladder wall and at the ureteric orifices become continuous with the superficial trigonal muscle (Tanagho et al 1968).



Bladder neck. The non-striated muscle of this region is histologically, histochemically and pharmacologically distinct from that which comprises the detrusor proper (Nergardh & Boreus 1972, Kluck 1980). Hence the bladder neck should be considered as a separate functional unit. The arrangement of non-striated muscle in this region is quite different in males and females and consequently each sex will be described separately.

Male. In the male bladder neck, the non-striated muscle cells form a complete circular collar which extends distally to surround the preprostatic portion of the urethra. Because of the location and orientation of its constituent fibres, the terms internal, proximal or preprostatic urethral sphincter are suitable alternatives for this particular component of urinary tract smooth muscle. Distally, the bladder neck muscle merges with and becomes indistinguishable from the musculature in the stroma and capsule of the prostate gland.

Female. The female bladder neck also consists of morphologically distinct non-striated muscle, since the large diameter fasciculi characteristic of the detrusor are replaced in the region of the bladder neck by those of small diameter. However, unlike the circularly orientated preprostatic non-striated muscle, the muscle fasciculi in the female extend obliquely or longitudinally into the urethral wall. The female does not therefore possess a smooth muscle sphincter at the bladder neck and it is unlikely that active contraction of this region plays a significant part in the maintenance of female urinary continence.



The Mucosa

This has a structure similar to that of the ureters and consists of an epithelium (urothelium, transitional epithelium, p. 56) supported by a layer of loose connective tissue, the lamina propria. The latter consists of loose fibro-elastic connective tissue and forms a relatively thick layer, varying in depth from 500 μm in the fundus and inferolateral walls to about 100 μm in the trigone. Small-diameter bundles of non-striated muscle cells also occur in the subepithelial connective tissue forming an incomplete and rudimentary muscularis mucosae. The connective tissue elements immediately beneath the urothelium, particularly in the region of the trigone, are densely packed. At deeper levels they are more loosely arranged, thus allowing the bladder mucosa to form numerous thick folds when the volume of fluid contained within the lumen is small. An extensive network of blood vessels is present throughout the lamina propria and supplies a plexus of thin-walled fenestrated capillaries lying in grooves at the base of the urothelium.

8.185 Transverse section through the urinary bladder wall of a monkey. Masson's trichrome stain. The section shows the folded transitional epithelium (grey-brown on the left), the connective tissue (blue-green), and fasciculi of the detrusor muscle (green-brown, to the right), surrounded externally by the connective tissue adventitia. Magnification × 20.

Non-trigonal urothelium is often up to six cells in thickness. These cells can be classified according to position and consist of highly differentiated superficial or luminal cells, one or more layers of smaller intermediate cells and a layer of undifferentiated basal cells. The large superficial cells frequently bulge into the bladder lumen and are often binucleate. In contrast the intermediate and basal cells are smaller and each contains a single darkly-staining nucleus. The flattened urothelium of the trigone

8.186 Scanning electron micrograph of the luminal surface of the bladder (murine) showing the plate-like organization of the urothelial plasma membranes of its lining cells. Magnification × 7000.

usually consists of only two or three layers of cells and a similar appearance prevails throughout the bladder when in the distended state.

In addition to the basal, intermediate and superficial cells described above, a fourth type of cell occurs in the urothelium of the human bladder neck and trigone. These flask-shaped cells extend throughout the depth of the urothelium and are characterized by the presence of numerous large membrane-bound vesicles each containing a central dense granule. Vesicles of this type are believed to be involved in the storage of amines and it seems likely that these cells belong to the so-called APUD (amine-precursor-uptake and decarboxylation, see p. 1466) series which have a wide distribution throughout the body. The functional significance of cells of this type in the urothelium of the bladder remains a mystery.

Several morphological variations have been described in the mucosa of the bladder which, because of their occurrence in otherwise normal healthy adults, are not considered to represent pathological conditions. One of the commonest epithelial variants found in bladder biopsy samples or at post-mortem is the occurrence of so-called Brunn's nests. these consist of proliferations of morphologically normal basal urothelial cells which project into the underlying connective tissue of the lamina propria and are particularly frequent in the trigone. Mucus-secreting glands with single or branched ducts are another frequently observed feature of the bladder mucosa. When present these structures are particularly numerous near the ureteric and internal urethral orifices. Non-keratinizing squamous metaplasia of the vaginal type also frequently occurs in the urinary bladder mucosa, especially over the trigone. This histological appearance, whilst occasionally observed in males and in children, is more common in adult females.

The Vascular Supply of the Bladder

The *principal arteries* of supply to the bladder are the superior and inferior vesical, derived from the anterior trunk of the internal iliac artery. The obturator and inferior gluteal arteries also send small branches to it and in the female additional branches are derived from the uterine and vaginal arteries.

The *veins* form a complicated plexus on the inferolateral surfaces and pass backwards in the posterior ligaments of the bladder to end in the internal iliac veins.

The *lymph vessels* are described on p. 855.

The Nerve Supply of the Bladder

The nerves supplying the bladder form the vesical plexus (see pp. 1167, 1168) and consist of both sympathetic and parasympathetic components, each of which contains both efferent and afferent fibres.

Efferent fibres. Parasympathetic fibres arise from the second to the fourth sacral segments of the spinal cord (*nervi erigentes*); the sympathetic fibres are derived from the lower two thoracic and upper two lumbar segments of the spinal cord. In addition to the branches from the vesical plexus, small groups of autonomic neurons occur throughout all regions of the bladder wall. These multipolar intramural neurons are rich in acetylcholinesterase and occur in ganglia consisting of five to 20 nerve cell bodies. Numerous preganglionic autonomic fibres form both axosomatic and axodendritic synapses with the ganglion cells. The majority of these preganglionic nerve terminals correspond morphologically to presumptive cholinergic fibres. Noradrenergic terminals also relay on cell bodies in the pelvic plexus although it is unknown whether similar nerves synapse on intramural bladder ganglia.

The urinary bladder (including trigonal detrusor muscle) is profusely supplied with nerves which form a dense plexus among the detrusor smooth muscle cells. The majority of these nerves contain acetylcholinesterase and occur in abundance throughout the muscle coat of the bladder. Axonal varicosities adjacent to detrusor non-striated muscle cells possess features which are considered to typify cholinergic nerve terminals and contain clusters of small (50 nm diameter) agranular vesicles together with occasional large (80–160 nm diameter) granulated vesicles and small mitochondria. Terminal regions approach to within 20 nm of the muscle cells' surface and are either partially surrounded by or more often totally denuded of Schwann cell cytoplasm. The human detrusor possesses a sparse supply of sympathetic noradrenergic nerves (Sundin et al 1977). Nerves of this type generally accompany the vascular supply and only rarely extend among the non-striated myocytes of the urinary bladder. A further component plays a part in the autonomic innervation of the urinary bladder (Ambache & Zar 1970), which has been classified as a non-adrenergic, non-cholinergic nerve mediated effect. A number of other neurotransmitters or neuromodulators have been detected in intramural ganglia, including the peptide somatostatin (see p. 891). Superficial trigonal muscle is associated with few cholinergic (parasympathetic) nerves while those of the noradrenergic (sympathetic) variety occur relatively frequently. These differences support the view that the superficial trigonal muscle should be regarded as 'ureteric' rather than 'vesical' in origin. It should be emphasized that the superificial trigonal muscle forms a very minor part of the total muscle mass of the bladder neck and proximal urethra in either sex and is probably of little significance in the physiological mechanisms which control these regions.

In the male, bladder neck non-striated muscle is sparsely supplied with cholinergic (parasympathetic) nerves but possesses a rich noradrenergic (sympathetic) innervation (Gosling et al 1977). A similar distribution of autonomic nerves also occurs in the non-striated muscle of the prostate gland, seminal vesicles and ducti deferentes. From a functional standpoint, sympathetic nerves on stimulation cause contraction of non-striated muscle in the wall of the genital tract resulting in seminal emission. Concomitant sympathetic stimulation of the proximal urethral muscle causes sphincteric closure of the bladder neck, thereby preventing reflux of ejaculate into the bladder. Although this genital function of the male bladder neck is well established it is not known whether the non-striated muscle of this region plays an active role in maintaining urinary continence.

In contrast with this rich sympathetic innervation in the male, the non-striated muscle of the female bladder neck receives relatively few noradrenergic nerves but is richly supplied with presumptive cholinergic fibres. The sparse supply of sympathetic nerves presumably relates to the absence of a functioning 'genital' portion incorporated within the wall of the female urethra.

The lamina propria of the fundus and inferolateral walls of the bladder is virtually devoid of autonomic nerve fibres, apart from some noradrenergic and occasional presumptive cholinergic perivascular nerves. However, as the urethral orifice is approached the density of nerves unrelated to blood vessels increases. At the bladder neck and the trigone a nerve plexus extends throughout the lamina propria. The constituent nerves are cholinesterase positive and run through the connective tissue unassociated with blood vessels. Some of the larger diameter axons are myelinated and others lie adjacent to the basal urothelial cells. As in the ureter, the subepithelial nerve plexus of the bladder is assumed to subserve a sensory function in the absence of any obvious effector target sites (Gosling & Dixon 1974).

Afferent fibres. Vesical nerves are also concerned with pain and awareness of distension. Pain fibres are stimulated by distension or spasm due to a stone, inflammation or malignant disease; they are in sympathetic *and* parasympathetic nerves, predominantly the latter. Hence, simple division of the sympathetic paths (e.g. 'presacral neurectomy'), or of the superior hypogastric plexus (p. 1166), does not materially relieve vesical pain. The spinal path for pain is in the anterolateral white columns and considerable relief follows bilateral anterolateral cordotomy. Since nerve fibres mediating awareness of distension are in the posterior columns (fasciculus gracilis), after anterolateral cordotomy the patient still retains awareness of the need to micturate. The nerve endings detecting noxious stimuli are probably of more than one type; a subepithelial plexus of fibres containing dense vesicles, probably afferent endings, has been described by Dixon & Gilpin (1987).

Applied Anatomy

A distended bladder may be ruptured in lower abdominal or pelvic injuries, either extraperitoneally or, if the superior surface is involved, with tearing of the peritoneum and escape of vesical

contents into the peritoneal cavity. In progressive chronic obstruction to micturition, e.g. by prostatic enlargement (p. 1435) or urethral stricture, vesical musculature hypertrophies, its fasciculi increasing in size and interlacing in all directions to produce an enlarged, 'trabeculated bladder'. Mucosa between the fascicles forms 'diverticula', which may contain phosphatic concretions. When outflow is thus obstructed, emptying is not complete; some urine remains and may become infected; infection may extend to the ureters and kidneys. Back pressure from a distended bladder may gradually dilatate the ureters, renal pelves and even the renal collecting tubules. Lesions of the fasciculus gracilis (e.g. tabes dorsalis) cause loss of desire to micturate; the distended bladder may empty merely by overflow. Severe spinal cord lesions above its sacral segments, interrupting efferent and afferent tracts involved in normal micturition, may result in 'automatic' emptying.

The vesical interior can be examined with a cystoscope, introduced via the urethra after distending the bladder with fluid. A special cystoscope is used to catheterize the ureters, to obtain a direct specimen of urine from either kidney or to inject radio-opaque fluid for retrograde pyelography (**8**.169B). The vesical outline can be similarly demonstrated.

The distended bladder may be punctured just above the symphysis pubis without traversing the peritoneum *(suprapubic cystostomy)*. When the bladder contains about 300 ml its antero-inferior surface contacts the anterior abdominal wall directly for about 7.5 cm above the pubis. Surgical access to the bladder is usually by this route. In females, owing to the shorter and more dilatable urethra, small calculi, foreign bodies and growths may be removed through it.

Congenital abnormalities of the bladder are described on p. 260.

The Male Urethra

The male urethra (**8**.181, 187) from 18–20 cm long, extends from an internal orifice in the urinary bladder to an external opening, or meatus, at the end of the penis. It may be considered in four regional parts: pre-prostatic, prostatic, membranous and spongiose and presents a double curve while the penis is in its ordinary flaccid state (**8**.181). Except during the passage of fluid along it, the urethral canal is a mere slit; in the prostatic part the slit is transversely arched in transverse section, in the membranous portion it is stellate, in the spongiose portion transverse, while at the external orifice it is sagittal in orientation.

The Pre-prostatic Part

The pre-prostatic urethra possesses a stellate lumen and is approximately 1–1.5 cm in length, extending almost vertically from the bladder neck to the superior aspect of the prostate gland. The non-striated muscle bundles surrounding the bladder neck and pre-prostatic urethra are arranged as a distinct circular collar which becomes continuous distally with the capsule of the prostate gland. The bundles which form this pre-prostatic or *internal sphincter (sphincter vesicae)* are separated by connective tissue containing many elastic fibres (Gilpin & Gosling 1983). Unlike the detrusor muscle, the non-striated muscle surrounding the proximal urethra is almost totally devoid of parasympathetic cholinergic nerves but is richly supplied with sympathetic noradrenergic nerves. Similar nerves also supply the non-striated muscle of the prostate, ducti deferentes and seminal vesicles and are involved in causing muscle contraction at the time of ejaculation (Learmonth 1931). Contraction of the pre-prostatic sphincter serves to prevent the retrograde flow of ejaculate through the proximal urethra into the bladder.

The Prostatic Part

The prostatic urethra is approximately 3–4 cm in length and tunnels through the substance of the prostate closer to the anterior than the posterior surface of the gland. It is continuous above with the pre-prostatic part and emerges from the prostate slightly anterior to its apex (its most inferior point). Throughout most of its length the posterior wall possesses a midline ridge, the *urethral crest* which projects into the lumen causing it to appear crescentic

8.187 The whole length of the lumen of the male urethra exposed by an incision extending into it from its dorsal aspect. Note openings of prostatic utricle and ejaculatory ducts on the colliculus seminalis.

in transverse section. On each side of the crest there is a shallow depression, termed the *prostatic sinus*, the floor of which is perforated by the orifices of the prostatic ducts. About the middle of the length of the urethral crest the *colliculus seminalis* or (*verumontanum*) forms an elevation on which the slit-like orifice of the *prostatic utricle* is situated; on both sides of or just within this orifice there are the two small openings of the ejaculatory ducts. The prostatic utricle is a cul-de-sac about 6 mm long, which runs upwards and backwards in the substance of the prostate behind its medial lobe. Its walls are composed of fibrous tissue, muscular fibres and mucous membrane; the latter presents the openings of numerous small glands. Developed from the paramesonephric ducts or urogenital sinus, it is thought to be homologous with the vagina of the female (p. 260). The prostatic utricle is therefore called by some '*the vagina masculina*', but the more usual view is that it is a uterine homologue and hence the term 'utricle'. The ejaculatory ducts are described on p. 1430. Distally the prostatic urethra possesses an outer layer of circularly disposed skeletal muscle cells which are continuous with a prominent collar of striated muscle (the external urethral sphincter) within the wall of the membranous urethra.

The Membranous Part

The membranous part is the shortest, least dilatable and, with the exception of the external orifice, the narrowest section of the urethra. It descends with a slight ventral concavity from the prostate to the bulb of the penis (**8**.181), passing through the perineal membrane about 2.5 cm postero-inferior to the pubic symphysis. The hind part of the bulb of the penis is closely apposed to the inferior aspect of the urogenital diaphragm (perineal membrane) but anteriorly it is slightly separated from the latter, so that the wall of the urethra is related anteriorly neither to the perineal membrane nor the penile bulb. This part of the anterior wall of

the urethra is regarded as the 'membranous' part; anteriorly it is about 2 cm long, whilst posteriorly it is only 1.2 cm. The wall of the membranous urethra consists of a muscle coat which is separated from the epithelial lining by a narrow layer of fibro-elastic connective tissue. This muscle coat consists of a relatively thin layer of non-striated muscle bundles continuous proximally with those of the prostatic urethra and a prominent outer layer of circularly orientated skeletal muscle fibres forming the external urethral sphincter. The skeletal muscle fibres which comprise this external sphincter are unusually small in cross-section, with diameters of only 15–20 μm (Hayek 1969). The fibres are physiologically of the slow twitch type (Gosling et al 1981), unlike the pelvic floor musculature which is a heterogeneous mixture of slow and fast twitch fibres of larger diameter (Parks et al 1977). Moreover the external sphincter is devoid of muscle spindles and is supplied by the pelvic splanchnic nerves, further distinguishing it from the periurethral levator ani muscle (Donker et al 1976). The slow twitch fibres of the external sphincter are capable of sustained contraction over relatively long periods of time and actively contribute to the tone which closes the urethra and maintains urinary continence.

The Spongiose Part

The spongiose part is contained in the corpus spongiosum penis (p.1432). It is about 15 cm long and extends from the end of the membranous urethra to the external urethral orifice on the glans penis. Commencing below the perineal membrane, it continues the ventrally concave curve of the membranous urethra to a point anterior to the lowest level of the symphysis pubis. From here, when the penis is flaccid, the urethra curves downwards in the 'free' part of the penis. It is narrow, with a uniform diameter of about 6 mm in the penis; it is dilated at its commencement as the *intrabulbar fossa* and again within the glans penis, where it becomes the *navicular fossa*. The enlargement of the intrabulbar fossa affects the floor and side walls but not the roof of the urethra. The *bulbo-urethral glands* open into the spongiose section of the urethra about 2.5 cm below the perineal membrane (p. 1435).

The *external urethral orifice* is the narrowest part of the urethra: it is a sagittal slit, about 6 mm long, bounded on each side by a small labium.

The epithelium of the urethra, except in its most anterior part, presents the orifices of numerous small mucous glands and follicles situated in the submucous tissue and named the *urethral glands*. Besides these there is a number of small pit-like recesses, or *lacunae*, of varying sizes; the orifices of these are directed forwards and may intercept the point of a catheter in its passage along the canal. One, larger than the rest, the *lacuna magna*, is situated on the roof of the navicular fossa.

Mucous Membrane of the Male Urethra

The epithelium lining the preprostatic urethra and the proximal part of the prostatic urethra is of the urothelial type and is in continuity with that lining the bladder; it is also continuous with the ducts of the prostate and bulbo-urethral glands and with the linings of the seminal vesicles, deferent ducts and ejaculatory ducts, a relationship which is important in the spread of urinary tract infections. However, below the openings of the ejaculatory ducts this epithelium changes to a patchily pseudostratified or stratified columnar variety which lines the membranous urethra and the major part of the penile urethra (p. 56). Mucus-secreting cells are common throughout this epithelium and frequently occur in small clusters in the penile urethra. The mucous membrane of the penile urethra shows many recesses which continue into deeper branching tubular mucous glands (of Littré) which are especially numerous on the dorsal aspect. In older individuals many of the recesses of the urethral mucosa contain concretions similar to those found within the substances of the prostate. Towards the distal end of the penile urethra the epithelium changes once again, becoming stratified squamous in character with well-defined connective tissue papillae. This type of epithelium lines the navicular fossa and becomes keratinized at the external meatus.

Urethral Sphincters

Of the two urethral sphincters, the internal *sphincter vesicae* (p. 1418) controls the vesical neck and the prostatic urethra above the ejaculatory ducts. It is composed of non-striated muscle and supplied by sympathetic and parasympathetic fibres from the vesical plexus (vide supra and p. 1166). The external *sphincter urethrae* (p. 608) surrounds the membranous urethra; it consists of striated muscle and is supplied by the perineal branches of the pudendal nerve (S2,3 and 4); it is voluntary after early infancy.

The existence of an internal sphincter is, however, controversial. Many consider that its non-striated muscle fibres are multidirectional as in the vesical wall, no true circumferential fibres being identifiable (Woodburne 1961, Angell 1969). However, all agree that a substantial muscular aggregation, with an admixture of elastic and collagenous fibres, exists at the vesical outlet (Vincent 1966a). Its significance in micturition is noted on p. 1423.

THE FEMALE URETHRA

The female urethra is about 4 cm long and 6 mm in diameter. It begins at the internal urethral orifice of the bladder, approximately opposite the middle of the symphysis pubis, and runs antero-inferiorly behind the symphysis pubis, embedded in the anterior wall of the vagina. It traverses the perineal membrane and ends at the external urethral orifice, an anteroposterior slit with rather prominent margins, which is situated directly anterior to the opening of the vagina and about 2.5 cm behind the glans clitoridis. Except during the passage of urine the anterior and posterior wall of the urethra are in apposition and the epithelium is thrown into longitudinal folds, one of which, on the posterior wall of the canal, is termed the *urethral crest*. Many small mucous *urethral glands* and minute pit-like recesses or *lacunae* open into the urethra. On each side, near the lower end of the urethra, a number of these glands are grouped together and open into a duct, named the *para-urethral duct*; each duct runs down in the submucous tissue and ends in a small aperture on the lateral margin of the external urethral orifice.

Microscopic Structure of the Female Urethra

The wall of the female urethra comprises an outer muscle coat and an inner mucous membrane which lines the lumen and is continuous with that of the bladder. The muscle coat consists of an outer sleeve of striated muscle (*the external urethral sphincter*) together with an inner coat of smooth muscle fibres. The female external urethral sphincter is anatomically separate from the adjacent peri-urethral striated muscle of the anterior pelvic floor. The constituent fibres of this sphincter are circularly disposed and form a sleeve which is thickest in the middle one-third of the urethra. In this region skeletal muscle completely surrounds the urethra although the posterior portion lying between the urethra and vagina is relatively thin. The skeletal muscle extends into the anterior wall of both the proximal and distal thirds of the urethra but is deficient posteriorly in these regions. The myocytes forming the external urethral sphincter are all of the slow twitch variety. As in the male, muscle fibres of the external urethral sphincter are unusually small and have diameters of 15–20 μm on average. Although the thickness of the external urethral sphincter in the female is less than that of the male, its constituent fibres are able to exert tone upon the urethral lumen over prolonged periods, especially in relation to the middle third of its length. Peri-urethral skeletal muscle (pubococcygeus) aids urethral closure during events which require rapid, albeit short-lived, elevation of urethral resistance. The *smooth muscle coat* extends throughout the length of the urethra and consists of slender muscle bundles, the majority of which are orientated obliquely or longitudinally. A few circularly arranged muscle fibres occur in the outer aspect of the non-striated muscle layer and intermingle with the skeletal muscle fibres forming the inner part of the external urethral sphincter. Proximally the urethral smooth muscle extends as far as the bladder neck where it is replaced by fascicles of detrusor non-striated muscle. This region in the female is devoid of a well-defined circular non-striated muscle component comparable with the pre-prostatic sphincter of the male. When

traced distally, urethral smooth muscle bundles terminate in the subcutaneous adipose tissue surrounding the external urethral meatus. The smooth muscle of the female urethra is associated with relatively few noradrenergic nerves but receives an extensive presumptive cholinergic parasympathetic nerve supply identical in appearance to that which supplies the detrusor (Ek et al 1977). From a functional viewpoint it seems unlikely that competence of the female bladder neck and proximal urethra is solely the result of non-striated muscle activity, in the absence of an anatomical sphincter. The innervation and longitudinal orientation of most of the muscle fibres suggest that urethral smooth muscle in the female is active during micturition, serving to shorten and widen the urethral lumen. For further details, see Gilpin & Gosling 1983. The *mucous membrane* lining the female urethra consists of a stratified epithelium and a supporting layer of loose fibro-elastic connective tissue (the lamina propria). The lamina propria contains an abundance of elastic fibres orientated both longitudinally and circularly around the urethra. Numerous thin-walled veins are another characteristic feature and in the past have been falsely likened to erectile tissue. A fine plexus of acetylcholinesterase-positive nerves is present throughout the lamina propria and these fibres are believed to be sensory branches of the pudendal nerves. The proximal part of the urethra is lined by urothelium, identical in appearance to that of the bladder neck. Distally the epithelium changes into a non-keratinizing stratified squamous type which lines the major portion of the female urethra. This epithelium is keratinized at the external urethral meatus and becomes continuous with the skin of the vestibule.

FUNCTIONAL ANATOMY OF THE LOWER URINARY TRACT

The urinary bladder performs a dual function, acting at times as a reservoir for fluid accumulating within its lumen and at others as a contractile organ actively expelling its contents into the urethra. In the following account the tissue components and, where appropriate, their neurological control will be considered under the headings *continence of urine* and *micturition*.

Continence of Urine

To achieve urinary continence, the bladder acts as a passive reservoir retaining fluid because the forces acting on the urethra produce an intra-urethral pressure greater than bladder pressure. Several tissue components play a part in generating this urethral resistance and make either an active or passive contribution. Since the non-striated muscle of the bladder is replaced in the bladder neck region by a different type of non-striated muscle, the detrusor does not play a part in closing the proximal urethra.

In the male, a distinct collar of circularly orientated non-striated muscle occurs in the bladder neck and pre-prostatic urethra, continuous distally with the muscular components of the genital tract. This smooth muscle sphincter is supplied by a rich plexus of sympathetic nerve fibres which, on stimulation, cause the sphincter to contact, thereby preventing retrograde flow of semen into the urinary bladder at ejaculation. During seminal emission, the sympathetic nervous system also prevents coincidental contraction of detrusor smooth muscle. This inhibitory effect on bladder contractility is mediated by noradrenergic nerves which synapse in the vesical plexus upon parasympathetic motor neurons. Despite this well defined genital role, it is not known whether the non-striated muscle of the bladder neck region and pre-prostatic urethra plays an active part in the maintenance of continence. Intramural collagen and elastic fibres within the wall of the bladder neck, proximal urethra and prostate generate passive forces which help to close the urethral lumen. However, postoperative incontinence of urine does not usually follow radical surgical excision of the bladder neck, pre-prostatic urethra and prostate, suggesting that these regions make only a minor contribution to urinary continence.

In the female, a non-striated muscle sphincter cannot be anatomically recognized in the wall of the bladder neck and proximal urethra. Consequently it is even less likely that active smooth muscle contraction can be considered as an important factor in the continence of urine. However, the bladder neck and proximal urethra possess within their walls innumerable elastic fibres which are of particular importance in producing passive occlusion of the urethral lumen (Lapides 1958). Indeed, it has been suggested that the passive elastic resistance offered by the urethral wall is the most important single factor responsible for the closure of the bladder neck and proximal urethra in the continent woman.

In both sexes the urethra contains within its walls the external urethral sphincter, the location of which corresponds anatomically to the zone where maximal urethral closure pressures are normally recorded. This skeletal muscle sphincter is morphologically adapted to maintain tone over relatively long periods without fatigue and plays an important active role in producing urethral occlusion at rest. It remains to be determined, however, whether the force exerted by the sphincter is maximal at all times between two consecutive acts of micturition or whether additional motor units are recruited during coughing, sneezing, etc. to enhance the occlusive force on the urethra during these events. The external sphincter is innervated by nerve fibres which travel via the pelvic splanchnic nerves (Gil Vernet 1968) and *not* the pudendal nerves as often described. The clinical relevance of this arrangement is that pudendal blockade or neurectomy performed in order to reduce urethral resistance will not achieve the desired effect since the motor innervation of the striated sphincter remains unaffected by these procedures.

Concerning the role of peri-urethral muscle in the maintenance of continence, the medial parts of the levator ani muscles in both sexes are related to (but structurally separate from) the urethral wall. These peri-urethral fibres are innervated by the pudendal nerve and consist of an admixture of large diameter fast and slow twitch fibres. Therefore, unlike the external sphincter, peri-urethral muscle possesses morphological features which are similar to other 'typical' voluntary muscles. This pelvic floor musculature plays an important part (especially in the female) by providing an additional occlusive force on the urethral wall, particularly during events which are associated with an increase in intra-abdominal pressure. In addition, the muscles provide support for the pelvic viscera.

Micturition

To enable fluid to flow along the urethra it is necessary for the pressure in the urinary bladder to exceed that within the urethral lumen. Under normal circumstances, in order to initiate micturition, a fall in urethral resistance immediately precedes a rise in pressure within the lumen of the bladder. This pressure rise is usually produced by active contraction of detrusor smooth muscle at the onset of micturition. The detrusor muscle coat consists of numerous interlacing bundles forming a complex meshwork of smooth muscle which, on contraction, reduces all dimensions of the bladder. The muscle coat is collectively involved and it is unnecessary to attach special significance to the precise orientation of individual bundles within the wall of the viscus.

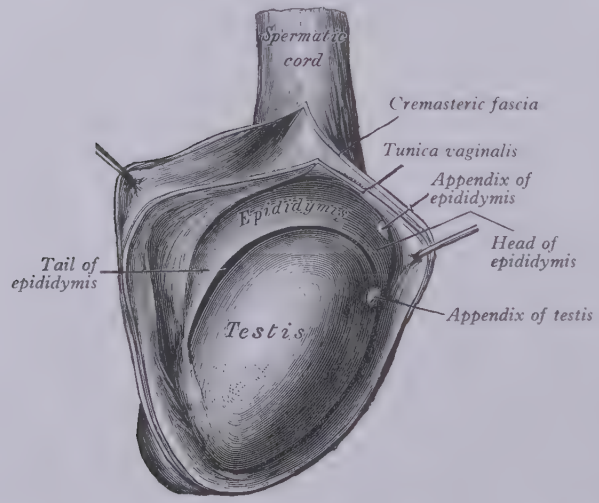
The preganglionic nerve supply travels in the pelvic splanchnic nerves before synapsing on neurons located within the vesical part of the pelvic plexuses and within the wall of the bladder. These peripheral neurons supply nerve fibres which ramify throughout the thickness of the detrusor smooth muscle coat. The profuse distribution of these motor nerves emphasizes the importance of the autonomic nervous system in initiating and sustaining bladder contracting during micturition. For micturition to occur the pressure differential between the bladder and urethra must overcome the elastic resistance of the bladder neck. Immediately prior to the onset of micturition, the tonus of the external sphincter is reduced by central inhibition of its motor neurons located in the second, third and fourth sacral spinal segments. This inhibition is mediated by descending spinal pathways originating in higher centres of the central nervous system. Concomitantly, other descending pathways activate (either directly or via sacral interneurons) the preganglionic parasympathetic motor outflow to the urinary bladder. This central integration of the nervous control of the bladder and urethra is essential for normal micturition.

Applied Anatomy. After urethral rupture, the extravasation of urine may complicate micturition; urine usually extends between the perineal membrane and the membranous layer of the

superficial fascia. As both of these are attached firmly to the ischiopubic rami, extravasated fluid cannot pass posteriorly because the two layers are continuous around the superficial transverse perineal muscles. Laterally, the spread of urine is blocked by the pubic and ischial rami; it cannot enter the lesser pelvis through the perineal membrane and, if this remains intact, fluid can make its way only anteriorly into the scrotal and penile loose connective tissue and thence to the anterior abdominal wall. When the lesser pelvis is crushed the urethra may be ruptured between the prostatic and membranous parts; extravasation of urine then occurs into the pelvic extraperitoneal tissue.

The lower urinary tract is subject to many congenital anomalies (p. 260), some amenable to surgical correction. For an anatomical survey, consult Paul & Kanagasuntheram (1956).

REPRODUCTIVE ORGANS OF THE MALE



The male genital organs include the *testes*, *epididymides*, *deferent* and *ejaculatory ducts* and *penis*, with the accessory glandular structures: *seminal vesicles*, *prostate* and *bulbo-urethral glands*.

The Testes and Epididymes

These, the *primary male reproductive organs* or *gonads*, are suspended in the scrotum by scrotal tissues including the non-striated dartos muscles and the spermatic cords, the left testis usually being about 1 cm lower than the right. Average testicular dimensions are 4–5 cm in length, 2.5 cm in breadth and 3 cm in anteroposterior diameter; their weight varies from 10.5–14 g. Each testis, ellipsoidal (**8**.188) and compressed laterally, is obliquely set in the scrotum, its upper pole tilted anterolaterally and the lower posteromedially. The anterior aspect is convex, the posterior nearly straight, with the spermatic cord attached to it. Anterior, medial and lateral surfaces and both poles are convex, smooth and covered by the visceral layer of the serosal tunica vaginalis, which separates them from the parietal layer and the scrotal tissues external to this. The posterior aspect is only partly covered by tunica serosa; the epididymis adjoins its lateral part.

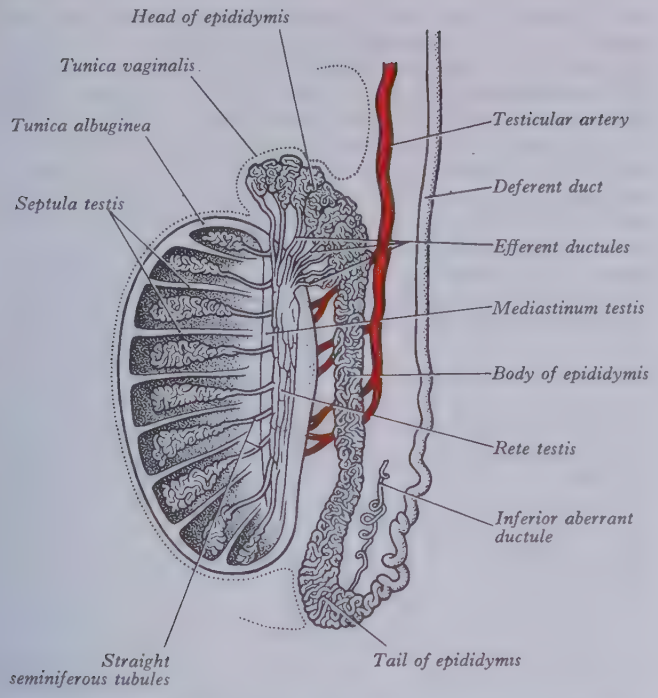
The epididymis, a tortuous canal and the first part of the efferent route from the testis, is much folded and tightly packed to form a long, narrow mass attached posterolaterally to the testis. It has a central *body*, a superior enlarged *head* and an inferior pointed *tail*. The head is connected to the upper testicular pole by *efferent ductules* and the tail to the lower pole by areolar tissue and the reflected tunica vaginalis. Laterally the head and tail are covered by the tunica and are here 'free'; the body is also so invested, except on its posterior aspect. The tunica vaginalis is recessed between the epididymal body and the lateral surface of the testis, forming the *sinus of the epididymis*.

Testicular and epididymal appendices. At the upper pole of the testis, just inferior to the epididymal head, is a minute, oval, sessile *appendix of the testis*, a remnant of the upper end of the paramesonephric duct. On the epididymal head is a small, stalked appendage (sometimes double), the *appendix of the epididymis*, usually considered a mesonephric vestige (p. 250, **2**.116).

8.188 The right testis, exposed by incising and laying open the cremasteric fascia and parietal layer of the tunica vaginalis on the lateral aspect of the testis.

The testis is invested by three coats, from outside inwards: the tunica vaginalis, tunica albuginea and tunica vasculosa.

The tunica vaginalis (**8**.188, 197) is the lower end of the peritoneal processus vaginalis, which precedes the descent of the fetal testis from abdomen to scrotum (p. 257); after this migration, the tunica's proximal part, from the internal inguinal ring almost to the testis, contracts and obliterates, leaving a closed distal sac invaginated by the testis and reflected to the internal scrotal surface, thus forming the visceral and parietal layers of the tunica.



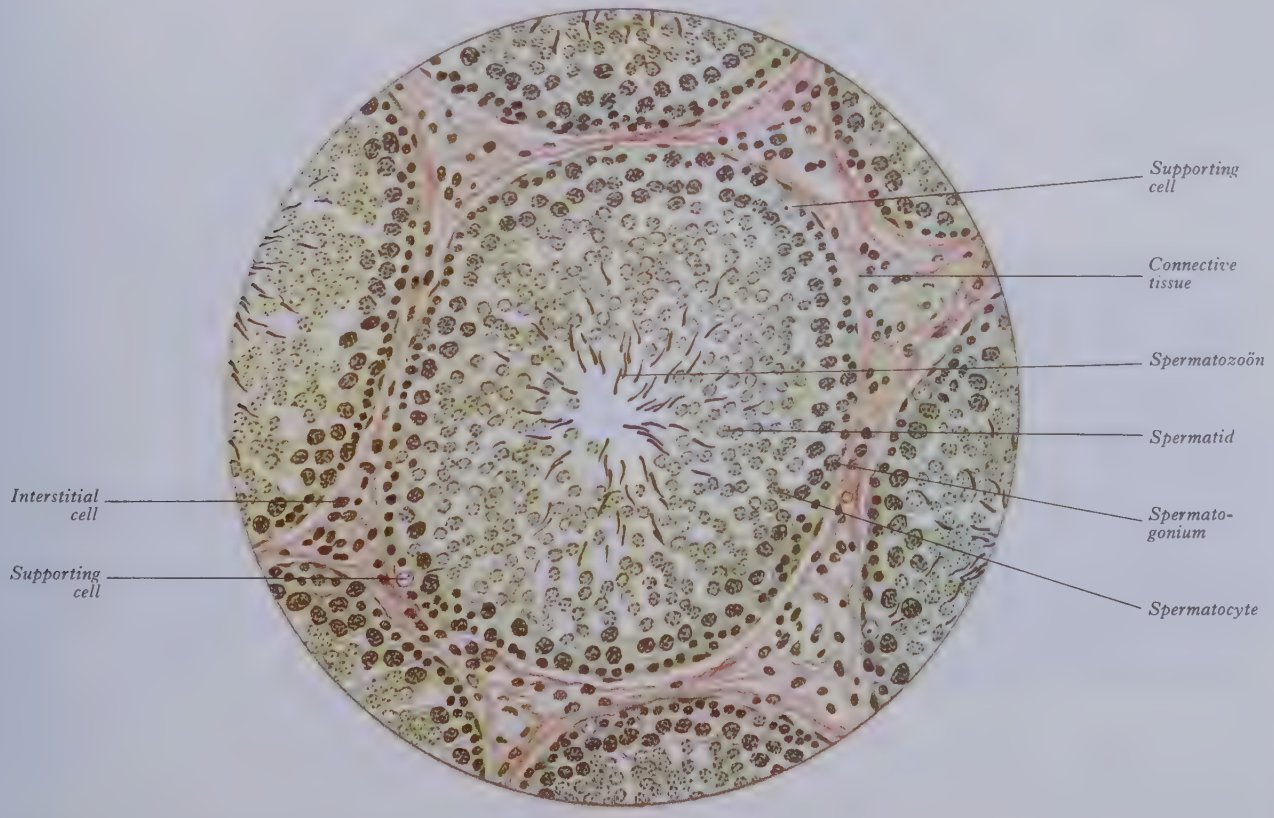
The *visceral layer* covers all aspects of the testis except the posterior border. Posteromedially it is reflected forwards as the parietal layer; posterolaterally it passes to the medial aspect of the epididymis, lining its sinus, and then laterally to its posterior border where it is reflected forwards into the parietal layer. The visceral and parietal layers are also continuous at both poles but at the upper the visceral layer surmounts the head of the epididymis before reflexion.

The *parietal layer*, more extensive than the visceral, reaches below the testis and ascends in front of and medial to the spermatic cord. Internally the tunica vaginalis has a smooth, moist mesothelium, the potential space between its visceral and parietal layers being its cavity.

In the embryo, the male and femal gonads project into the coelom, covered by so-called 'germinal' epithelium; even in the adult the mesothelium covering the testis (and ovary) has been considered atypical peritoneum, a remnant of the original 'germinal' epithelium. The parietal tunica vaginalis would then be considered continuous with the germinal epithelium at the posterior aspect of the testis. Structurally, however, in the testis the parietal and visceral epithelia are similar and like that of the general peritoneum, although the epithelium covering the ovary is a specialized, cuboidal layer. Doubtless the term germinal epithelium reflects the misconception that generations of gonocytes develop from the specialized mesothelium of the genital ridge.

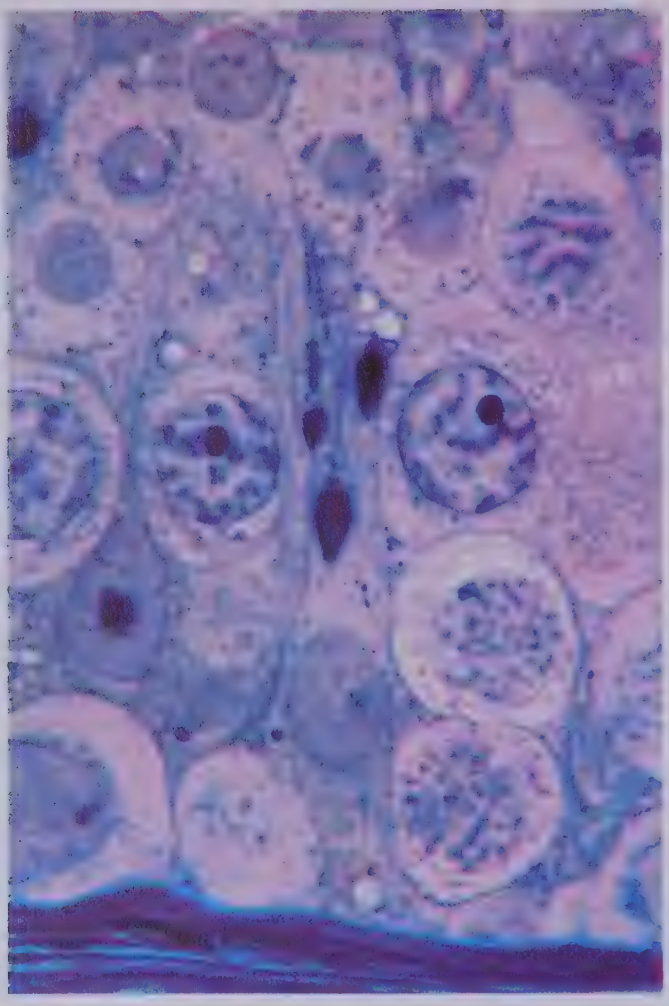
The obliterated part of the processus vaginalis is often seen as a fibrous thread in the anterior part of the spermatic cord, extending from the internal end of inguinal canal and connected here to peritoneum, the tunica vaginalis. Sometimes it disappears in the cord or its proximal part remains patent, the peritoneal cavity then communicating with the tunica, or the proximal processus may persist, although shut off distally from the tunica (pp. 257, 1377). Occasionally its cavity may persist at an intermediate level as a cyst.

The tunica albuginea is a dense, bluish-white covering for the testis, composed mainly of interlacing bundles of collagen fibres, covered externally by the visceral layer of the tunica vaginalis, except at the epididymal head and tail and the posterior testicular aspect, where vessels and nerves enter the testis. It covers the tunica vasculosa and, at the posterior border of the testis, projects into it as a thick, vertical but incomplete septum, the **mediastinum testis** (**8**.189); this extends from the upper almost to the lower end of the testis and is wider above than below. From its front and sides numerous incomplete *septula testis* radiate towards the surface of the testis, attached there to the deep aspect of the tunica albuginea; these divide the organ



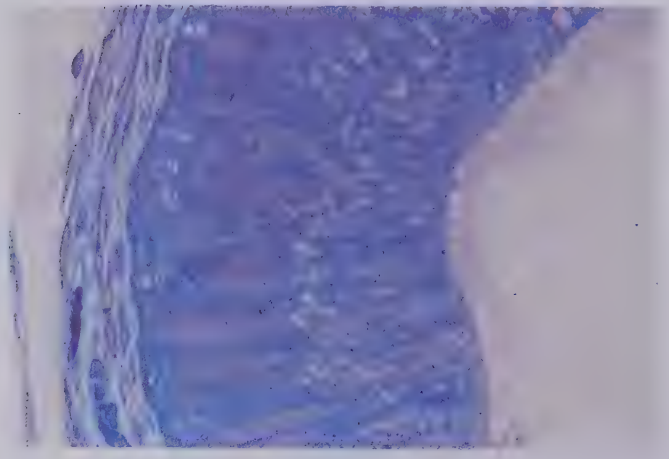
8.189 Vertical section through the testis and epididymis, showing, diagrammatically, the arrangement of the ducts of the testis and the mode of formation of the deferent duct.

incompletely into cone-shaped lobules, their bases at the surface and their apices converging upon the mediastinum. For a detailed comparative account of the mediastinum consult Dhingra (1977). Its connective tissue is very variable; in some species, including man (Holstein 1967), non-striated myocytes occur amid the collagen fibres (p. 1429). It is traversed by many vessels and by efferent tubules of the rete testis. Leydig cells are absent from the human mediastinum testis but are present in some ungulates.



The tunica vasculosa contains a plexus of blood vessels and delicate loose connective tissue, extending over the internal aspect of the tunica albuginea and covering the septa and therefore all lobules.

STRUCTURE OF THE TESTIS



At the surface is a layer of flat mesothelial cells resembling those of the surrounding peritoneum; some consider them to be remnants of a 'germinal' epithelium (see, however, p. 255). Internally the testicular architecture is dominated by the lobules (**8**.189), their number in a human testis being 200–300. They differ in size, those centrally placed being larger and longer. Each contains one to three or more minute *convoluted seminiferous tubules*. When unravelled these are seen to begin blindly or by anastomotic loops. Clermont & Huckins (1961) and Roosen-Runge (1961) have described them (in rats) as closed loops, opening at both ends into the tubuli recti and thus into the rete testis, and this pattern is now generally accepted. Their loose supporting connective tissue contains grouped *interstitial cells* (**8**.190) of yellow pigment granules. The tubules in each testis total 400–600 and the length of each is 70–80 cm. Their diameter varies from 0.12–0.3 mm. They are pale in early life, but in old age they contain much fat and are deep yellow. Each (**8**.190) has a basement membrane of laminated connective tissue containing numerous elastin fibres, with flat cells between the layers, and covered externally by flat epithelioid cells. Nicander (1967) has described intercellular contacts between these cells. As it ages the basement membrane becomes thicker and denser. Internal to it the seminiferous epithelium consists of *spermatogenic* and *supportive* cells. The former (**8**.191, 194), when active, include an array of types from spermatogonia through their derived forms, spermatocytes and spermatids, to mature spermatozoa. Among the spermatids may be *residual bodies* (pp. 120, 122), spherical structures containing membranous and mitochondrial residues and numerous free ribosomes, derived from spermatids from which they have separated. Their role in

8.191 The epithelium of a seminiferous tubule in an adult man. A thin section of glutaraldehyde-fixed material, stained with toluidine blue. Spermatogonium (bottom left), primary spermatocytes (bottom right), and late spermatids (central) are visible. The spermatids are attached to a supportive cell of Sertoli (below them). For further details compare with 8.194. (From Holstein & Wulfhekel 1971 with permission of Grosse Verlag, Berlin.)

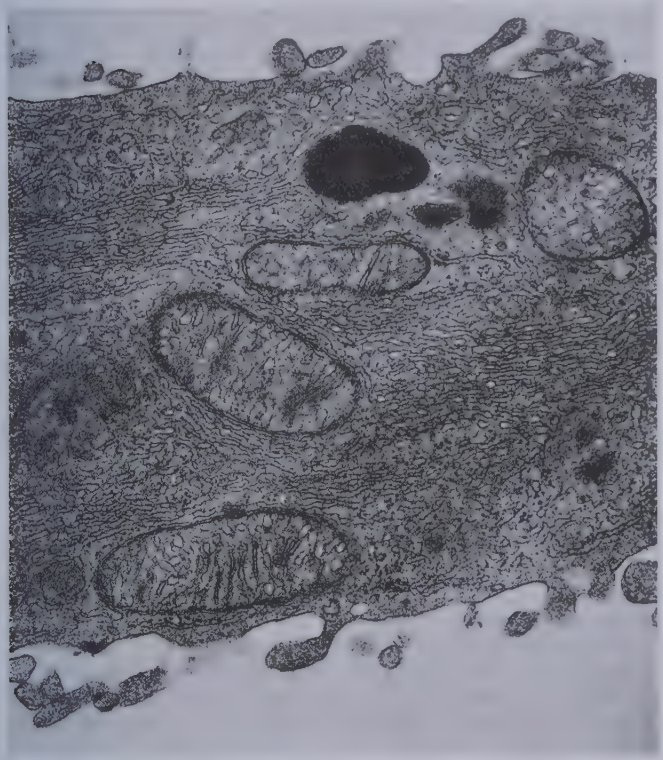
8.192 Section through the corpus of the human adult epididymis, showing deep columnar ciliated epithelium, small contractile cells, arranged circumferentially, immediately external to the epithelium, and larger non-striated muscle cells more externally. A thin glutaraldehyde-fixed section stained with toluidine blue. Supplied by A F Holstein, University of Hamburg. (For details see Baumgarten et al 1971.)

spermatogenesis is not yet clarified (Vaughn 1966) but may be regulatory; they are autolysed and perhaps phagocytosed by sustentacular cells, as the mature spermatozoa separate.

Spermatogonia, the stem cells for all spermatozoa, are descended from primordial germ cells which reach and multiply in the genital cords of developing testis, becoming *gonocytes*. In fully differentiated testis they appear along the basal laminae of the seminiferous tubules. Changes in the structure and appearance of human spermatogonia from birth to the onset of puberty have been described by Paniagua & Nistal (1984). Their cytological characteristics, like those of the generations of spermatocytes and spermatids produced from them, have been noted (p. 122). Several types of spermatogonia were early recognized (Regaud 1901) on the basis of cell and nuclear dimensions, distribution of nuclear chromatin and histochemical and ultrastructural data, as is generally accepted, though disagreements over minor details persist (Courot et al 1970). Similarly, various stages in the maturation of spermatocytes and spermatids (p. 122) have been recognized and a complex lineage of cells, from spermatogonia to spermatozoa, can now be defined and identified in the seminiferous tubules of most vertebrates. Mammals have been most studied, especially rodents and domestic cattle, the latter under the impetus of artificial insemination.

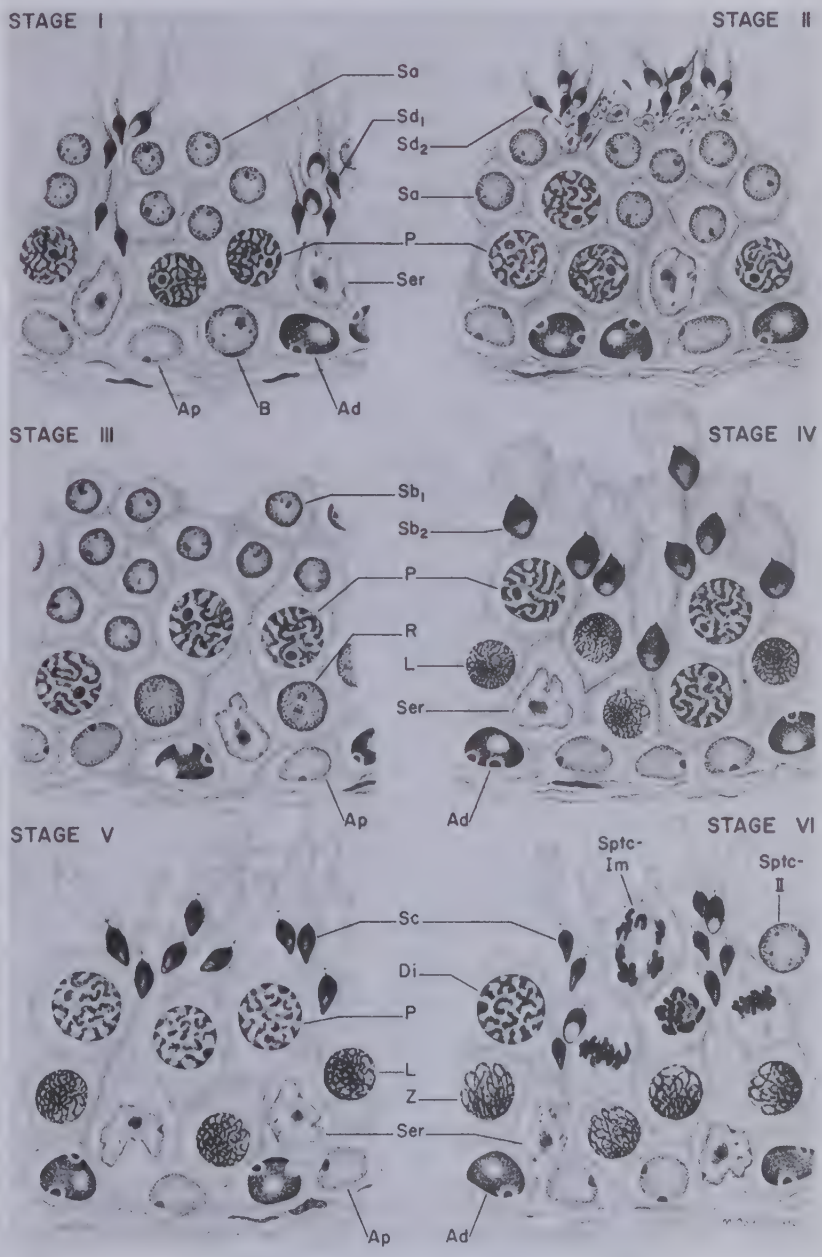
Three basic groups, *dark type A*, *pale type A*, and *type B* have been noted (p. 122); the first divides to maintain the basic store of spermatogonia, producing also some *pale* type A cells which divide and differentiate into type B, the immediate precursors of spermatocytes. More complex classifications are current; e.g. a *pro-spermatogonial stage* (A_0) is recognized, and a series, designated A_1–A_4, is utilized in describing the intermediate types in active seminiferous epithelium. Similarly, several grades of B type are recognized. Much of the complexity of current nomenclature is merely due to the successive divisions of spermatogonia, which can be investigated by labelling with radioactive thymidine. Extensive studies have been carried out in primates (Clermont 1963, 1969) and the findings are probably applicable to man. The dark A spermatogonia (A_1) form a reserve of resting cells, whereas the pale type (A_2) form further A_2 cells, one of which repeats this divisional step while the other divides into two type B spermatogonia. Since the latter produces, by serial division, several generations, these are designated B_1, B_2, etc. In monkeys (*Cercopithecus aethiops*) five generations of B spermatogonia occur, the final product being *primary spermatocytes*. There are four B spermatogonial generations in man and, since the cells (ignoring degeneration) are doubled at each stage, very large number of spermatozoa are formed during the active reproductive life of male vertebrates. The number of spermatogonial generations varies, being high in fish (six to 14), low in birds (one to three) and from four to seven in the mammals so far investigated (p. 122, Holstein 1976).

Primary spermatocytes with a diploid chromosome content divide into **secondary spermatocytes** with a haploid complement, the nuclear division designated as meiosis I. Secondary spermatocytes undergo the second meiotic division to form spermatids. Both types of spermatocytes and spermatids pass through a series of changes recognized chiefly by their nuclear activities; the latter also show profound modifications in cell structure to become the mature flagellated spermatozoa. The events of meiosis are described on p. 42.



Spermatids do not divide again but gradually mature into spermatozoa by a series of nuclear and cytoplasmic modifications (p. 122); several stages in this process have been described, according to their nuclear shape, including 'round' and 'elongating' spermatids. The range of cell types in the seminiferous epithelium is thus quite complex and to this must be added the supportive element.

Sustentacular, supporting cells (of Sertoli) **or sustentocytes**, the non-germinal element in the complex cell population of the seminiferous tubules, are variable in overall cell shape and nuclear configuration. Changes in the form and distribution of the human Sertoli cells from birth to the onset of puberty have been described by Nistal et al (1982). They observed a progressive diminution in their numbers from three years onwards, as seen in transverse sections of the tubules; but they ascribe this to



testicular growth and consider the total number constant. They have been the subject of much controversy; in developing seminiferous tubules various supporting cells beside the 'Sertolian' category are also described; but it is generally assumed that most non-germinal cells in the adult functioning tubules are of this limited type. Sustentacular cells, sited on the tubular limiting membrane, occupy it almost to the exclusion of all but occasional spermatogonia. In tangential section they are polygonal, in transverse irregular, but approximately columnar. Their apices are complicated by recesses into which spermatids and spermatozoa fit until the latter are mature enough for release. Long cytoplasmic processes also extend among the spermatogonia and spermatocytes, suggesting that sustentacular cells maintain structural cohesion in the epithelium. Electron microscopy (Fawcett 1975) has disproved the view that they are syncytial, revealing that they are in fact held together by specialized contacts similar to 'tight' junctions (p. 24) but of at least three types (Nicander 1967, Flickinger & Fawcett 1967). Sertoli demonstrated the individuality of these cells in 1865. The nucleus is irregular, often indented, weakly positive to Feulgen staining, and contains one or two nucleoli which may be tripartite, consisting of a nucleolonema (p. 40) and two associated electron-dense bodies (p. 40). Cytoplasmic organelles are numerous, particularly mitochondria, endoplasmic reticulum, secretory granules, Golgi complexes, ribosomes, microfilaments and microtubules, the last named perhaps helping to form a cytoskeleton and being also a factor in the cohesive effect of sustentacular cells on the total epithelium. These details suggest that the cells exercise a metabolic influence in relation to the germinal elements. These cells are also considered to be phagocytic (Carr et al 1968) and perhaps exert an endocrine influence too. They change considerably during the spermatogenic cycle (vide infra) and are influenced by the hypophysial hormones, LH and FSH. They are also concerned in the '*blood–testis barrier*'. For a general review consult Johnson & Gomes (1977).

THE SPERMATOGENIC CYCLE

The elements of the seminiferous epithelium noted above form an intimately related and dynamic population, details of which have been extensively investigated in several laboratory animals (particularly rats), in species of commercial or 'domestic' importance and in man. In addition to much detail on the cytological progression from spermatogonia to spermatozoa, quantitative aspects of this cycle have been assessed, including the timing of its phases, relative numbers of different germinal cells at definable temporal points and so on. It is clearly established that, at any locus in a seminiferous tubule, activities in the several generations of germinal cells and hence in the qualitative and quantitative associations of cell types pass through a *cycle*, the length and stages of which vary in different species (Clermont 1972). The cycle occupies 12–13 days in rats, only 8.6 in mice, 10.5–11.6 days in monkeys (Arsenieva et al 1961) and about 16 in mankind (Heller & Clermont 1964). Stages have been classified in two ways, one involving the development of the spermatid acrosomal

8.193 Transmission electron micrograph of part of an interstitial cell of the testis (Leydig cell) showing the profuse agranular endoplasmic reticulum and prominent mitochondria (murine). Magnification × 20 000.

8.194 The cycle of spermatogenesis in the human seminiferous tubule. For details of the six stages see accompanying text. Ser = sustentacular cells of Sertoli. Ad, Ap and B = A type (dark and pale) and B type of spermatogonia. R = resting primary spermatocyte. L, Z, P and Di = primary spermatocytes in leptotene, zygotene, pachytene and diplotene stages. Sptc-Im = dividing primary spermatocyte. Sptc-II = secondary spermatocyte in interphase. Sa, b, etc. = generations of spermatids. (From Clermont 1963 with permission of the author and the Wistar Institute of Anatomy and Biology.)

system (Leblond & Clermont 1952) and the other based on changes in cell nuclei (Roosen-Runge & Giesel 1950). Both methods were elaborated in rats, but have been applied to other mammals, birds and men. The two methods respectively indicate 14 and eight stages in rats. The *acrosomalic technique* identifies only six human stages, which will be detailed here. In many mammals the whole circumference of a short length of seminiferous tubule is in the same stage of the cycle, with adjoining, cylindrical regions displaying preceding or succeeding stages. All stages can thus be recognized in numerical succession along the tubules, the last being followed by a cylinder undergoing activity of the first stage. Each region of the tubule therefore passes through all stages and begins again. Hence there exists not only a *local* succession of stages, spread over the period of the cycle characteristic of species involved, but also a procession of stages undulating along the tubule. Such a '*spermatogenic wave*' has been measured in some species (e.g. rats and bulls, see Mochereau 1963) but the 'wavelength' has been found to be irregular and variable. Not even all quadrants of a local cylinder of human seminiferous epithelium are in the same phase at any moment. These different stages are as follows (**8**.194).

Stage I is typified by two spermatid generations: one newly formed with spherical nuclei and an older one with elongating nuclei and deeply invaginated in groups into the cytoplasm of sustentacular cells. Associated with these are primary spermatocytes starting the long pachytene stage of the first meiotic prophase division; type A (dark and pale) and type B spermatogonia adjoin the basal lamina.

Stage II also contains these two phases of spermatid maturation but they are further advanced; older spermatids are near their final change to spermatozoa and hence there are residual bodies present. Primary spermatocytes are still in pachytene but type B spermatogonia now appear in greater numbers among the dark and pale A types.

Stage III. Older spermatids are ending spermatogenesis and escaping as spermatozoa (spermiation). Nearest to them is a generation of well-advanced spermatids, external to which are two generations of primary spermatocytes, the older still in the pachytene stage, the younger cells in the proleptotene or resting stage of meiosis. Type A spermatogonia predominate, type B having become spermatocytes.

Stage IV. Spermatid nuclei are elongating, but are irregular in shape. Older primary spermatocytes are in the pachytene stage, the younger ones moving into leptotene. Type A spermatogonia are gathered external to the above cells.

Stage V. Groups of spermatids display nuclei elongated centrifugally towards the tubular periphery. Primary spermatocytes are now in *late* pachytene and some in leptotene.

Stage VI. Groups of maturing spermatids occur between primary spermatocytes dividing into secondary spermatocytes, of which some are in the interphase stage. External to them are primary spermatocytes in the zygotene stage. Type A spermatogonia (pale and dark) predominate again near the basal lamina.

Details of these complex stages accord with the successive divisions and differentiations known to occur in the germinal cell series. The process appears less regular, particularly in human biopsy material, perhaps due to mechanical disturbance; an unknown number of cells retrogress and degenerate.

The epithelium of seminiferous tubules is perhaps unique in its organization (Fawcett 1975), consisting of a permanent population of non-proliferative sustentacular cells seated on its basement membrane and interspersed proliferating spermatogonia and their derivatives; the latter are related to the basal parts of the Sertolian cells, the lateral junctions of which (**8**.191) are considered to create a '*basal compartment*' for preleptotene spermatocytes. These junctions must break down to allow spermatocytes to move towards the tubular lumen into a so-called '*adluminal compartment*'. In primates the 'blood–testis barrier' may reside in these junctions, perhaps under hormonal control; spermatogonia and early spermatocytes may be accessible to all substances crossing capillary walls, the later spermatocytes and spermatids being screened from substances incapable of passing the 'barrier'. As spermatids mature they move towards the lumen from the lateral aspects of sustentacular cells, at first embedded largely in their cytoplasm, and attached by a junctional specialization which changes (Ross 1976) until the spermatozoa are released into the lumen of the seminiferous tubule.

THE EFFERENT DUCTULES AND EPIDIDYMIS

The events described above occur in the highly coiled parts of the seminiferous tubules. As these reach the lobular apices they are less convoluted, assume an almost straight course and unite into 20–30 larger straight ducts, about 0.5 mm in diameter (**8**.189). Straight seminiferous tubules enter the fibrous tissue of the mediastinum testis, ascending backwards as a close network (*rete testis*) of anastomosing tubes lined by a flat epithelium. At the upper pole of the mediastinum, 12–20 *efferent ductules* perforate the tunica albuginea to pass from the testis to the epididymis. They are at first straight, becoming enlarged and very convoluted and forming conical *lobules of the epididymis*, which make up its head (caput). Each lobule is a convoluted duct, 15–20 cm in length. Opposite the lobular bases the ducts open into a single *duct of the epididymis*, whose coils form the epididymal body (corpus) and tail (cauda). With the coils unravelled the tube measures more than 6 metres, increasing in thickness as it approaches the epididymal tail, where it becomes the deferent duct. The coils are held together by bands of fibrous connective tissue. The epididymal body and tail are thus a single tube.

Efferent ductules are lined by ciliated columnar epithelium, with a thin circular layer of non-striated myocytes in their walls. In the epididymal duct the muscle is thicker and the epithelium composed of columnar pseudostratified cells, the superficial cells having long (15 μm) regular microvilli about 0.2 μm in diameter. Called '*stereocilia*' from a superficial resemblance to cilia, they lack the ultrastructure of true cilia. Tracer experiments have demonstrated the uptake of proteins by epithelial cells of the efferent ductules by phagocytic vesicle formation; presumably they modify the composition of seminal fluid. Electron microscopy shows inclusion bodies in the nuclei of human epididymal epithelial cells (Horstmann 1962, 1966). In man fragments of ingested spermatozoa appear in small round cells, which have cytoplasmic processes projecting into the epididymal duct (Holstein 1967). In several species the presence of lysosomal enzymes indicates an absorptive function in the epididymal epithelium (Moniem & Glover 1972). Baumgarten et al (1970) suggest that three ultrastructurally distinct types of contractile cell occur in both ductules and epididymis. These receive a sparse adrenergic innervation; few nerve fibres penetrate between the myocytes, unlike the more profuse innervation of non-striated muscle in the caput epididymis and ductus deferens. These differences accord with the slow, spontaneous, local contractions of the ductules and proximal epididymis and the rapid, reflex contractions of the caput and ductus during seminal emission.

THE TESTICULAR INTERSTITIAL TISSUE

Interstitial cells of the testis, usually equated with *cells of Leydig* (1850), also include others, some of them cells of the connective tissue lying among vessels and nerves between the seminiferous tubules. The interstitial cells of Leydig are probably mesenchymal in origin but may arise from mesonephric blastema (Witschi 1951). Such cells (**8**.193), isolated or clustered, occur in the intertubular tissue of most vertebrates including man, being large and polyhedral, with an eccentric nucleus containing: one to three nucleoli, a scanty, poorly staining cytoplasm (Hooker 1971), much agranular endoplasmic reticulum (rich in ascorbic acid), vacuoles containing fats, phospholipids and cholesterol, thus resembling the interstitial cells of the ovary (p. 1436), luteal cells of the corpus luteum (p. 1437) and secretory cells in the adrenal cortex (p. 1469). Their ultrastructural features in the human ageing testis have been described by Paniagua et al 1986. Their masculinizing effect was demonstrated by Bouin & Ancel (1903) but whether they are the sole source of testicular androgens is uncertain. Most experimental evidence demonstrates a lack of endocrine function in the tubules, rather than proving that interstitial cells are a source of androgens. However, that they do

secrete androgens is accepted; no other function can be attributed to them (Christensen 1975). They are stimulated by interstitial-cell-stimulating hormone (ICSH—identical with luteinizing hormone, LH) and possibly follicle-stimulating hormone (FSH) of the anterior lobe of the hypophysis cerebri (p. 1451). In cryptorchidism, where testes are retained in the inguinal canal and hence in a warmer environment, the rate of production of androgens and spermatozoa is depressed, without visible changes in the interstitial cells. Androgens stimulate the growth and activity of male accessory reproductive glands (prostate, seminal vesicles and bulbo-urethral glands) and also secondary sexual changes at puberty (growth of facial, axillary and pubic hair, enlargement of the larynx and paranasal air sinuses and greater skeletal growth), as well as a plethora of other actions on the general metabolism of the body, nervous system, etc. Most of these changes are inhibited or altered by oestrogens (in sufficient amounts), especially when androgenic output is depressed, as in some eunuchoid conditions (p. 1452.)

The proportion of interstitial cells of Leydig to other intertubular components varies with age and in some diseases. After initial multiplication in early fetal life, they appear to atrophy at birth; but whether they disappear or are merely depressed in number in the immediate postnatal period is uncertain (Cooper 1929, Sohval 1954). It is accepted that they reappear before puberty, perhaps developing from mesenchyme (Hisakayu & Harrison 1971). They are not reduced in the elderly (55–65 years) according to Kothari & Gupta (1974). In cryptorchid testes they are absent but total intertubular tissue is increased. For techniques of quantitative assessment in human and other mammalian testes see Dykes (1969), Heller et al (1971), Christensen (1975), and Kothari et al (1978).

THE TESTICULAR CAPSULE

Testicular coverings, already noted (p. 1424), may be summarized, proceeding internally from the surface, as composed of: skin, dartos muscle, superficial perineal fascia, external and internal spermatic fasciae with cremasteric fascia interposed, parietal and visceral layers of the tunica vaginalis (with an intervening capillary interval), tunica albuginea and tunica vasculosa. The last three form the so-called '*testicular capsule*', a concept perhaps justified by the demonstration of a contractile element in this otherwise inert, largely fibrous tissue structure (Davis & Langford 1969). In rabbits and rats isolated preparations of testicular capsule may show spontaneous contractions, reacting also to both cholinergic and adrenergic agents. Abundant autonomic nerve endings near blood vessels have been described (Norbert et al 1967); non-striated myocytes have been demonstrated in the tunica in rodents and man (Holstein 1967); the distribution of these myocytes varies and, while widely scattered in the human tunica albuginea, they are concentrated posteriorly near the epididymis. This contractile capsule probably massages or pumps the ducts in the testis, impelling spermatozoa onwards. For a review consult Davis et al (1971).

TEMPERATURE REGULATION IN THE TESTIS

Testes are external or *scrotal* in most marsupials and eutherians, but *abdominal* in fish, amphibians, reptiles, birds and monotremes. There are exceptions in some mammals: the testes are abdominal in sloths, elephants and hyraces. In aquatic mammals they are either abdominal (whales and dolphins) or in the inguinal region (seals). They may be scrotal during breeding seasons but inguinal or abdominal at other times (rodents, bats and insectivores). Such variations in mammals are puzzling but it is generally accepted that the predominantly scrotal suspension is associated with homeothermic specialization; this does not, however, explain the abdominal position of the avian testes. Regulation of internal temperature (Hammel 1968) appears to create too warm an environment for spermatogenesis. Experimental evidence, reviewed by Bishop & Walton (1960), confirms this. Scrotal temperature is usually several degrees below abdominal (three degrees in man); but the optimal range for spermatogenesis, though lower, must be maintained. Mechanisms for this are numerous (Waites 1970) and testicular thermoregulation can only be summarized here. The scrotal skin is usually hairy but this heat-conserving cover varies; it is scant in man, profuse in marsupials. Sweat glands are well developed and numerous, while subcutaneous fat is generally absent. The radiant area of scrotal skin, well vascularized, is much reduced in cold conditions by contraction of the dartos muscle, probably by direct stimulation or perhaps by local reflexes. Primate scrotal skin has many nerve endings responsive to chilling or warming, the latter type being more numerous (Iggo 1969). The cremaster muscles, by approximating the testes to the perineum, may conserve heat. *Countercurrent heat exchange* is said to exist between the arteries and veins of the spermatic cord, where both are coiled and in close apposition (Harrison & Weiner 1949). In dogs blood delivered to the testis is pre-cooled by 3°C by this mechanism (Waites & Moule 1961). Respiratory gases and other substances (including, experimentally, labelled testosterone and prostaglandin-F) are also transferred between these arteries and veins in several species, including man (Free 1977). Thus a surprising array of factors are concerned in testicular thermoregulation and maintenance of fertility; while these appear jointly involved in this function, it is suggested that the scrotum may also act in a reciprocal control of *general* body temperature.

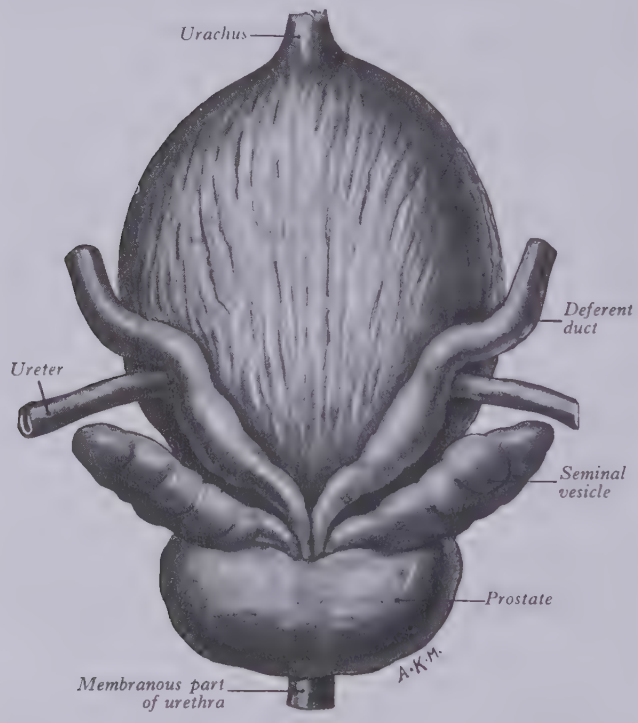
Vessels and Nerves

The *testicular artery and veins* are described on pp. 774 and 818. Intratesticular arteries have been much studied in man (Hundeiker & Keller 1963). Kormano & Suoranta (1971) noted that they are markedly coiled. Capillaries adjoining seminiferous tubules penetrate the layers of interstitial tissue and are of interest as part of the 'blood–testis barrier' (Setchell & Waites 1975, Neaves 1977). They run either parallel to the tubules or across them but do not enter their walls, being separated from germinal and supporting cells by a basement membrane and variable amounts of fibrous tissue containing interstitial cells, at which level occur selective exchange phenomena involving androgens and immune substances.

Lymph vessels of the testis end in lateral and pre-aortic lymph nodes (p. 855).

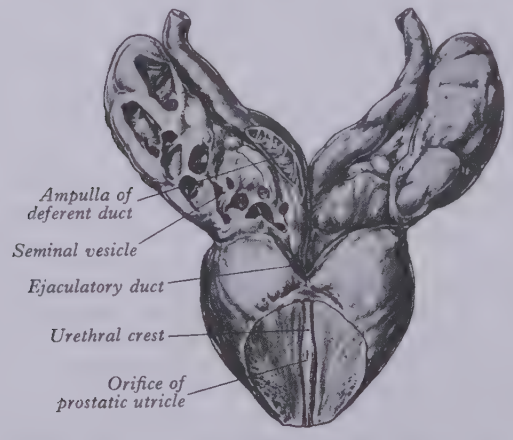
Nerves accompany the testicular vessels and are derived from the tenth and eleventh thoracic spinal segments through the renal and also the aortic autonomic plexuses (pp. 1163, 1165). Catecholaminiferous nerve fibres occur in the human testis and epididymis, forming plexuses around smaller blood vessels and among the interstitial cells (Baumgarten & Holstein 1967). Hodson (1970) has reviewed this topic.

Applied Anatomy



At an early fetal period the testes are located posteriorly in the abdominal cavity. Their descent to the scrotum (p. 256) appears to be under hormonal control (gonadotropins and androgens). In the scrotum the testes are cooler, favouring spermatogenesis (vide supra). Testicular descent may be arrested (1) in the abdomen, (2) at the deep inguinal ring, (3) in the inguinal canal, (4) between the superficial inguinal ring and the scrotum. A retained testis is probably infertile; a man with both retained (*anorchism*) is sterile but may not be impotent. Absence of one is *monorchism*. Retention in the inguinal canal is often complicated by congenital hernia, the processus vaginalis remaining patent. The testis may traverse the canal but reach an abnormal site (*ectopia testis*, p. 257). It may be inverted in the scrotum, with its normally posterior or attached border anterior and the tunica vaginalis posterior.

Serous fluid often accumulates in the scrotum, as a *hydrocele*. Usually such fluid is in the sac of the tunica vaginalis, forming a *vaginal hydrocele*. In *congenital hydrocele* the fluid is in the tunical sac but this communicates with the peritoneal cavity through a non-obliterated processus vaginalis. *Infantile hydrocele* occurs when the processus is obliterated only at or near the deep inguinal ring; it resembles vaginal hydrocele but fluid extends up the cord into the inguinal canal. If the processus is obliterated both at the deep inguinal ring *and* above the epididymis, leaving a central open part, this may distend as an *encysted hydrocele of the cord*. *Encysted hydrocele of the epididymis*, or *spermatocele*, is a cyst related



to the caput epididymis; it may contain spermatozoa and it is probably a retention cyst of one of the seminiferous tubules.

The Ductus Deferens (Vas Deferens)

The deferent duct (ductus or vas deferens), the distal continuation of the epididymis (**8**.189), starts at the epididymal tail and is at first very tortuous but, becoming straighter, ascends along the posterior aspect of the testis, medial to the epididymis. From the superior pole of the testis it ascends in the posterior part of the spermatic cord, to traverse the inguinal canal. At the internal (deep) inguinal ring it leaves the cord, curves round the lateral side of the inferior epigastric artery and ascends for about 2.5 cm anterior to the external iliac artery. It turns back and slightly down obliquely across the external iliac vessels to enter the lesser pelvis, where it continues posteriorly between the peritoneum and lateral pelvic wall medial to the obliterated umbilical artery,

8.195 Posterosuperior aspect of the male internal urogenital organs.

8.196 Anterior aspect of the seminal vesicles, terminal parts of the deferent ducts and the prostate. The lamina of the right seminal vesicle, the ampulla of the right deferent duct and of the prostatic part of the urethra have been exposed by appropriate removal of tissues.

the obturator nerve and vessels and the vesical vessels (**8**.181). It crosses the ureter (**8**.195) and medial to it bends acutely to pass anteromedially between the posterior surface of the bladder and the upper pole of the seminal vesicle, medial to which it descends in contact with it, gradually approaching the opposite duct. Here it lies between the vesical base and the rectum, separated by rectovesical fascia. It finally descends to the base of the prostate, joining at an acute angle the duct of the seminal vesicle to form the ejaculatory duct (**8**.196). Due to its thick wall and small lumen it feels cord-like when grasped. Its lumen is generally small, but posterior to the bladder it becomes dilated and tortuous, as the *ampulla*; beyond this, where it joins the seminal vesicular duct, it is again greatly diminished in calibre (**8**.195).

Structure. The wall of the deferent duct has external loose connective tissue, intermediate muscular and internal mucosal layers. The thick muscular layer is composed of non-striated myocytes arranged in external longitudinal and internal circular strata; an additional internal longitudinal layer exists at the duct's commencement. All muscle strata intermingle. The mucosa is longitudinally folded and its epithelium is columnar and non-ciliated through most of the duct; towards its distal end a bilaminar columnar epithelium appears, the superficial tier displaying non-motile stereocilia. Many of the columnar cells are secretory; for histochemical studies consult Wendler (1968). Elastic fibres are present in its connective tissue (Paniagua et al 1983).

Vessels

The deferent duct has its own artery (p. 777), usually derived from the superior vesical artery. It anastomoses with the testicular artery, thus also supplying the epididymis and testis. The anastomosis is of especial interest in connection with the toxic effects of cadmium on the mammalian testis (Gunn & Gould 1975, Johnson 1977). These appear to be due to interference with vascularization, but the artery to the ductus deferens (in rats) is apparently immune from this effect.

Aberrant Ductules

A narrow, blind, *caudal aberrant ductule* often occurs, connected with the caudal part of the epididymal duct or with the commencement of the deferent duct. Uncoiled, it varies in length from 5 to 35 cm; it may be dilated near its end, but is otherwise uniform. In structure it is like the deferent duct; occasionally it is not connected with the epididymis. A *rostral aberrant ductule* occurs in the epididymal head, connected with the rete testis. Aberrant ductules are derived from mesonephric tubules (p. 250).

Paradidymis

This is a small collection of convoluted tubules, found anterior in the spermatic cord above the epididymal head. They are lined by ciliated columnar epithelium and probably represent the remains of the mesonephros (p.250).

Seminal Vesicles and Ejaculatory Ducts

The two seminal vesicles (**8**.195) are sacculated, contorted tubes placed between the bladder and rectum. Each vesicle is about 5 cm long, somewhat pyramidal, the base being directed up and posterolaterally, and is a single coiled tube with irregular diverticula (**8**.196); the coils and diverticula are connected by fibrous tissue. The diameter of the tube is 3–4 mm and its uncoiled length is from 10–15 cm. The upper pole is a cul-de-sac, the lower narrowing to a straight duct, which joins the deferent duct to form the ejaculatory duct. The *anterior surface* contacts the posterior aspect of the bladder, extending from near the entry of the ureter to the prostatic base. The *posterior surface* is related to the rectum, separated from it by rectovesical fascia. The seminal vesicles diverge superiorly, are related to the deferent ducts and the terminations of the ureters and are partly covered by peritoneum; each has a dense, fibromuscular sheath. Along the medial margin of each vesicle is the ampulla of a deferent duct. Lateral are the veins of the prostatic venous plexus draining posteriorly to the internal iliac veins.

Structure

The wall of the seminal vesicle has three layers: external connective tissue, middle *muscular* (thinner than in the deferent duct and arranged in external longitudinal and internal circular layers) and an internal *mucosal* layer with a reticular structure. The columnar epithelium of the mucosa contains goblet cells in the diverticula, the secretion of which forms much of the seminal fluid; it is alkaline, and contains fructose (an energy source for spermatozoa) and a coagulating enzyme (vesiculase). The vesicles are *not* reservoirs for spermatozoa, these being stored in the epididymis (and possibly the ampulla of the deferent duct). The vesicles contract during ejaculation, their secretion forming most of the ejaculate.

Electron microscopy of human vesicular mucosa reveals a second epithelial type among the columnar, a small stellate cell, usually between the basal parts of the columnar cells, containing few cytoplasmic organelles. Columnar cells have microvilli, contain numerous mitochondria, a well-developed granular endoplasmic reticulum and a Golgi apparatus with numerous secretory vacuoles (Riva 1967).

Vessels and Nerves

The *arteries* of the seminal vesicles are derived from the inferior vesical and middle rectal arteries. *Veins* and *lymph vessels* accompany the arteries. *Nerves* are derived from the pelvic plexuses.

Applied anatomy. The seminal vesicles can be palpated per rectum. Abscesses in them may rupture into the peritoneal cavity.

The Ejaculatory Ducts (8.181, 196)

These are formed on each side by union of the duct of a seminal vesicle with a deferent duct. Each is almost 2 cm in length, starts from the base of the prostate, runs antero-inferiorly between its median and right or left lobes, and skirts the prostatic utricle to end on the colliculus seminalis at two slit-like orifices on, or just within, the utricular opening (p. 1421). They diminish and converge towards their ends.

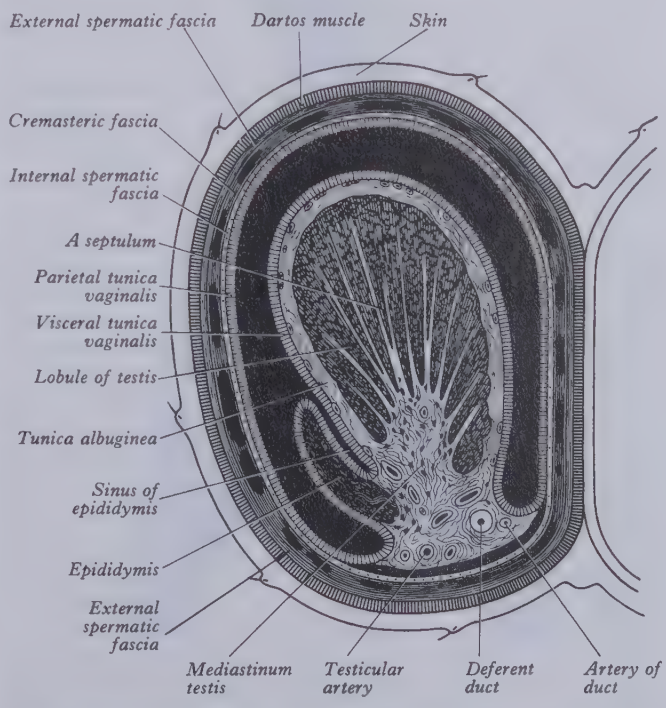
Structure. The walls of the ejaculatory ducts are thin, containing an *outer fibrous layer*, almost absent beyond their entrance into the prostate, a layer of *non-striated myocytes* in thin outer circular and inner longitudinal strata and a *mucosa* having a columnar epithelium. For details of the ejaculatory musculature, see Schlager (1967).

The Spermatic Cord and its Coverings

As the testis traverses the abdominal wall into the scrotum, it carries its vessels, nerves and deferent duct with it. These meet at the deep inguinal ring to form the *spermatic cord*, suspending the testis in the scrotum and extending from the deep inguinal ring to the posterior aspect of the testis; the left cord is a little longer than the right. Between the superificial ring and testis the cord is anterior to the rounded tendon of adductor longus and is crossed here *anteriorly* by the *superficial* and *posteriorly* by the *deep* external pudendal arteries respectively. The cord traverses the inguinal canal (p. 603) with its walls as relations, the ilio-inguinal nerve being inferior. In the canal it acquires coverings from the layers of the abdominal wall, which extend into the scrotal wall as internal spermatic, cremasteric and external spermatic fasciae.

The *internal spermatic fascia* is a thin, loose layer around the spermatic cord, derived from the transversalis fascia (p. 603). The *cremasteric fascia* contains fasciculi of skeletal muscle united by loose connective tissue to form the cremaster and is continuous with the obliquus internus abdominis (p. 599). The *external spermatic fascia*, a thin fibrous stratum continuous above with the aponeurosis of the obliquus externus abdominis, descends from the crura of the superficial ring (p. 604).

Structure of the Vessels and Nerves of the Spermatic Cord



The cord is composed of arteries, veins, lymph vessels, nerves and the deferent duct, conjoined by loose connective tissue. The *arteries* are the testicular (p. 774), cremasteric (p. 781) and deferential (p. 777). *Testicular veins* are described on p. 815. *Lymph vessels* of the testis are described on p. 855. The *nerves* are: the genital branch of the genitofemoral (p. 1141), the cremasteric nerve and the testicular sympathetic plexus (p. 1165), joined by filaments from the pelvic plexus accompanying the deferential artery.

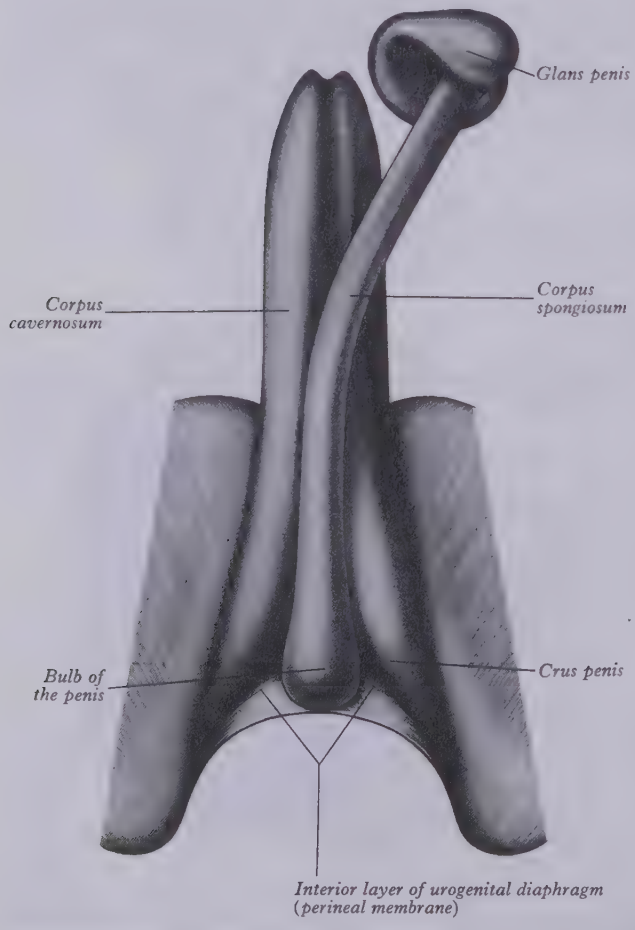
The Scrotum

The scrotum, a cutaneous fibromuscular sac containing the testes and lower parts of the spermatic cords, depends below the pubic symphysis between the anteromedial aspects of the thighs. It is divided into right and left halves by a cutaneous *raphe*, continued ventrally to the inferior penile surface and dorsally along the midline of the perineum to the anus; its left side is usually lower, due to the greater length of the left spermatic cord. The raphe indicates the bilateral origin of the scrotum from the genital swellings (p. 259). The external appearance varies: thus, when warm and in the elderly and debilitated, the scrotum is smooth, elongated and flaccid; but when cold and in the young and robust, it is short, corrugated and closely applied to the testes. It consists of skin, dartos muscle and external spermatic, cremasteric and internal spermatic fasciae. The internal spermatic fascia is loosely attached to the parietal layer of the tunica vaginalis (8.197).

The *scrotal skin*, thin, pigmented and often rugose, bears thinly scattered, crisp hairs, their roots visible through the skin; it has sebaceous glands, whose secretion has a characteristic odour and also numerous sweat glands, pigment cells and nerve endings responding to mechanical stimulation of the hairs and skin and to variations in temperature. Subcutaneous adipose tissue is lacking.

The *dartos muscle* is a thin layer of non-striated myocytes, continuous beyond the scrotum with the superficial inguinal and perineal fasciae, extending into a *scrotal septum*, connecting the raphe to the inferior surface of the penile radix and dividing the scrotum into two cavities. The septum contains all the layers of scrotal wall except skin. The dartos muscle is closely united to the skin, but is connected to subjacent parts by delicate loose connective tissue, giving it marked independence. Shafik (1977) has described a fibromuscular '*scrotal ligament*' extending from the dartos sheet to the inferior testicular pole, regarding this as thermoregulatory (p. 1429).

8.197 Diagrammatic transverse section through the left half of the scrotum and the left testis. The tunica vaginalis is represented as artificially distended to show its visceral and parietal layers.



Vessels and Nerves

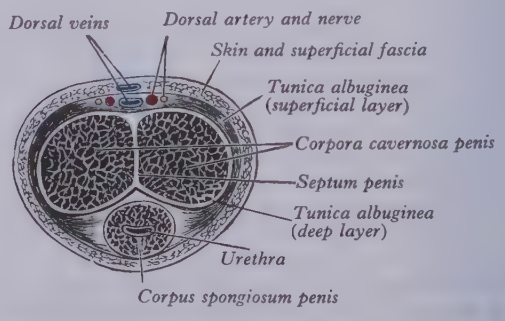
The *arteries* supplying the scrotum are the external pudendal branches of the femoral (p. 782), the scrotal branches of the internal pudendal (p. 778) and a cremasteric branch from the inferior epigastric (p. 781). Dense subcutaneous plexuses of scrotal vessels carry a substantial blood flow effecting loss of heat (Esser 1932). Arteriovenous anastomoses of a simple but large-calibre type are also prominent (Molyneux 1965 and p. 1429). The *veins* follow the corresponding arteries. The *lymph vessels* end in the inguinal lymph nodes (p. 856). The *nerves* are: the ilio-inguinal and the genital branch of the genitofemoral (p. 1141), the two posterior scrotal branches of the perineal (p. 1149) and the perineal branch of the posterior femoral cutaneous nerve (p. 1145). The scrotum's anterior third is supplied mainly from the first lumbar spinal segment (by way of the ilio-inguinal and genitofemoral nerves), while the posterior two-thirds come mainly from the third sacral (via the perineal and posterior femoral cutaneous nerves). The ventral axial line of the lower limb (p. 1151) passes between these areas. A spinal anaesthetic therefore must be injected much higher to anaesthetize the anterior region.

The Penis

The penis, the male copulatory organ, comprises an attached *radix* or *root* in the perineum and a free, normally pendulous *corpus* or *body* completely enveloped in skin.

The radix of the penis comprises the three masses of erectile tissue in the urogenital triangle: the two crura and the bulb of the penis, firmly attached to the pubic arch and perineal membrane respectively. The crura and bulb are posterior regions of the corpora cavernosa and corpus spongiosum. Each *crus penis* (**8**.198) commences behind as a blunt, elongate but round process, attached firmly to the everted edge of the ischiopubic ramus and covered by ischiocavernosus (p. 608). Anteriorly it converges towards its fellow and is slightly enlarged posterior to this. Near the inferior symphysial border the two crura bend sharply down and forwards to become the corpora cavernosa. The *bulb of the penis* (**8**.181, 198) is between the crura and firmly connected to the inferior aspect of the perineal membrane, from which it receives a fibrous covering. Oval in section, it narrows anteriorly into the corpus spongiosum, bending sharply down and forwards here. Its convex superficial surface is covered by bulbospongiosus; its flat deep surface is pierced by the urethra, which traverses it to reach the corpus spongiosum. This part of the urethra has an intrabulbar fossa (p. 1422).

8.198 Ventral aspect of the constituent erectile masses of the penis in erect position. The glans penis and the distal part of the corpus spongiosum are shown detached from the corpora cavernosa penis and turned to the left.



The corpus of the penis contains three elongated erectile masses, capable of much enlargement when engorged with blood during erection. When flaccid it is cylindrical, but when erect it is triangular with rounded angles (**8**.199). The surface which is posterosuperior during erection is termed the *dorsum of the penis* and the opposite aspect the *urethral surface*. The erectile masses are termed the right and left *corpora cavernosa* and the median *corpus spongiosum penis*, continuations of the crura and bulbus penis.

The *corpora cavernosa penis* form most of its body. In close apposition throughout, they have a common fibrous envelope and are separated only by a median fibrous septum. On the urethral surface their combined mass has a wide median groove, adjoining the corpus spongiosum (**8**.199); dorsally a similar but narrower groove contains the deep dorsal vein. The corpora end in the hollow, proximal aspect of the glans penis in a rounded cone, on which each has a small terminal projection (**8**.198). They are enclosed in a strong fibrous *tunica albuginea*, consisting of superficial and deep strata. The superficial fibres are longitudinal, forming a single tube round both corpora; the deep fibres are circular and surround each corpus separately, joining as a median *septum of the penis*, which is thick and complete proximally but imperfect distally where it is a pectiniform series of bands; hence the term *pectiniform septum*.

The *corpus spongiosum penis*, traversed by the urethra, adjoins the median groove on the urethral surface of the conjoined corpora cavernosa. It is cylindrical, tapering slightly distally, and surrounded by the tunica albuginea. Near the end of the penis it expands into a somewhat conical enlargement like an acorn, whence its name, *glans penis* (**8**.198).

The *glans penis* projects dorsally over the end of the corpora cavernosa, with a shallow concave surface to which they are attached. Its base has a projecting *corona glandis*, overhanging an obliquely grooved *neck of the penis*. The navicular fossa (p. 1151) of the urethra is in the glans and opens by a sagittal slit on or near its apex.

Penile skin is remarkably thin, dark and loosely connected to the tunica albuginea. At the neck of the penis it is folded to form the *prepuce* or foreskin, variably overlapping the glans. The internal preputial layer is confluent at the neck with the thin skin covering and firmly adherent to the glans and by this with the urethral mucosa at the external urethral orifice. On the urethral aspect of the glans a median fold passes from the deep surface of the prepuce to the glans immediately proximal to the orifice; this is the *frenulum*. Cutaneous sensitivity, high on the general surface of the glans, is accentuated near the frenulum. The prepuce and

8.199 Transverse section of human penis.

glans penis enclose a potential cleft, the *preputial sac*, with two shallow fossae flanking the frenulum. On the corona glandis and penile neck are numerous small *preputial glands*, secreting sebaceous *smegma*.

The *superficial penile fascia*, devoid of fat, consists of loose connective tissue, invaded by a few fibres of dartos muscle from the scrotum (p. 1431). As in the suprapubic abdominal wall, the deepest layer is condensed, here as the *fascia penis* surrounding both the corpora cavernosa and corpus spongiosum and separating the superficial and deep dorsal veins. At the penile neck it blends with the fibrous covering of all three corpora. Proximally, it is continuous with the dartos muscle and with the fascia covering the urogenital region of the perineum (p. 1431).

The corpus penis is supported by two ligaments continuous with its fascia and consisting largely of elastin fibres. The *fundiform ligament* (5.45), from the lowest part of the linea alba, splits into two lamellae which skirt the penis and unite below with the scrotal septum. The triangular *suspensory ligament*, deep to the fundiform ligament, is attached above to the front of the pubic symphysis, blending below, on each side, with the fascia penis.

Structure of the Penis

From the inside of the fibrous sheaths of the corpora cavernosa and the sides of their septum numerous *trabeculae* arise, crossing them in all directions and creating *cavernous spaces*, which give them a spongy form (8.199). These trabeculae are of collagen and elastin fibres and non-striated myocytes and contain numerous vessels and nerves. The cavernous spaces are filled with blood during erection, but most are empty in the flaccid penis. They are lined by flat endothelial cells without fenestrae (Leeson & Leeson 1965).

The fibrous tunica albuginea of the corpus spongiosum is thinner, whiter, more elastic than that of the corpora cavernosa and is formed partly of non-striated myocytes; a layer of the same tissue surrounds the urethral epithelium (p. 1422).

Vessels and Nerves

The *arteries* supplying the cavernous spaces are the deep penile arteries (p. 779) and branches of the dorsal penile arteries which perforate the tunica albuginea along the dorsum, especially near the glans. On entry the cavernous arteries divide into branches in the trabeculae, some ending in capillary networks opening into the cavernous spaces; others become convoluted and somewhat dilated *helicine arteries*, which open into the cavernous spaces and from them capillary branches supply the trabeculae. Helicine arteries are most abundant in the posterior region of the corpora cavernosa (Alvarez-Morujo 1968).

The veins drain the cavernous spaces by means of a series of vessels, some emerging from the base of the glans and converging on the dorsum penis to form the deep dorsal vein, others leaving the corpora cavernosa to join the same vein; some also emerge inferiorly from the corpora cavernosa and, receiving tributaries from the corpus spongiosum, curve round to the deep dorsal vein, but many leave at the root of the penis to join the prostatic plexus (p. 816).

Erection is purely vascular and independent of compression by the ischiocavernosi and bulbospongiosus. Rapid inflow from the helicine arteries fills the cavernous spaces and the resulting distension also contributes to erection by pressure on the veins which drain the erectile tissue.

The lymph vessels are described on p. 855.

The *nerves* are from the second, third and fourth sacral spinal segments via the pudendal nerve and pelvic plexuses (p. 1115). On the penile glans and bulb some cutaneous filaments connect with lamellated corpuscles and many end in characteristic end bulbs (p. 910). Cutaneous stimulation of the glans and frenulum contributes much to the maintaining erection and to initiation of orgasm and ejaculation.

The Prostate

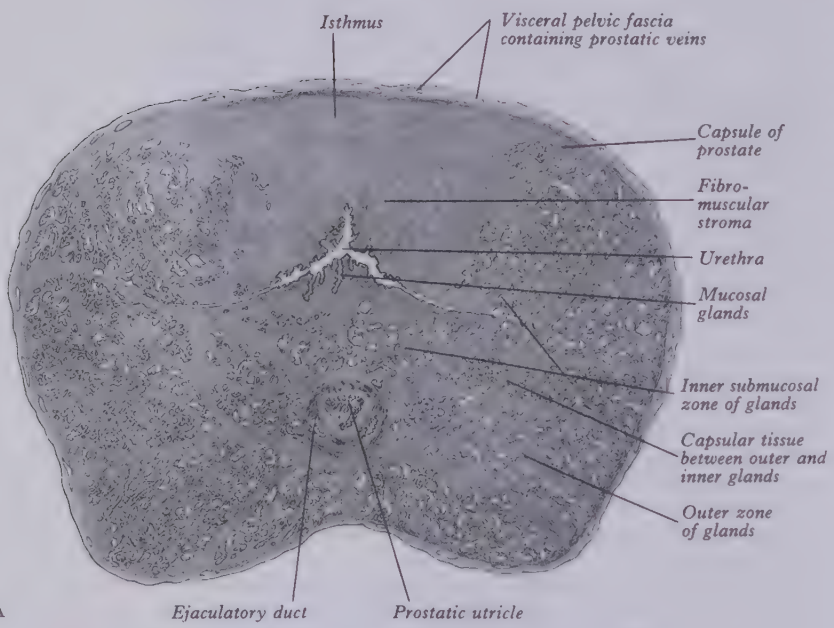
The prostate (8.187,195,196), a firm, partly glandular, partly fibromuscular body, surrounds the beginning of the male urethra. It lies at a low level in the lesser pelvis, behind the inferior border of the symphysis pubis and pubic arch and anterior to the rectal ampulla, through which it may be palpated. Being somewhat conical, it presents: above, a base or vesical aspect; below, an apex and also a posterior, an anterior and two inferolateral surfaces.

The *base* is largely contiguous with the neck of the bladder above it; the urethra enters here, nearer its anterior border. The *apex* is inferior and in contact with the fascia on the superior aspects of the sphincter urethrae and tranversi perinei profundi (p. 607).

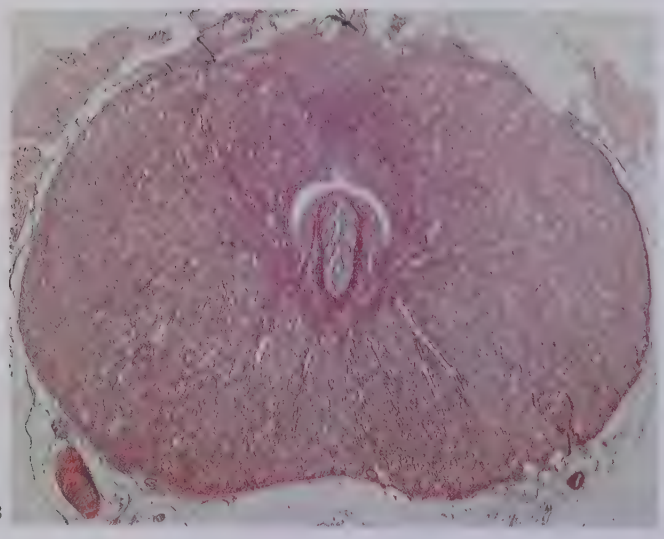
The *posterior surface*, transversely flat and vertically convex, is separated from the rectum by the prostatic sheath and loose connective tissue external to the sheath. Near its superior (juxtavesical) border is a depression where the two ejaculatory ducts penetrate the gland, dividing this surface into a superior and an inferior, larger part. The superior part is variable in size and usually regarded as the external aspect of the *median lobe*; the inferior part shows a shallow, median sulcus, usually considered to mark a partial separation into *right and left lateral lobes*, forming the main prostatic mass and continuous behind the urethra. A band of fibromuscular tissue, ventral to the urethra, joins these lobes together and is often referred to as the anterior lobe; it contains less glandular tissue than the rest of the gland. This simplified view of prostatic lobation, based mainly on the classic work of Lowsley (1912), is retained here despite many modifications introduced by subsequent observers with persistent confusions and inconsistencies which have not yet been completely resolved. Some deny any topographical lobation and those who favour it differ on boundaries and terminology. McNeal (1975) has analysed these disagreements. Lobation became important through the conviction among some investigators that malignant tumours occur in particular prostatic regions. This interest prompted the work of Tisell & Salander (1975) who claim to have confirmed a recognizable lobar structure after dissection of more than 100 human prostate glands. They recognize two large *lateral lobes* but consider that these do not appear on the dorsal (rectal) aspect, which they describe as occupied by paired *dorsal lobes* extending laterally to form the apex. They recognize *median lobes*, around the urethra (except at the apex), deep to the dorsal and lateral lobes; their median lobes may be equated with the *internal zone* described below. All three pairs of lobes are, they affirm, separable by dissection. It is impossible to reconcile the differences between this and other descriptions and the question of lobation must be left sub judice (Goland 1975).

The *anterior surface*, transversely narrow and convex, extends from the apex to the base, about 2 cm behind the pubic symphysis from which it is separated by a venous plexus and loose adipose tissue. Near its superior limit it is connected to the pubic bones by the puboprostatic ligaments. The urethra emerges from this surface anterosuperior to the apex.

The *inferolateral surfaces* are related to the anterior parts of the levatores ani, which are separated from them by a plexus of veins embedded in the fibrous prostatic sheath.



The prostatic base measures about 4 cm transversely, the gland being about 2 cm in anteroposterior and 3 cm in its vertical diameters. It weighs about 8 g. It has a fibrous sheath, partly vascular; on each side this consists of fibrous tissue containing the prostatic venous plexus (6.170); anteriorly it blends with the puboprostatic ligaments (p. 1417) and inferiorly with fascia on the deep surfaces of the sphincter urethrae, the deep transverse perineal muscles and with the perineal body (5.54). Posteriorly the sheath has a different origin and is avascular. In male fetuses, at the fourth month, the rectovesical peritoneal pouch descends to the pelvic floor, separating prostate from rectum; its lower part is obliterated and the fused peritoneal layers here form the posterior prostatic sheath (Smith 1908), sometimes termed the *rectovesical fascia*. Traces of its separate layers persist as a plane of cleavage. Above, it ascends over the posterior aspects of the seminal vesicles and deferent ducts and is connected to the floor of the rectovesical pouch (5.54); on each side, it joins with the posterior vesical ligament (p. 1417). Below, adherent to the prostate, it joins the perineal body. Some have denied this peritoneal fusion and consider the rectovesical fascia to be a condensation of areolar tissue (Silver 1956). The anterior parts of the levatores ani pass back from the pubis around the prostate as *levatores prostatae*.



The prostate is traversed by the urethra and ejaculatory ducts and contains the prostatic utricle. The urethra usually passes between its anterior and middle thirds. The ejaculatory ducts pass antero-inferiorly through its posterior region to open into the prostatic urethra (p. 1421).

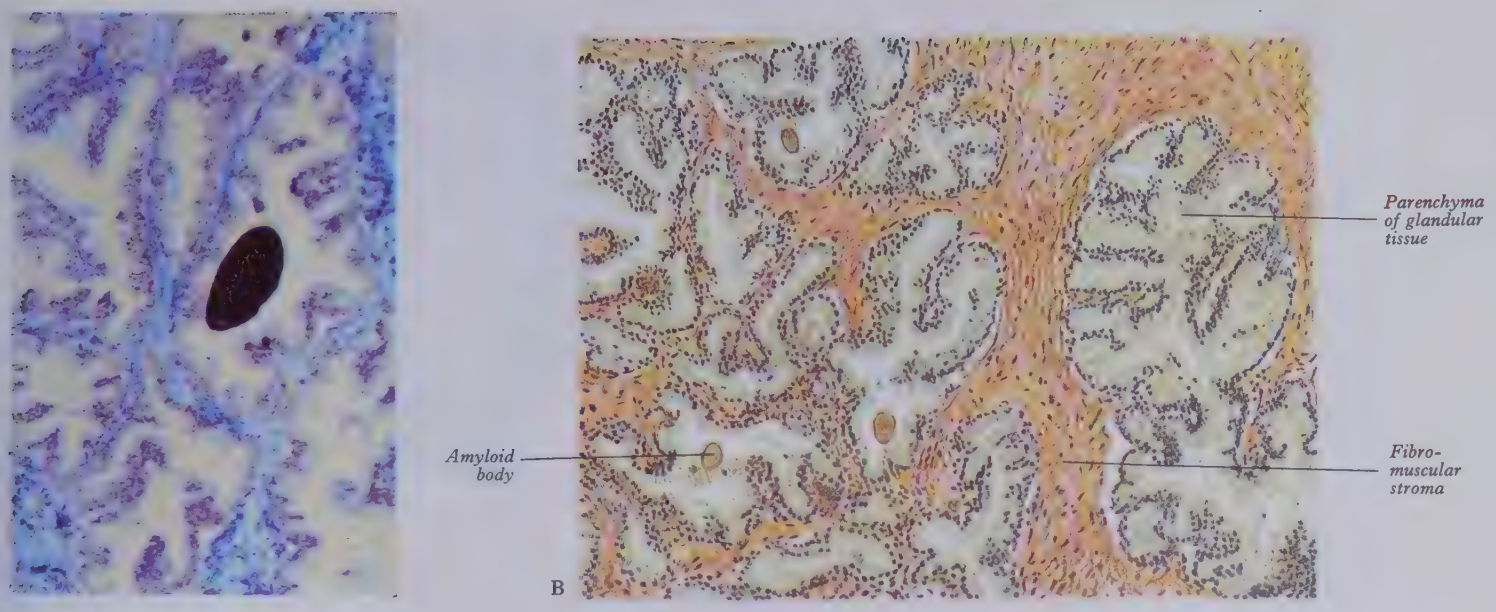
Structure (**8**.200, 201)

The prostate is grey to reddish according to its activity and very dense. It is enveloped in a thin, dense, fibrous capsule within a sheath derived from pelvic fascia, the latter containing a venous plexus. The capsule is firmly adherent to the gland and continuous with a median septum in the urethral crest separating the lateral masses below the level of the colliculus seminalis. It is also continuous with numerous fibromuscular septa enmeshing the glandular tissue.

The *muscular tissue* is mainly non-striated (Hutch & Rambo 1970); ventral to the urethra a layer of non-striated myocytes curves to merge with the main mass of muscle in the fibromuscular septa; superiorly it is continuous with vesical non-striated muscle. However, anterior to this a transversely crescentic mass of skeletal muscle is continuous inferiorly with the sphincter urethrae in the deep perineal pouch. Its fibres pass transversely internal to the capsule, attached to it laterally by diffuse collagen bundles; other collagen bundles pass posteromedially, merging with the prostatic fibromuscular septa and the septum of the urethral crest. This muscle, supplied by the pudendal nerve, probably compresses the urethra (Haines 1969) but it is suggested that it may pull the urethral crest back and the prostatic sinuses forwards, dilating the urethra; glandular contents may be expelled simultaneously into the urethra, thus expanded to contain seminal fluid (3–5 ml) during the period of sexual excitement prior to ejaculation.

8.200 Human prostate. A. Transverse section at a level to show the prostatic utricle and ejaculatory ducts. B. Transverse section to show the urethral crest. Stained by haematoxylin and eosin and lent by L M Franks, Imperial Cancer Research Institute, London and photographed by K Fitzpatrick. Compare with A and see text for further details. Both A and B are slightly more than twice the natural size. Ventral is to the top in both figures.

The *glandular tissue* consists of numerous follicles with frequent internal papillae. Follicles open into elongated canals, which join to form 12–20 excretory ducts. The follicles are conjoined by loose connective tissue, supported by extensions of the fibrous capsule and muscular stroma and enclosed in a delicate capillary plexus. Canalicular and follicular epithelium is columnar; electron microscopy reveals luminal microvilli, relatively few short profiles of granular endoplasmic reticulum and some free ribosomes. Lysosomal vesicles, containing acid phosphatase, also occur. The apposed borders of these cells are mainly straight, the plasma membranes being united by desmosomes (Fisher & Jeffrey 1965). *Prostatic ducts* open mainly into the prostatic sinuses in the floor of the prostatic urethra; they have a bilaminar epithelium, the luminal layer is columnar and the basal has small cubical cells. Small colloid *amyloid bodies* often occur in the follicles. The prostatic and seminal vesicular secretions form the bulk of the seminal fluid. The former is slightly acid, containing acid phosphatase and fibrinolysin.



Histological sections (**8**.200) do not show a lobar pattern, but two concentric zones of glandular tissue, being partially circumurethral, are distinguishable (Le Duc 1939, Franks 1954, Fergusson & Gibson 1956). The larger *peripheral zone* has long, branched glands, whose ducts curve posteriorly to open mainly into the prostatic sinuses, though a few open on the lateral urethral walls. The *internal zone* consists of 'submucosal' glands, with ducts opening on the floor of the prostatic sinuses and colliculus seminalis and an *innermost* group of simple 'mucosal' glands, surrounding the upper prostatic urethra. Anteriorly, in the prostatic isthmus (**8**.200A), the peripheral zone and 'submucosal' glands are absent. Peripheral and internal zones are said to be separated by an ill-defined 'capsule'. Carcinoma affects almost exclusively the peripheral zone, the internal being prone to benign hypertrophy, such enlargements projecting into the bladder, displacing the peripheral zone postero-inferiorly and thus accentuating the 'capsule' between outer and inner zones. This provides a 'cleavage plane' which is used in surgical enucleation.

Vessels and nerves. The *arteries* (Clegg 1955, 1956) are rami of the internal pudendal, inferior vesical and middle rectal arteries. The *veins* form a plexus around the prostatic sides and base (p. 816), receiving in front the deep dorsal penile vein and draining to the internal iliac veins. The *lymph vessels* are described on p. 856. The *nerves* come from the inferior hypogastric (pelvic) plexus (p. 1116).

Age Changes in the Prostate

At birth (Swyer 1944) the prostate has a system of ducts embedded in a stroma which forms a large part of the gland. Follicles are represented by small end buds on the ducts. There is hyperplasia and squamous metaplasia of epithelium of the ducts, colliculus seminalis and prostatic utricle, possibly due to maternal oestrogens in the fetal blood. These changes subside within six or seven weeks and little structural change follows until about the ninth year, when hyperplasia of the ductual epithelium and formation of side buds causes an elaboration of the system of ducts; up to puberty the prostate grows slowly and continuously.

At puberty, over a period of six to twelve months, the gland more than doubles in size, due almost entirely to follicular development, partly from end buds on ducts, partly from modification of the ductual branches. This growth is associated with

8.201 Characteristic fields of the human prostate. Note the highly convoluted columnar epithelium, forming papillary projections into the lumen of a follicle, and abundant interfollicular fibromuscular tissue. Specimen shown in A provided by Abla el Nasser (1980).

a condensation of the stroma, which diminishes relative to the glandular tissue, probably due to the secretion of testosterone into the bloodstream by the testis.

During the third decade the glandular epithelium grows by irregular multiplication of the epithelial infoldings into the lumen of the follicles. *After the third decade* the size remains unaltered until 45–50 years. Epithelial foldings tend to disappear, follicular outlines becoming more regular, and amyloid bodies increase in number. All of these changes are signs of prostatic involution.

After 45–50 years the prostate may undergo benign hypertrophy, its size increasing until death, or alternatively it may undergo progressive atrophy.

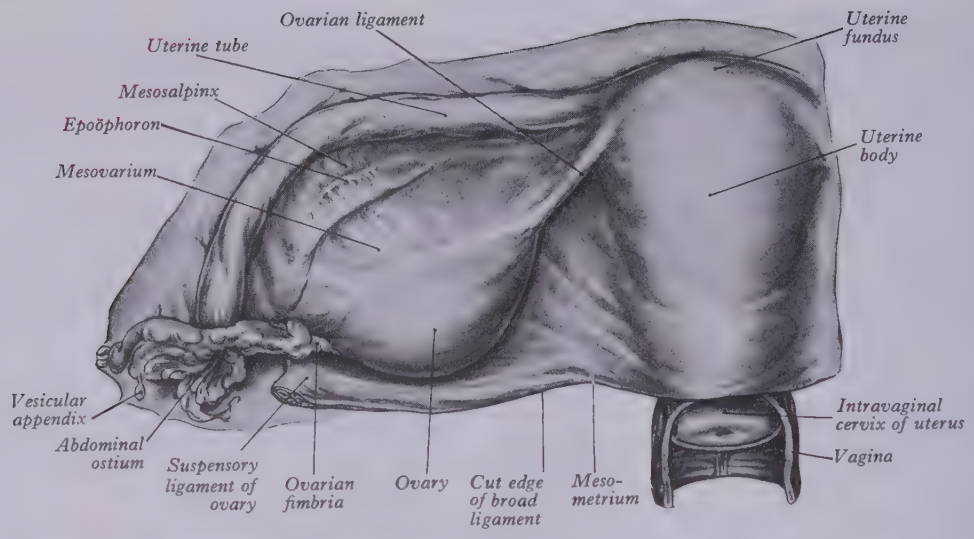
Applied Anatomy

After middle age the prostate often enlarges, projecting into the bladder to impede urination by distorting the prostatic urethra. The median lobe may enlarge the most, with even a small enlargement obstructing the internal urethral orifice; the more the patient strains, the more the prostatic mass, acting like a valve, blocks the opening. The hypertrophied part may be removed surgically (prostatectomy).

Valveless venous communications between the prostatic and extradural venous plexuses normally occur, probably an important factor in the metastasis of prostatic neoplasms to the vertebral bodies (Batson 1940, Franks 1953).

THE BULBO-URETHRAL GLANDS

The two bulbo-urethral glands (**6**.112), small, round, yellow, somewhat lobulated and about a centimetre in diameter, lie lateral to the membranous urethra above the perineal membrane and penile bulb and are enclosed by fibres of the sphincter urethrae. They gradually diminish in size in the later decades. The excretory duct of each, almost 3 cm long, passes obliquely forwards external to the mucosa of the membranous urethra and penetrates the inferior urogenital fascia (perineal membrane) to open by a minute orifice on the floor of the spongiose urethra about 2.5 cm below the perineal membrane.



Structure. The gland has several lobules held together by a fibrous capsule. The lobules consist of acini of columnar epithelial cells. Their secretion is added to the seminal fluid but human bulbo-urethral glands are comparatively small and their role is uncertain.

REPRODUCTIVE ORGANS OF THE FEMALE

The female reproductive system consists of: *internal organs* situated within the lesser pelvis, namely the ovaries, uterine tubes, uterus and vagina; and *external organs* lying antero-inferior to the pubic arch, namely the mons pubis, labia majora et minora, pudendi, clitoris, vestibular bulbs, greater vestibular glands and vestibule.

The Ovaries

The ovaries (**8**.202, 209), are homologous with the testes and like these they develop from the genital ridges (p. 255). Situated one on each side of the uterus close to the lateral pelvic wall, they are attached to the posterosuperior aspect of the broad uterine ligament, postero-inferior to the uterine tube (**8**.202). They are greyish-pink and smooth before ovulation begins but thereafter are distorted by the degeneration of successive corpora lutea. Each is almond-shaped (amygdaloid), about 3 cm long, 1.5 cm wide and 1 cm thick. Its position varies much in parous women, because it is displaced in the first pregnancy and probably never returns to its original location. Also variably mobile, it may change position according to the state of surrounding organs, such as the intestines. In nulliparous women, in the upright position, its long axis is vertical; it has lateral and medial surfaces, tubal and uterine extremities and mesovarian and free borders. It occupies the *ovarian fossa*, on the lateral pelvic wall, bounded anteriorly by the obliterated umbilical artery and posteriorly by the ureter and internal iliac artery. To the *tubal* (superior) *extremity*, near the external iliac vein, are attached the ovarian fimbria of the uterine tube and a peritoneal *ovarian suspensory ligament*, which contains the ovarian vessels and nerves and passes over the external iliac vessels (**8**.209) to join the peritoneum on the psoas major, posterior to the caecum or descending colon. The *uterine* (inferior) *extremity* faces downwards towards the pelvic floor; it is usually narrower than the tubal extremity and is attached to the lateral uterine angle postero-inferior to the uterine tube by a

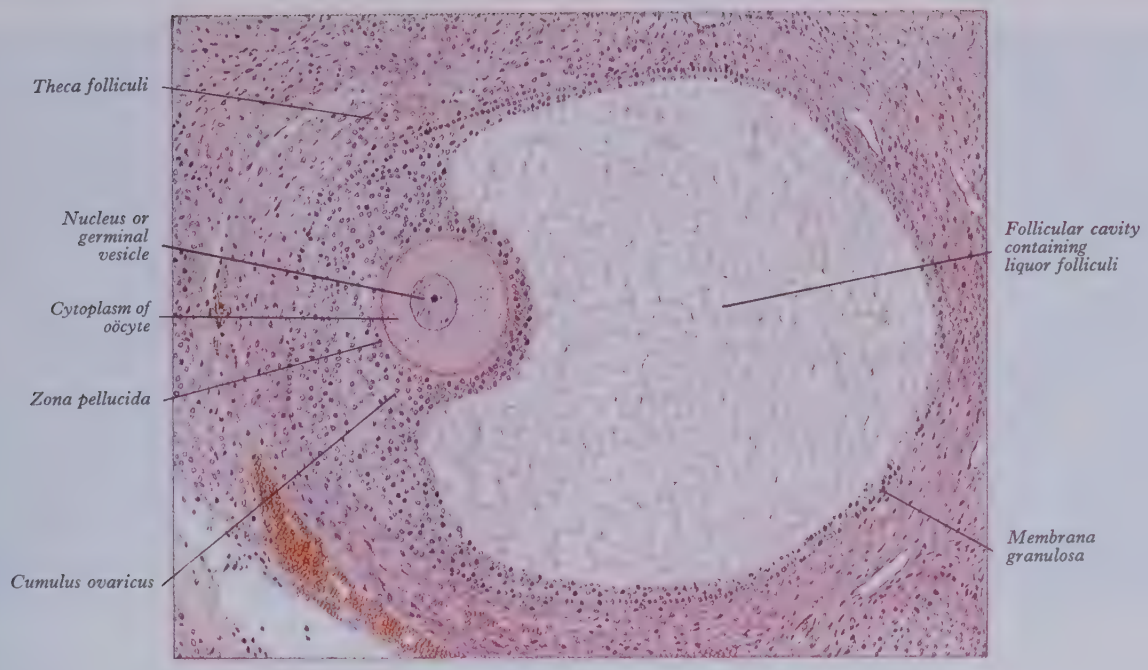
8.202 Posterosuperior aspect of the uterus and the left broad ligament. The 'ligament' has been spread out and the ovary is displaced downwards.

rounded *ovarian ligament* which lies in the the broad ligament and contains non-striated myocytes. The *lateral surface* contacts parietal peritoneum in the ovarian fossa and is separated by it from extraperitoneal tissue and the obturator vessels and nerve. The uterine tube largely covers the *medial surface*; the peritoneal recess here, between the ovary and overlapping mesosalpinx (p. 1445), is termed the *ovarian bursa*. The *mesovarian border*, straight and facing the obliterated umbilical artery, is attached to the back of the broad ligament by a short peritoneal fold, the *mesovarium*, in which blood vessels and nerves reach the ovarian hilum. The convex *free border* faces the ureter. The uterine tube arches over the ovary, ascending in relation to its mesovarian border, to curve over its tubal end and pass down on its free border and medial surface (**8**.209).

In embryonic and early fetal life the ovaries are, like the testes, juxtarenal in the lumbar region but they gradually descend into the lesser pelvis (p. 429). Accessory ovaries may occur in the mesovarium or in the adjacent broad ligament.

Structure of the Ovary

The surface is covered, in young females, by a layer of cuboidal cells which flatten in later life. This so-called *germinal epithelium* gives to the ovary a dull grey colour, contrasting with the shining, smooth peritoneum; the transition between peritoneum and ovarian epithelium is usually marked by a white line around the anterior, mesovarian border.



8.203 Semi-diagrammatic section of an ovary.

After puberty the ovary has a thick cortex containing ovarian follicles and corpora lutea surrounding a vascular medulla, except at the hilum. The dense *cortical stroma* contains woven reticular fibres and many fusiform cells, resembling non-striated myocytes but possibly mesenchymal. These cells contribute to growth of the theca folliculi (vide infra) and may secrete oestrogens. *Medullary* stroma consists of a looser connective tissue, with many elastin fibres, non-striated myocytes and numerous blood vessels, particularly veins. At the hilum, strands of myocytes enter the medulla from the mesovarium. The cortex is much less vascular than the medulla. Beneath the germinal epithelium, the cortical connective tissue condenses into a delicate *tunica albuginea*, increasing in density with age. It is collagenous, unlike the general ovarian stroma. The prenatal cortical stroma contains small groups of *interstitial cells*, persisting after puberty only in the thecae of atretic follicles.

Ovarian Follicles

At birth, the ovarian cortex contains many *primary ovarian follicles*. Each has a large central *oögonium* surrounded by a single layer of small cuboidal or flat *follicular cells*. Their prenatal development is described on p. 255. Many degenerate during childhood and after puberty, some developing each month as *vesicular ovarian (Graafian) follicles*, one usually maturing and rupturing (ovulation). During the child-bearing period (i.e. until menopause) the cortex contains ovarian follicles, corpora lutea and atretic follicles (**8**.203).

Primary follicles become vesicular as follows: follicular cells multiply to form many layers and a cavity (the *antrum folliculi*) containing *liquor folliculi* appears among them between an outer group, forming the *membrana granulosa* and an inner around the presumptive ovum, attaching it to one pole of the follicle and forming the *cumulus ovaricus* (**8**.204). Cortical stromal cells form a *theca folliculi* around the follicle; this consists of an inner *tunica interna*, which is cellular and permeated by capillaries, and an outer, fibrous *tunica externa*. The tunica interna is separated from the membrana granulosa by a basal lamina. As follicles mature, the tunica interna is well-defined as the '*thecal gland*'. Its cells and those of the membrana granulosa produce oestrogenic hormones (primarily oestradiol), the follicular development being stimulated by the hypophysial gonadotropic hormone (follicle stimulating hormone, FSH). Meanwhile the oögonium becomes a *primary oöcyte*, dividing meiotically into a haploid *secondary oöcyte* and first polar cell. When a mature follicle ruptures (ovulation), the secondary oöcyte is extruded; a second polar cell is only formed if fertilization occurs. During maturation a presumptive ovum grows from 30 μm in the primordial follicle to 110 μm in the mature follicle, largely due to the accumulation of *deutoplasm* or yolk within the cell.

8.204 Section through an ovarian follicle from a woman aged 28 years. Stained with haematoxylin and eosin. Magnification × 90.

A mature follicle is about 10 mm in total diameter; usually one matures and ruptures in each monthly cycle; *anovulatory* cycles may occur. However, several other small vesicular follicles may also develop but degenerate to form *atretic follicles*, cells of their tunicae internae becoming interstitial ovarian cells like those of the testis (p. 1425).

Ovulation

When a mature vesicular follicle ruptures at the ovarian surface the secondary oöcyte, surrounded by the cumulus ovaricus, is expelled and enters the uterine tube at its fimbriated end. If fertilization occurs, it usually does so in the lateral third of the uterine tube; if it does not, the oöcyte begins to degenerate after 24–48 hours. Ovulation is usually 12–16 days before the expected onset of a menstrual cycle.

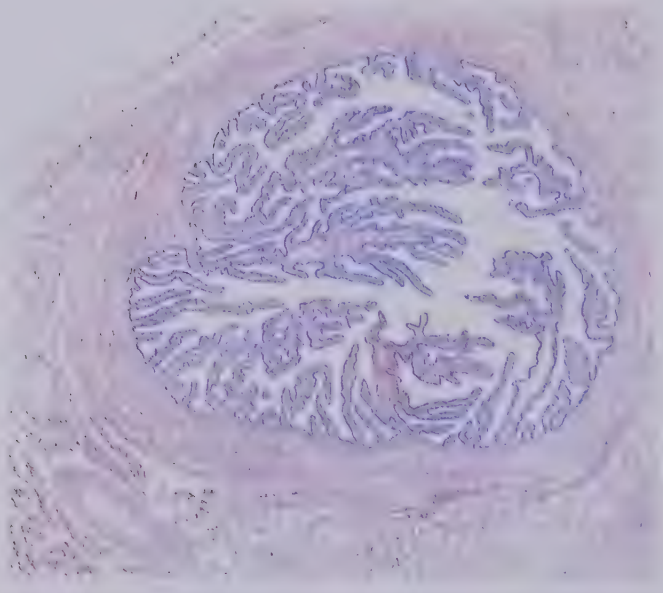
Corpus Luteum

After ovulation, the walls of the empty follicle collapse and fold, cells of the membrana granulosa increasing in size and forming a cytoplasmic carotenoid pigment (lutein). Such *luteal cells* form most of the *corpus luteum* (8.203). Smaller *paraluteal cells*, derived from the tunica interna, appear among the superficial luteal cells. The basement membrane outside the granulosa cells vanishes, allowing capillaries to grow in between the luteal cells from vessels in the tunica interna. Blood coagulum forms in the corpus luteum; if fertilization fails, the corpus luteum functions for about 12–14 days, then degenerates into a *corpus luteum of menstruation*. Changes include fatty degeneration of the luteal cells and gradual replacement by fibrous tissue; eventually, after about two months, a small cicatricial *corpus albicans* remains. Hypophysial follicle stimulating (FSH), luteinizing (LH) and luteotropic (LTH, prolactin or lactogen) hormones activate the conversion of granulosal into luteal cells, which produce progesterone; luteal and paraluteal cells also produce some oestradiol. (For the action of these ovarian hormones on uterine endometrium see pp. 146–149.)

If fertilization occurs, implantation of the blastocyst into the endometrium usually begins on the seventh day thereafter; the trophoblast begins to produce FSH, LH, progesterone and oestradiol. These chorionic gonadotropins (FSH and LH) stimulate the corpus luteum of menstruation to grow and become a *corpus luteum of pregnancy*. Whereas the former is active for 12–14 days and is usually about 1 cm in diameter, the latter increases to about 2.5 cm in diameter at mid-gestation and remains active. By the end of pregnancy it is reduced to about 1 cm and in the next few months it degenerates like a corpus luteum of menstruation.

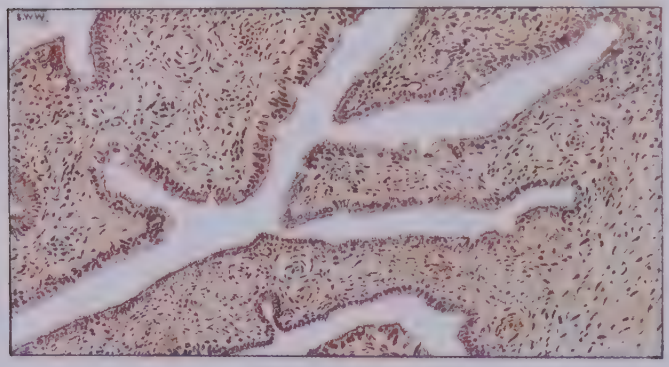
As females age, ovaries are increasingly fibrosed by corpora albicantia; after menopause, usually near 50 years, ovarian activity involving the formation of follicles and corpora lutea ends.

Vessels and Nerves



The *arteries* of the ovaries and uterine tubes are the ovarian branches of the abdominal aorta (p. 776). The *veins* emerge from the ovarian hila as a *pampiniform plexus*, drained by the ovarian veins (p. 818). *Lymph vessels* are described on p. 856. The *nerves*, derived from the ovarian plexuses (p. 1165), are postganglionic sympathetic, parasympathetic and autonomic afferent fibres, but little is known of their actual distribution or function, particularly in humans. Bulmer (1965) and Owman et al (1967) have demonstrated cholinergic nerve fibres in the stroma histochemically. (See Neilson et al 1970, for a review.) Balboni (1971) has described the distribution of adrenergic fibres. The structures innervated, apart from the vessels, remain uncertain.

Vestigial Structures



The *epoöphoron* (8.202), in the lateral part of the mesosalpinx (p. 250) between the ovary and uterine tube, consists of 10–15 short, blind-ended *transverse ductules* converging towards the ovary; their other ends open into a rudimentary *longitudinal duct*, running medially in the broad ligament, parallel with the lateral part of the uterine tube. Between the epoöphoron and the fimbriated end of the tube are often one or more small cystic *vesicular appendices*. Occasionally the longitudinal epoöphorontic duct (*duct of Gartner*) runs along the uterus nearly to the internal os, penetrating its muscular wall to descend in the wall of the cervix uteri, gradually approaching the mucosa though remaining superficial to it and descending in the lateral vaginal wall to end near or at the free margin of the hymen. The *paroöphoron* consists of a few rudimentary tubules scattered in the broad ligament between the epoöphoron and uterus, most easily seen in children. Both the epoöphoron and paroöphoron tubules are remnants of mesonephric tubules; the duct of the epoöphoron is a persistent part of the mesonephric duct (p. 250).

The Uterine Tubes

The two **uterine (Fallopian) tubes** (8.202, 208), which carry ova to the uterine cavity, lie in the upper margins (mesosalpinges) of the broad ligaments. Each is about 10 cm long and opens medially into the uterine cavity's superior angle and laterally into the peritoneal cavity near its ovary. The uterine ostium is minute; the peritoneal opening or *abdominal ostium*, when relaxed, has a diameter of about 3 mm; it is deep within a trumpet-shaped expansion of the uterine tube, the *infundibulum* and its circumference is prolonged by a varying number of *fimbriae*, hence the term *fimbriated end*. The fimbriae are lined by mucosa which, in larger fimbriae, has longitudinal folds continuous with those in the infundibulum. One *ovarian fimbria*, longer and more deeply grooved than the others, is applied to the tubal pole of the ovary. The infundibulum opens into the *ampulla*, which is thin-walled, has a tortuous lumen and is rather more than half the tube's length; this leads into the *isthmus*, rounded and firm, and forms approximately the tube's medial third. The terminal, intramural, *uterine* part is about 1 cm long. The tube extends laterally as far as the inferior (uterine) pole of the ovary, ascends along the mesovarian border to the tubal pole, arches over this and turns down to end close to the ovary's free border and medial surface. On the fimbriae, or adjacent broad ligament, one or more small, pedunculated *vesicular appendices* often occur (vide supra and 8.202).

8.206 Section showing the plicated mucous membrane in the ampullary part of human uterine tube. Note the columnar epithelium. Stained with haematoxylin and eosin. Magnification × 75.

Structure (8.205, 206)

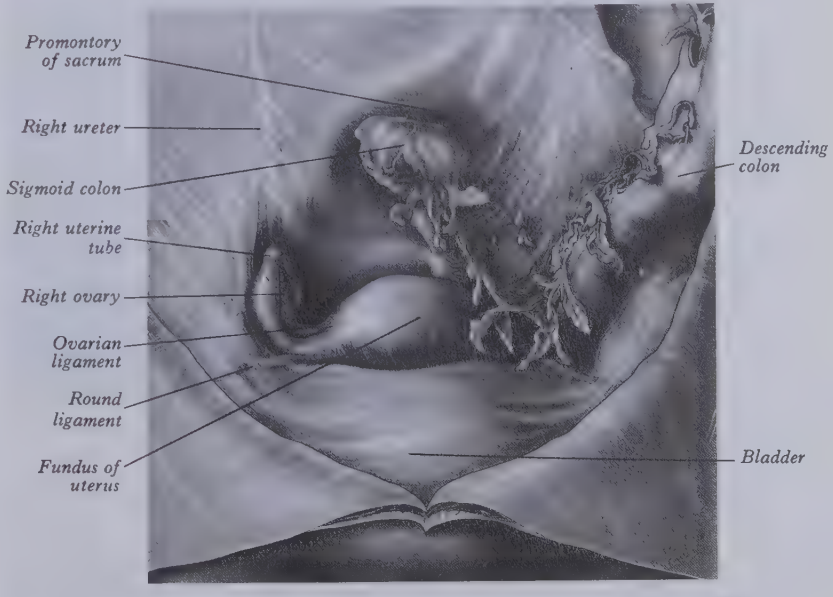
The uterine tube has an external *serosa*, an intermediate *muscular* stratum and an internal *mucosa*. The *serosa* is peritoneum with subjacent connective tissue. The *muscular layer* has external longitudinal and internal circular layers of non-striated muscle; additional *internal* longitudinal fibres appear in some parts. The uterine or intramural region has attracted attention (Lisa et al 1954, Sweeney 1962), because of the notion that a sphincter might exist to cut off the uterine cavity from the tube and peritoneum, guarding against infection. No such sphincter has been found but internal longitudinal fibres have been confirmed. The isthmal part has the thickest muscular layer, most reduced where the isthmus joins the ampulla, the thickening largely involving the circular muscle, and usually has the smallest lumen here, varying from 0.1 to 1.0 mm. Isthmal mucosal folds are less complex than in the infundibulum and ampulla, with usually three to six primary folds. Evidence suggests that this stretch of the tube acts as a sphincter, delaying progress of the segmenting zygote perhaps to ensure that it reaches a sufficiently advanced state of development to implant in the endometrium. (An agent able to overrule this sphincter might be a valuable postcoital contraceptive, Mastroianni 1962.) In the ampulla, internal longitudinal muscle is absent and the external longitudinal and circular one much intermingled. Infundibular musculature is similar but attempts to explain fimbrial movements are not yet very convincing. A sphincter at the abdominal ostium has been described, on the basis of experimental distension (Whitelaw 1933, Woodruff & Pauerstein 1969) but has not been histologically confirmed.

The tubal *mucosa* has an epithelium and underlying connective tissue containing blood and lymph vessels and nerves. The epithelium is classically described as columnar ciliated but at least three types of cells occur, only one ciliated, the others secretory and intercalated. They have an incomplete basement membrane. Intercalary cells and another undifferentiated type with a dark nucleus (Pauerstein & Woodruff 1967) may be secretory precursors or their exhausted remnants. The ultrastructure of the ciliated cells shows no peculiarities (pp. 31–32); the secretory cells vary during the menstrual cycle, as seen by light (Snyder 1924) and electron (Hashimoto et al 1960) microscopy, indicating increased secretory preparation during the follicular, and augmented secretory discharge during the luteal, phases of the menstrual cycle.

Tubal mucosa is invaginated to form the major plicae, each with secondary and even tertiary folds. In transverse section (8.205, 206) the lumen appears much invaded by plicae, with cores of connective tissue, capillaries and supporting vessels, particularly in the ampulla. The tube transports ova, spermatozoa, zygote, the pre-implantation morula and blastocyst (p. 126). Spermatozoa must be maintained viable prior to fertilization; similarly, the blastocyst, though perhaps more dependent on its own resources, must be maintained in a suitable fluid environment. The dynamics of these activities have been much studied but are beyond the scope of this text. Why so many spermatozoa are required initially remains unexplained; or why so few reach the ampulla, where they await the presumptive ovum. Tubal fluid is an intermediary for respiratory gases, spermatozoal demands for oxygen being high. Capacitation (p. 121) also occurs in the tube. The mode of entry of presumptive ova into the tube is still uncertain; conveyance by fimbriae, suction by ciliary action and so on, have been suggested, but evidence is scant. However, in general it is agreed that muscular movements are the most important factor in the transport of ova and spermatozoa; this is demonstrated by the fact that women suffering from immobile cilium syndrome are still able to bear children. The highly plicated tubal epithelium, the isthmic sphincter and other details accord with the needs of interchange of gases, nutrients and hormones and with the delay necessary to ensure blastocystic readiness for implantation; but the mechanisms involved are not clear. Contractile patterns and the effects on them of nerves, hormones (oestrogens and progesterone) and transmitters have been extensively investigated in experimental animals. The transient arrest of the zygote at the

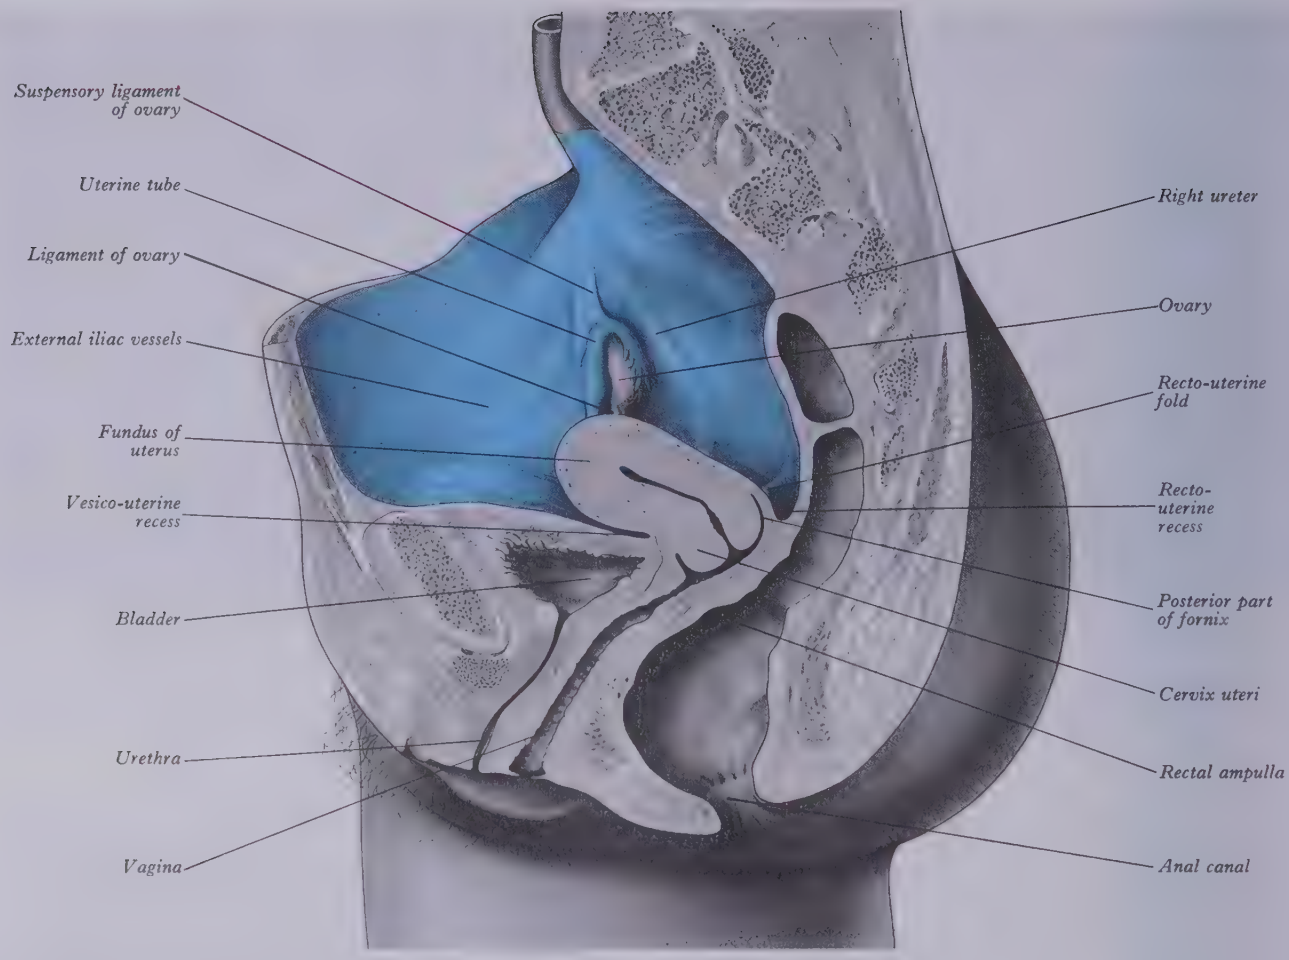
8.207 A radiograph of the uterus and uterine tubes after the introduction of a radio-opaque contrast medium through a cannula passed through the vagina into the cervix uteri. The shadow of the cannula is visible; above this is the triangular cavity of the uterine body and fundus. From the superior angles the lumina of the narrow (less than 1.0 mm diameter) intramural and isthmic parts of the uterine tubes may be traced in inferolaterally, where they expand into the wider (2–4 mm diameter) ampullary parts of the tubes. Some contrast medium has escaped into the pelvic cavity from the abdominal ostia. Radiograph provided by J Hilliger Smitham, Chelsea Hospital for Women, London.

isthmo-ampullary junction (the so-called isthmic block) has attracted special attention; the isthmic sphincter is probably adrenergic, like many others. Histochemical findings suggest an absence of cholinergic control in some parts, at least, of the human uterine tube (Nakanishi et al 1967). Prostaglandins (pp. 121, 1407), occurring in human semen, stimulate the muscle in the medial part of the tube and inhibit it in the ampullary region.



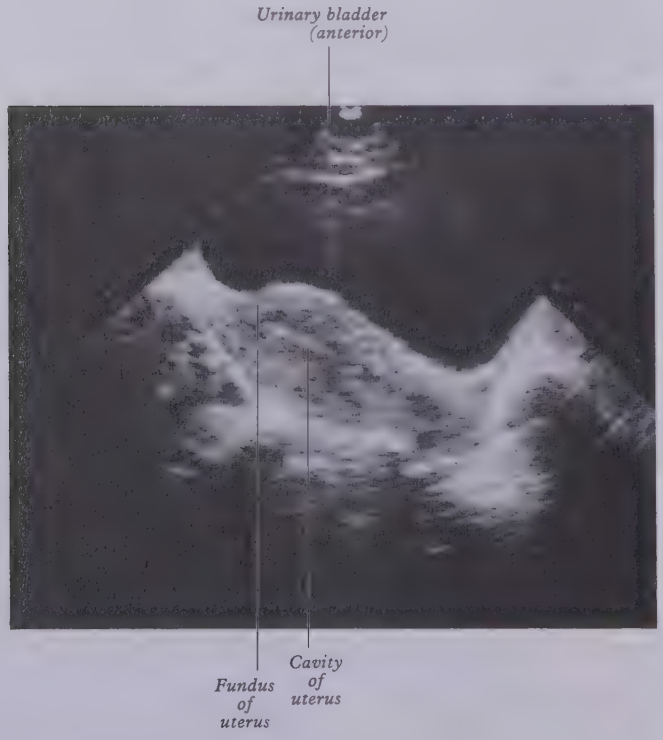
Vessels and Nerves

The vessels of the uterine tube arise from *ovarian* and *uterine* stems. Some disagreement on the regions supplied by the two arteries is apparent in the literature on this subject; it has even been claimed that the intramural tube is supplied by the ovarian artery, but arteriographic evidence (Borell & Fernstrom 1953) shows that the uterine artery usually supplies its medial two-thirds, the ovarian the remainder, partition between the two (which in any case anastomose) being variable (consult Koritke et al 1967). The veins are arranged similarly; intrinsic mucosal, muscular and subserous networks have been described (Gatsalov 1963, Koritke et al 1967). *Lymphatic drainage* follows the veins (p. 856); its intrinsic details have been extensively described (Sampson 1937, Gatsalov 1963). The *nerve supply*, largely along the ovarian and uterine arteries, shows a similar pattern of distribution. Most of the tube has sympathetic and parasympathetic supplies; vagal fibres reach the lateral half, pelvic splanchnic fibres the medial moiety. Sympathetic supply is from the tenth thoracic to the second lumbar spinal segments. Afferent fibres travel with the sympathetic motor supply, entering the cord through corresponding dorsal roots. Modified Pacinian corpuscles appear in the ampullary submucosa (Chiara 1959). Intrinsic innervation has been studied by metallic impregnations (Chiara 1959, Damiani et al 1961), and fluorescence microscopy (Owman & Capodacqua 1967, Kubo 1970). In the wall of the tube are postganglionic sympathetic fibres and visceral afferents, and preganglionic parasympathetic fibres which must form synapses, although ganglia have not been reliably reported in the wall or near it; the relay may be in paracervical ganglia. Afferent autonomic fibres may also accompany parasympathetic nerves.



Applied Anatomy

Pelvic peritonitis is said to occur more frequently in females because infection of the vagina, uterus or of the uterine tube may spread directly to the peritoneum, via the abdominal ostium. Pus in the recto-uterine pouch is palpable through the posterior vaginal fornix. Tubal inflammation (*salpingitis*) is usually secondary, having spread from the vagina or the uterus. The fimbriated end may be closed by adhesions and pus then collects in the tube (*pyosalpinx*).



Fertilization (p. 123) usually occurs in the ampulla; normally the segmenting zygote enters the uterus but it may adhere to and develop in the tube, the commonest variety of *ectopic gestation* (p. 131); an amnion and a chorion are formed, but true decidua never develop; such gestation usually ends by extrusion through the abdominal ostium, but sometimes by tubal rupture into the peritoneal cavity accompanied by severe haemorrhage (Pauerstein & Woodruff 1967, Woodruff & Pauerstein 1969).

The Uterus

The uterus (8.202, 208, 209), hollow, thick-walled and muscular, is normally situated in the lesser pelvis between the urinary bladder and rectum. Into its upper part open the uterine tubes, one on each side; below, it continues into the vagina. Presumptive ova, ova or their derivatives are carried to the uterine cavity by the tubes; if fertilized, a blastocyst forms which embeds in the uterine lining and is normally retained until development is complete, the uterus adapting in size and structure to the needs of the growing embryo and fetus. After parturition it returns almost to its former condition, though somewhat larger than in its nulliparous state. In the *adult nulliparous state* it is flat anteroposteriorly and piriform, its narrow end postero-inferior in position. It lies between the bladder antero-inferiorly and the sigmoid colon and rectum posterosuperiorly; it lies completely below the pelvic inlet. The long axis is usually approximately in the axis of the pelvic *inlet* (p. 429), but since it is movable its position varies with the distension of the bladder and rectum. Except when displaced by a much distended bladder, it forms almost a right angle with the vagina, since the latter's axis corresponds to that of the *pelvic outlet* (p. 430). It is about 7.5 cm in length, 5 cm in breadth at its widest, nearly 2.5 cm in thickness, weighs 30–40 g and is divisible into two regions. On the surface, a little below the uterine midpoint, is a slight constriction corresponding to narrowing of the cavity at the *internal os*, the part above being the *corpus* or *body* and, below, the *cervix*. The part of the corpus above the entry-points of the uterine tubes is the *fundus*. (It is, of course, the *highest* part but the *deepest* when approached via the cervix.)

The corpus uteri. The body gradually narrows from fundus to internal os. The *anterior (vesical) surface*, apposed to the

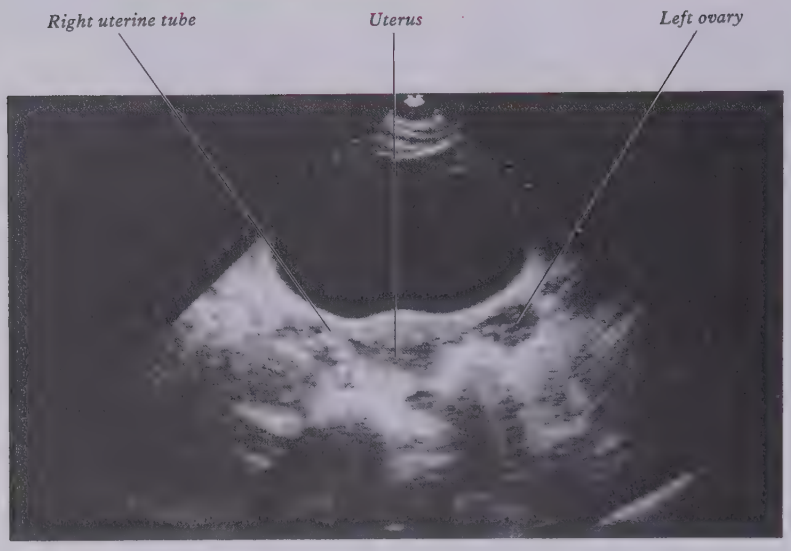
urinary bladder, is flattened and covered by peritoneum, reflected on to the bladder as the uterovesical fold level with the internal os. Between the bladder and uterus is the *vesico-uterine pouch*, usually empty but sometimes occupied by part of the intestine (p. 1338).

The *posterior (intestinal) surface*, convex transversely, is covered by peritoneum, which is continued down to the cervix and upper vagina and then reflected back to the rectum (8.209). It is related to the sigmoid colon and usually separated from it by the terminal ileal coil. The dome-like *fundus* is covered by peritoneum continuous with that on neighbouring surfaces. Coils of small intestine and occasionally distended sigmoid colon contact it. The *lateral margins* or sides are convex; at their upper ends the uterine tubes traverse the uterine wall. Antero-inferior to this are attached the round ligament and postero-inferior to it the ligament of the ovary, both running in the broad ligament and stretching from the lateral uterine margin to the lateral pelvic wall (p. 1444).

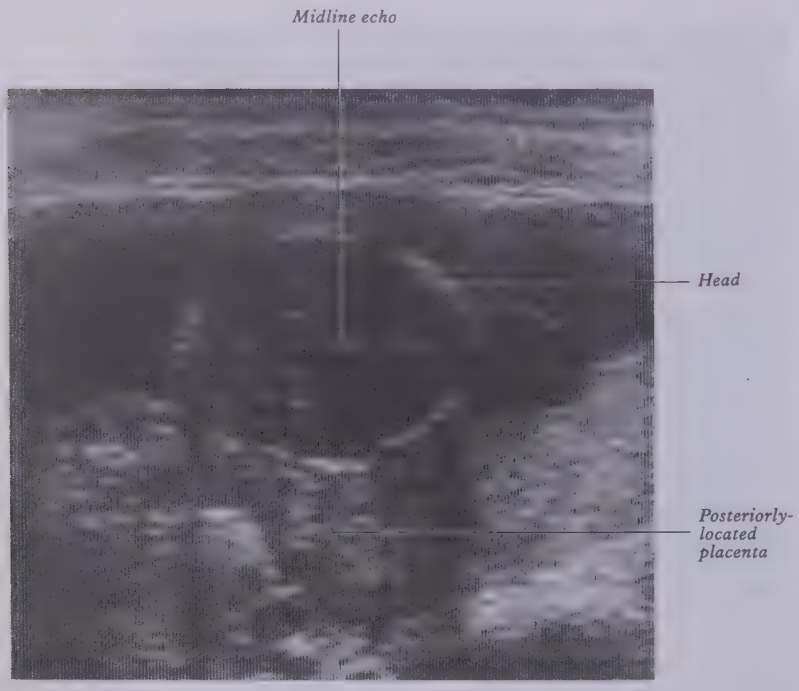


The cervix uteri, about 2.5 cm in length, is narrower and more cylindrical than the corpus, and is widest at its mid-level; it is also less mobile than the body of the uterus, so that their axes are seldom in line. The uterine long axis is concave forwards, described as *anteflexed*; occasionally there is an angular bend at the level of the internal os (*acute* anteflexion). With the bladder empty the cervix meets the vagina at an angle facing antero-inferiorly, the whole uterus being turned anteriorly on it or *anteverted*. The cervix bulges into the anterior vaginal wall, which divides it into supravaginal and vaginal regions (8.209).

The *supravaginal part* of the cervix is separated *in front* from the bladder by cellular connective tissue, the *parametrium*, which passes also to the sides of the cervix and laterally between the two layers of the broad ligaments. The uterine arteries flank the cervix in this tissue and the ureters descend forwards in it about 2 cm from the cervix (p. 1414). The relation of the arteries to the ureters is not always symmetrical; one ureter may be anterior to the cervix. *Posteriorly* the supravaginal cervix is covered by peritoneum, prolonged below on to the posterior vaginal wall and then reflected on to the rectum, forming a *recto-uterine recess* (8.209); it is related to the rectum, but may be separated from it by a terminal ileal coil.

The *vaginal part* of the *cervix* projects into the anterior vaginal wall, forming grooves termed *vaginal fornices* (p. 1445). On its rounded end the small, circular *external os* connects its cavity and the vagina. In parous women the external os has anterior and posterior lips, the anterior shorter, thicker and projecting lower than the posterior. Normally both contact the posterior vaginal wall.

The uterine cavity (8.207, 214) is relatively small, partly due to its thick wall. The *cavity of the body* is a mere transverse slit in sagittal section, the anterior and posterior walls being almost in contact. In coronal section it is triangular, its base being formed by the internal fundal surface between the openings of the uterine tubes; its apex is the internal os, leading to the cervical canal (8.209).



The *cervical canal* is somewhat fusiform, flattened transversely and broadest at mid-level. It communicates by the *internal os* with the main uterine cavity, by the *external os* with the vagina.

8.212 Transverse ultrasonogram of the female pelvis through the level of the uterus and left ovary. Supplied by Guy's Hospital; photography by Sarah Smith, UMDS, Guy's Hospital Campus, London.

From a longitudinal ridge on its anterior and posterior walls small oblique *palmate folds* ascend laterally, like branches of a tree (*arbor vitae uteri*). Folds on opposing walls interdigitate to close the canal. The total length of the uterine cavity from external os to the fundus is about 6 cm.

The *isthmus of the cervix*, the cervical upper third, has distinctive features (Stieve 1927, Frankl 1933). Although unaffected in the first month of pregnancy, it is gradually taken up into the uterine body during the second month to form the '*lower uterine segment*'. Fetal membranes, firmly blended elsewhere with the uterine mucosa, are not attached to this lower segment. In non-pregnant women the isthmus undergoes menstrual changes, though less pronouncedly than in the uterine body. Histologically it resembles the body: its epithelium is low, cylindrical and ciliated, its mucosa thinner and its glands fewer than in the cervix.

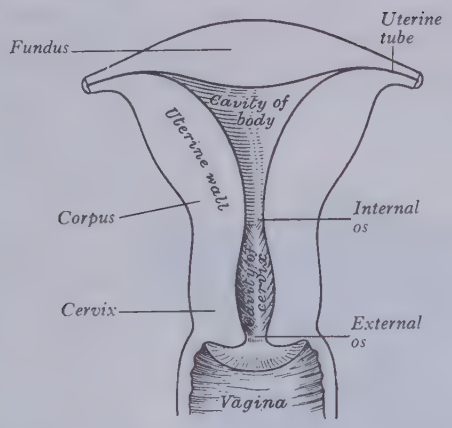
Age and Reproductive Changes

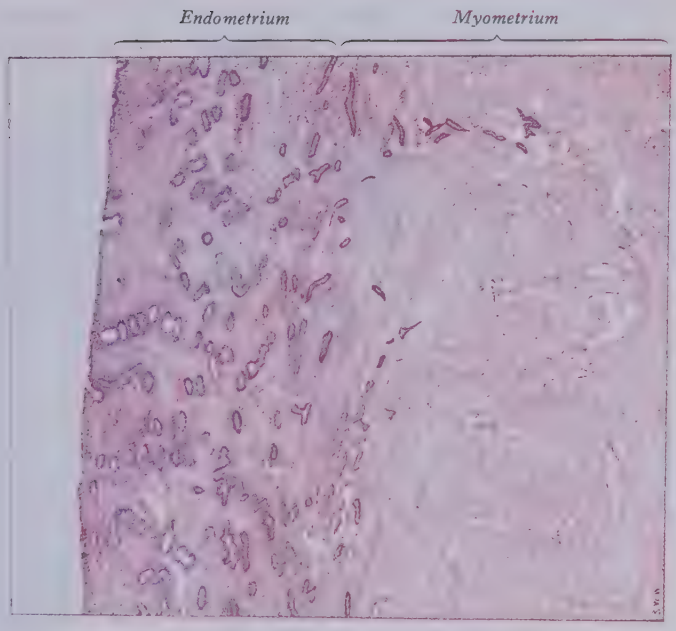
The functional anatomy of the human uterus has been described in details by Lopes & Barriere (1986). Uterine form, size and position vary in different periods and circumstances.

In fetal life the uterus projects above the lesser pelvis and the cervix is considerably larger than the body. *At puberty* it is piriform and weighs 14–17 g; the fundus is just below the superior pelvic aperture; palmate folds are distinct and extend to the upper part of the uterine cavity. *In adults* its position varies, depending chiefly on the contents of the bladder and rectum. With an empty bladder the entire uterus bends anteriorly, curved at the junction of the body and cervix, the body contacting the bladder. As the bladder fills, the uterus gradually becomes more erect until, with a full bladder, the fundus may turn towards the sacrum.



8.213B Ultrasonogram through the uterus showing the head and upper part of the vertebral column of a 16-week fetus, in sagittal section. Provided by Shaun Gallagher, Guy's Hospital; photography by Sarah Smith, UMDS, Guy's Hospital Campus, London.

During menstruation the organ is slightly enlarged and more vascular; its surfaces are rounder; the external os is rounded, its lips swollen; the endometrium is darker. *During pregnancy* the uterus becomes greatly enlarged and reaches the epigastric region in the eighth month. The increase in wall thickness is mainly due to hypertrophy of existing myocytes, but partly to formation of new fibres. As pregnancy proceeds, the wall progressively thins. *After parturition* the uterus nearly regains resting size, weighing about 42 g; but its cavity remains larger, its vessels tortuous and its muscular layers thicker and more defined; the external os is more prominent, its edges variably fissured.



In old age the uterus becomes atrophied, paler and denser in texture; a more distinct constriction separates the body and cervix. The internal os is frequently obliterated, the external os occasionally, when the latter's lips almost disappear.

Structure

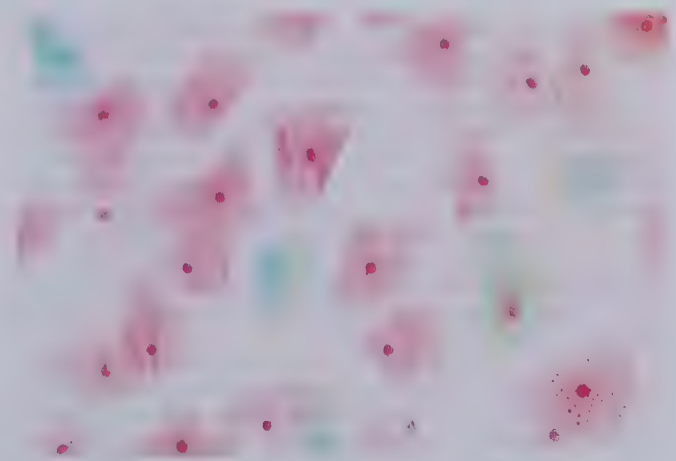
The uterine wall has an external serosal, middle muscular and an internal mucosal layer.

8.214A Sectional diagram showing the interior divisions of the uterus and its continuity with the vagina.

8.214B Section of human endometrium and underlying musculature in the interval phase. Note that some glands extend into the more internal layers of the myometrium. Stained with haematoxylin and eosin. Magnification × 20.

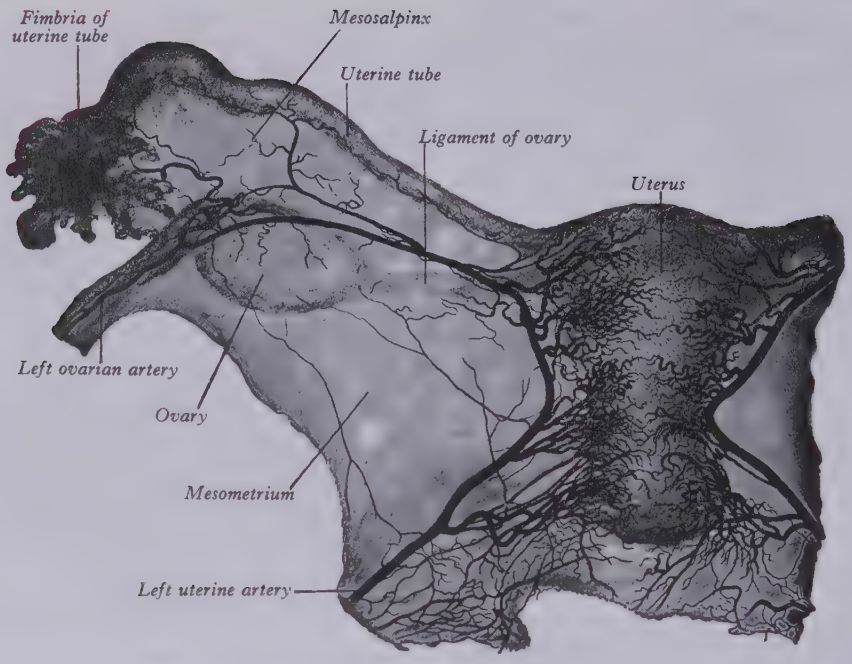
The serosa (perimetrium) is peritoneum, which posteriorly covers the uterine body and supravaginal cervix but in front only the body. In the lower posterior quarter the peritoneum is separated from the uterus by loose cellular tissue and large veins. Beneath is a subserous layer of areolar tissue.

The muscular layer (myometrium) forms most of the uterine wall. In nulliparae it is dense, firm, greyish and (in the fixed state) cuts almost like cartilage. It is about 1.25 cm thick at the mid-level and fundus and thin at the tubal orifices. Its bundles of non-striated myocytes intermix with loose connective tissue, blood vessels, lymph vessels and nerves. During pregnancy the muscle hypertrophies, the myocytes being much enlarged. Although these interlace in all directions, they form variably distinct external, middle and internal layers. The cervical muscle contains more collagen and elastin than does the body. The external layer is mostly longitudinal, fibres passing over the fundus to converge at the lateral angles and continuing into the uterine tubes and the round and ovarian ligaments; some enter the broad ligaments, others turn back into the uterosacral ligaments. The intermediate layer is thickest and contains longitudinal, oblique and transverse fibres, together with larger blood vessels. The myocytes of the internal layer are longitudinal and circular; deep parts of the uterine glands are related to it. An infundibular array of elastin and non-striated myocytes has been described in the cervix, its narow extremity adjacent to the external os (Hamper 1970); this may act as a valve in keeping the os closed. Toth (1977) has described bilateral non-striated longitudinal fascicles in the uterine wall, extending in the lateral regions from the fundal angle to the cervix and largely submucosal. Each fascicle, in its juxtafundal part, consists of dispersed subfascicles, but is more compact near the cervix; epithelial rests were observed in them, suggesting a mesonephric origin; their myocytes differ structurally from those of myometrium proper, suggesting that they may provide fast conducting pathways via gap junctions (p. 24) which might integrate uterine activity.



The mucosa (endometrium) (8.214B) is continuous through the uterine tubes with the peritoneum and, through the external os, with the vaginal mucosa. In the uterine body its epithelium is columnar, ciliated before puberty but usually non-ciliated over large areas in the adult uterus. The subepithelial layer consists of embryonic, highly cellular connective tissue containing blood vessels, lymphatic spaces and many tubular *uterine glands* lined by columnar cells, patchily ciliated, and opening into the uterine cavity (see p. 149).

Cyclical endometrial changes. Between puberty and the menopause, in each lunar month, the endometrium undergoes a *menstrual cycle*, with a duration varying even in the same individual. Histological details and hormonal factors are described on pp. 146–150.



In the upper two-thirds of the cervix, the mucosa has numerous, deep, glandular follicles secreting a clear, viscid, alkaline mucus; throughout the canal small cysts (*ovula Nabothi*) occur, presumably follicles occluded and distended by secretion. The mucosa of the lower half of the canal has numerous papillae. Its epithelium in the upper two-thirds is cylindrical and ciliated, but below this it loses cilia and, near the external os, becomes non-keratinized stratified squamous, as it is on the vaginal aspect of the cervix. The mucosa of the cervical lower two-thirds does not show menstrual changes (pp. 146–150). See Ferenczy (1980) for a review of the ultrastructure of the human cervix.

Vessels and Nerves

The main arterial supply to the whole uterus is by way of the uterine branch of the internal iliac artery on each side (p. 778). This anastomoses with ovarian and vaginal arteries, but the dominance of the uterine arteries is indicated by their marked hypertrophy during pregnancy, which affects them alone. They

8.215 Cells of the mature vaginal epithelium in a diagnostic smear preparation stained by Papanicolaou's technique (Shorr modification). All the cells shown are superficial keratinizing squames, some of which show actual keratin granules. The pink cells are the oldest and most superficial. Preparation provided by Max Levene, St Helier Hospital, Carshalton.

8.216 Posterior aspect of a cleared injected specimen (prepared by Hamilton Drummond) to show the distribution of the left uterine and ovarian arteries of a female aged 17½ years.

anastomose extensively with each other; one can be ligated without serious interference (Siegel & Mengert 1961) and even more extensive ligation has succeeded. Their tortuosity as they ascend in the broad ligaments is repeated in their branches within the uterine wall, but all sinuosities disappear as the pregnant uterus expands; however, they are obvious in nulliparae. Each uterine artery gives numerous branches which immediately enter the uterine wall, where they divide into groups of *anterior* and *posterior arcuate arteries*, passing transversely in the myometrium; their terminal branches anastomose across the midline (8.216). Anterior and posterior regions hence have median zones devoid of larger vessels, but which are *not* avascular. The arcuate arteries supply many tortuous *radial branches* which pass centripetally through the deeper myometrial layers, supplying these en route, to reach the endometrium. As microradiography and injections show, these provide a series of dense capillary plexuses in the myometrium and endometrium (Farrer-Brown et al 1970). From the former many helical arteriolar rami of the radial branches pass to supply the endometrium, their form being affected by menstrual cycles; during the proliferative phase helical arterioles are less prominent; in the secretory phase they grow in length and calibre, becoming even more tortuous (Ramsey 1955).

Uterine veins are arranged like arteries (Farrer-Brown et al 1970). Volumetrically they are, however, greater. Minute venous endometrial sinuses, a constant feature in pregnant uteri, have also been noted in the resting organ (Schlegel 1946), but not confirmed. During pregnancy *ovarian veins*, unlike their companion arteries, may be enlarged (O'Leary & O'Leary 1966). *Uterine lymphatic vessels* are described on p. 856. Intrinsic lymphatic plexuses of the uterine wall have been little studied in human females; Wislocki & Dempsey (1939) have, however, made a detailed study of arrangements in primates (macaque monkeys).

The *nerves* supplying the uterus are described on p. 1167. The autonomic supply is directly from the ovarian and hypogastric plexuses; sympathetic preganglionic fibres proceed from the twelfth thoracic and first lumbar spinal segments while parasympathetic preganglionic axons issue in the second to fourth ventral sacral spinal roots. Despite general agreement on these pathways, details of their distribution and physiological effects are still ill-defined. Cholinergic and adrenergic fibres have been identified in cervical muscular and submucous strata, the former predominating. Some observers consider that the corpus uteri is innervated only by sympathetic nerves. In a histochemical study (Owman et al 1967) only adrenergic terminals occurred throughout female internal genitalia, including the uterus. The effects of uterine innervation are complicated by hormonal influences and by the evocation of different responses by the same agent (e.g. adrenalin) in differing conditions (Wansbrough et al 1967).

Applied Anatomy

Small degrees of *anteversion* or *retroversion* are not pathological; but when flexion at the junction of the body with the cervix is marked it must be so regarded, especially when retroversion is combined with retroflexion. *Retroversion* is defined as a posterior inclination of the whole uterus, so that the cervix faces forwards; *retroflexion* is a posterior curvature of body alone, at the junction of body and cervix. These conditions are usually combined. Prolapse is another common condition; the uterus sinks abnormally low and may protrude at the vulva, usually after imperfect repair of the pelvic floor following damage sustained during parturition (p. 605).

THE UTERINE LIGAMENTS

The uterus is connected to the bladder, rectum and pelvic walls by 'ligaments'; some are merely peritoneal folds and can provide little mechanical support, others contain non-striated muscle and fibrous tissue and may be real ties, with also some measure of dynamic control.

The **anterior ligament** or *uterovesical fold* consists of peritoneum reflected on to the bladder from the uterus at the junction of its cervix and body. The **posterior ligament** or *rectovaginal fold* is composed of peritoneum reflected from the posterior vaginal fornix on to the front of the rectum, forming the deep *recto-uterine pouch*, bounded anteriorly by the uterus, supravaginal cervix uteri and posterior vaginal fornix, posteriorly by the rectum, laterally by two peritoneal crescentic folds passing back from the cervix uteri on each side of the rectum to the posterior pelvic wall; these *recto-uterine folds* contain much fibrous tissue and non-striated muscle and are attached to the front of the sacrum to form the **uterosacral ligaments**, which can be palpated per rectum lateral to it.

The two **broad ligaments** (8.202) extend from the sides of the uterus to the lateral pelvic walls, together with the uterus

forming a septum across the lesser pelvic cavity, dividing it into an anterior part containing the bladder and a posterior part containing the rectum, usually the terminal ileal coil and part of the sigmoid colon. With the bladder empty or almost so, the surfaces of each ligament are superior and inferior, with a free anterior and an attached posterior border. As the bladder fills, the plane of the ligaments rises, their free borders becoming superior and their layers anterior and posterior, continuous with each other at the free edge and diverging below near the superior surfaces of levatores ani. Each uterine tube lies in a free border, the part between this and the ovarian mesentery and ligament being the *mesosalpinx*. The tubal infundibulum projects from the free border near its lateral end. The ovary is attached posteriorly by a *mesovarium*. Between the infundibulum and upper (tubular) pole of the ovary and the lateral pelvic wall the broad ligament contains ovarian vessels and nerves, forming a *suspensory ligament of the ovary* (*infundibulopelvic ligament*), continued laterally over the external iliac vessels as a distinct fold. Between the ovary and uterine tube the mesosalpinx contains the epoöphoron (p. 1437) and medially the paroöphoron (p. 1437), and anastomoses between the uterine and ovarian vessels. The *mesometrium* is the part of broad ligament extending from the pelvic floor to the ovarian ligament and uterine body. The uterine artery passes between the two layers of broad ligament about 1.5 cm lateral to the cervix, after crossing the ureter (p. 778) and ascending in it; it turns laterally below the uterine tube to anastomose with the ovarian artery. The broad ligament also encloses the ovarian ligament (p. 1435), the proximal part of the round ligament of the uterus, non-striated muscle and areolar tissue.

The two uterine **round ligaments** (**8**.202) are narrow, flat bands 10–12 cm long lying between the layers of the broad ligament antero-inferior to the uterine tubes. From the lateral uterine angle each passes laterally across the vesical, obturator and external iliac vessels, the obturator nerve and the obliterated umbilical artery. The round ligament enters the deep inguinal ring, round the start of the inferior epigastric artery, traverses the inguinal canal and finally splits into strands which merge with connective tissue in the labium majus. Near the uterus it contains much non-striated muscle which gradually diminishes until its terminal part is purely fibrous. It is accompanied by blood vessels, nerves and lymphatics; the last drain the uterine region around the entry of the uterine tube to the superficial inguinal lymph nodes (p. 856); uterine neoplasms may spread by this route. In the fetus a peritoneal *processus vaginalis* is carried with the round ligament for a short distance into the inguinal canal, but it is generally obliterated in adults, although sometimes patent even in old age. In the canal the ligament receives the same coverings as the spermatic cord (p. 1431), although they are thinner and blend with the ligament itself, which may not reach the labium majus but ends by fusing with these coverings. The round and ovarian ligaments are together homologous with the gubernaculum testis (p. 257).

The **transverse cervical ligament** (of Mackenrodt) extends from the side of the cervix to the vault and lateral fornix of the vagina and is continuous with the fibrous tissue around the pelvic blood vessels; it probably plays a part in stabilizing the uterus (hence its gynaecological importance). Other dense strands of pelvic fascia connect the cervix and upper vagina to the back of the pubis.

While the above ligaments (and vagina) may act in varying measure as mechanical uterine supports, the levatores ani and coccygei, urogenital diaphragm and perineal body appear at least as important in this respect (Wendell-Smith & Wilson 1977).

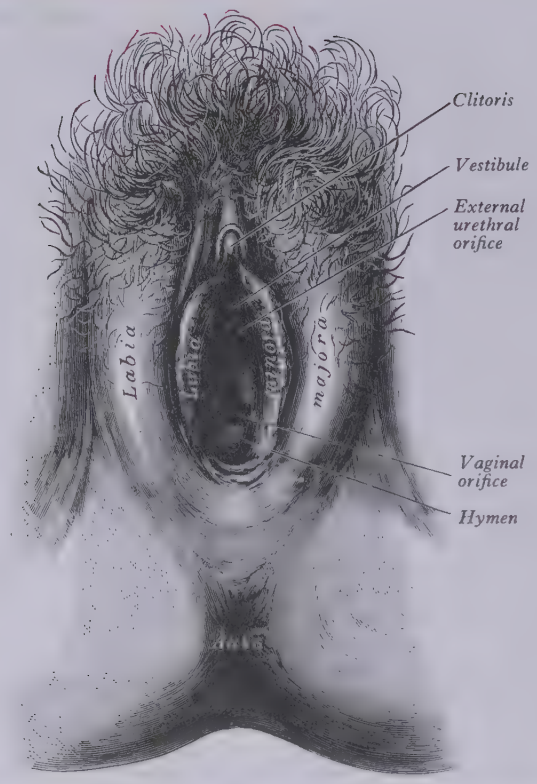
The Vagina

The vagina (**8**.209), the female copulatory organ, is a fibromuscular tube lined by stratified epithelium, extending from the vestibule (the cleft between the labia minora) to the uterus; the bladder and urethra are anterior, the rectum and anal canal posterior. The vagina ascends posterosuperiorly, at an angle of over 90° to the uterine axis, but which varies with the contents of the bladder and rectum. The inner surfaces of its walls are ordinarily in contact, its lumen forming an H in transverse section in its lower part, the transverse line being slightly convex forwards or backwards and the lateral limbs medially convex; at its intermediate level the lumen is a transverse slit. Its anterior wall is 7.5 cm in length, the posterior 9 cm; its width increases as it ascends. Its upper end surrounds the vaginal projection of the cervix uteri near the external os, attached higher on the posterior cervical wall than on the anterior. The annular recess between the cervix and vagina is the *fornix*; anterior, posterior and lateral parts of this recess are often named, but the recess is essentially continuous.

The *anterior* vaginal wall is related to the urethra, which is embedded in it, and to the base of the bladder. The *posterior* wall, covered by peritoneum in its upper quarter, is separated from the rectum by the recto-uterine pouch above, and by moderately loose connective tissue in its middle half; in its lower quarter it is separated from the anal canal by the musculofibrous *perineal body*. Laterally are the levatores ani (p. 605) and pelvic fascia. As the ureters pass anteromedially to reach the fundus of the bladder, they pass close to the lateral fornices and as they enter the bladder they are usually in front of the vagina (p. 1414). Each ureter is crossed transversely here by a uterine artery (p. 778).

Structure

The vagina has an inner mucosal and an external muscular stratum, the lamina propria of the former containing many thin-walled veins.

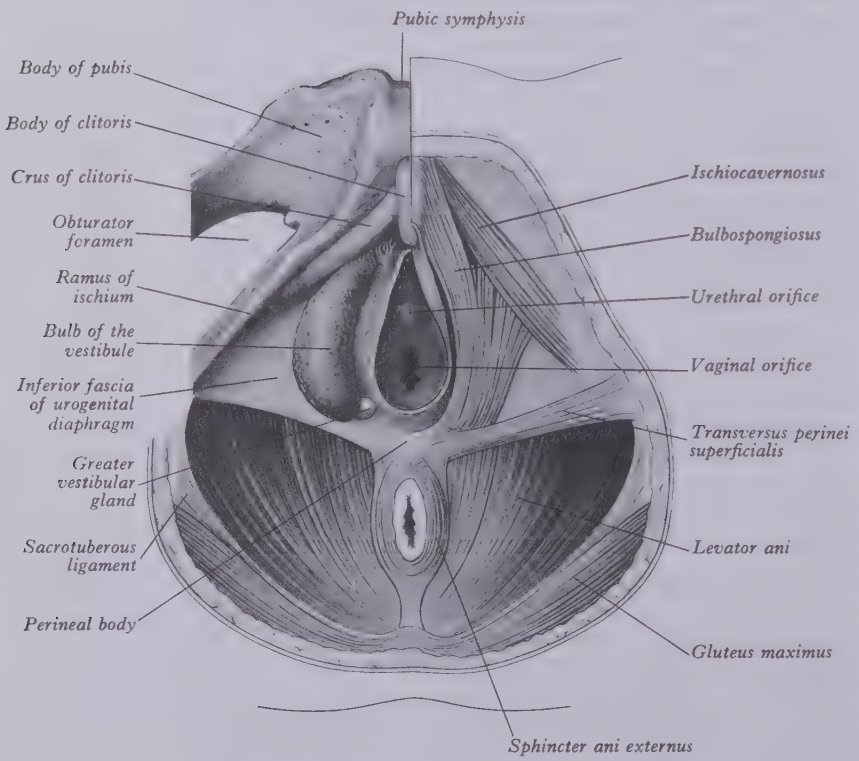


The mucosa adheres firmly to the muscular layer; on its epithelial surface are two median longitudinal ridges, one anterior and the other posterior. From these *vaginal columns* numerous transverse bilateral rugae extend, divided by sulci of variable depth, giving an appearance of conical papillae which are most numerous on the posterior wall and near the orifice. These are especially well developed before parturition. The epithelium is non-keratinized stratified squamous. After puberty it thickens and is rich in glycogen. Unlike many other mammals, human vaginal epithelium does not change markedly during the menstrual cycle, but glycogen increases after ovulation and then diminishes towards the cycle's end. The fermentative action of certain bacteria (Döderlein's bacillus) on the glycogen renders vaginal fluid acid. There are no mucous glands; mucus from the cervical glands lubricates the vagina.

Cyclical variations in the vaginal epithelium have been much studied in many animals, including the human, by taking 'smears' to examine cell types and their relative frequencies (Stockard & Papanicolaou 1917). The cells are mostly epitheliocytes and leucocytes (**8**.215). This technique has been useful in reproductive studies of experimental animals and is also applied in clinical gynaecology. Effects of hormonal therapy include changes in vaginal cellular debris, which also occur in uterine and especially cervical carcinoma (Papanicolaou & Traut 1943, Koss 1968).

The muscular layers are non-striated and consist of a stronger external longitudinal, and an internal circular layer. Longitudinal fibres are continuous with the superficial muscle fibres of the uterus, the strongest fasciculi being those attached to the rectovesical fascia on each side. The two layers are not distinct but connected by oblique decussating fasciculi. The lower vagina is also surrounded by the skeletal muscle fibres of *bulbospongiosus* (p. 607). Most external is a layer of loose connective tissue, containing extensive vascular plexuses.

Vessels and Nerves



The *arteries* are derived from the vaginal, uterine, internal pudendal and middle rectal branches of the internal iliac arteries (p. 777; **6**.121). The *veins* form lateral plexuses, drained through the vaginal veins to the internal iliac veins. *Lymph vessels* are described on p. 856. The *nerves* are derived from the vaginal plexuses and pelvic splanchnic nerves (p. 1166). The lower vagina is supplied by the pudendal nerve (p. 1149). Many nerve fibres in the lamina propria and muscle react strongly to tests for cholinesterase and are probably cholinergic.

8.217 Female external genitalia, with the labia majora et minora separated.

Female External Genital Organs

The female external genitalia (**8**.217) include: the mons pubis, labia majora et minora pudendi, the clitoris, vestibule, vestibular bulb and the greater vestibular glands. The term *pudendum* or *vulva* includes all these parts.

8.218 Dissection of the female perineum to show the bulb of the vestibule and greater vestibular gland on the right; on the left side of the body the muscles superficial to these structures have been left in situ.

The mons pubis, the rounded eminence anterior to the pubic symphysis, is formed by a mass of subcutaneous adipose connective tissue, covered by coarse hair at the time of puberty over an area usually limited above by an approximately horizontal boundary. (In males this upper limit is similar; its apparent continuation to the umbilicus consists of ordinary body hair.)

The labia majora (**8**.217), two prominent, longitudinal, cutaneous folds from mons pubis to perineum, form the lateral boundaries of the *pudendal cleft*, into which the vagina and urethra open. Each labium has an external, pigmented surface, covered with crisp hairs and a pink, smooth, internal surface with large sebaceous follicles. Between these surfaces is much loose connective and adipose tissue, intermixed with non-striated muscle resembling the scrotal dartos muscle, together with vessels, nerves and glands. The uterine round ligament ends in the adipose tissue and skin in the front part of the labium. A peristent processus vaginalis and congenital inguinal hernia may reach a labium. Labia are thicker in front, where they join to form the *anterior commissure*. Posteriorly they do not join but merge into neighbouring skin, ending near and almost parallel to each other; with the connecting skin between they form a *posterior commissure*, the posterior limit of the vulva; the interval between this and the anus, 2.5–3 cm, is the '*gynaecological' perineum*.

The labia minora (**8**.217), two small cutaneous folds, devoid of fat, between the labia majora, extend from the clitoris obliquely down, laterally and back for about 4 cm, flanking the vaginal orifice. In virgins their posterior ends may be joined by the cutaneous *frenulum of the labia minora*. Anteriorly, each labium minus bifurcates, its upper layer passing above the clitoris to form with its fellow a fold, the *prepuce*, overhanging the glans clitoridis. The lower layer passes below the clitoris to form with its fellow the *frenulum clitoridis*. Sebaceous follicles are numerous on the apposed labial surfaces.

The vestibule (**8**.218), between the labia minora, contains the vaginal and external urethral orifices and those of numerous mucous *lesser vestibular glands*. Between the vaginal orifice and the frenulum of the labia minora is a shallow *vestibular fossa*.

The clitoris (**8**.217,218) is an erectile structure, homologous with the penis, and lies postero-inferior to the anterior commissure, partially enclosed by the anterior, bifurcated ends of the labia minora. The *corpus clitoridis* has two corpora cavernosa, composed of erectile tissue and enclosed in dense fibrous tissue separated medially by an incomplete fibrous *pectiniform septum*; each corpus cavernosum is connected to its ischiopubic ramus by a *crus*. The *glans clitoridis* is a small round tubercle of spongy erectile tissue; its epithelium has high cutaneous sensitivity, important in sexual responses. The clitoris, like the penis, has a 'suspensory' ligament and two small muscles, the ischiocavernosi (p. 608), attached to its crura. In many details it is a small version of the penis, but differs from it basically in being separate from the urethra.

The vaginal orifice (*introitus*) (**8**.218) is usually a sagittal slit positioned postero-inferior to the urethral meatus; its size varies inversely with that of the *hymen*; like all the vagina it is capable of great distension during parturition and to a lesser degree during coitus.

The hymen vaginae, a thin fold of mucous membrane, is just within the vaginal orifice; the internal surfaces of the fold are normally folded to contact each other and the vaginal orifice appears as a cleft between them. The hymen varies greatly in shape and area; when stretched, it is annular and widest posteriorly; sometimes it is semilunar, concave towards the pubes; occasionally it is cribriform or fringed. It may be absent or form a complete, *imperforate* hymen. When it is ruptured, small round *carunculae hymenales* are its remnants. It has no established function.

The external urethral orifice (urinary meatus) (**8**.218) is about 2.5 cm postero-inferior to the glans clitoridis, anterior to the vaginal orifice: it is usually a short, sagittal cleft with slightly raised margins and very distensible.

The bulbs of the vestibule (**8**.218), homologues of the single penile bulb and corpus spongiosum, are two elongate erectile masses, flanking the vaginal orifice and united in front of it by a narrow *commissura bulborum* (pars intermedia). Each lateral mass

is about 3 cm in length; their posterior ends are expanded in contact with the greater vestibular glands, their anterior ends tapered and joined to one another by a commissure and to the glans clitoridis by two slender bands of erectile tissue. Their deep surfaces contact the inferior aspect of the urogenital diaphragm; superficially each is covered by a muscle, the bulbospongiosus. Thus the female corpus spongiosum is cleft into bilateral masses, except in its most anterior region, by the vestibule and the vaginal and urethral orifices.

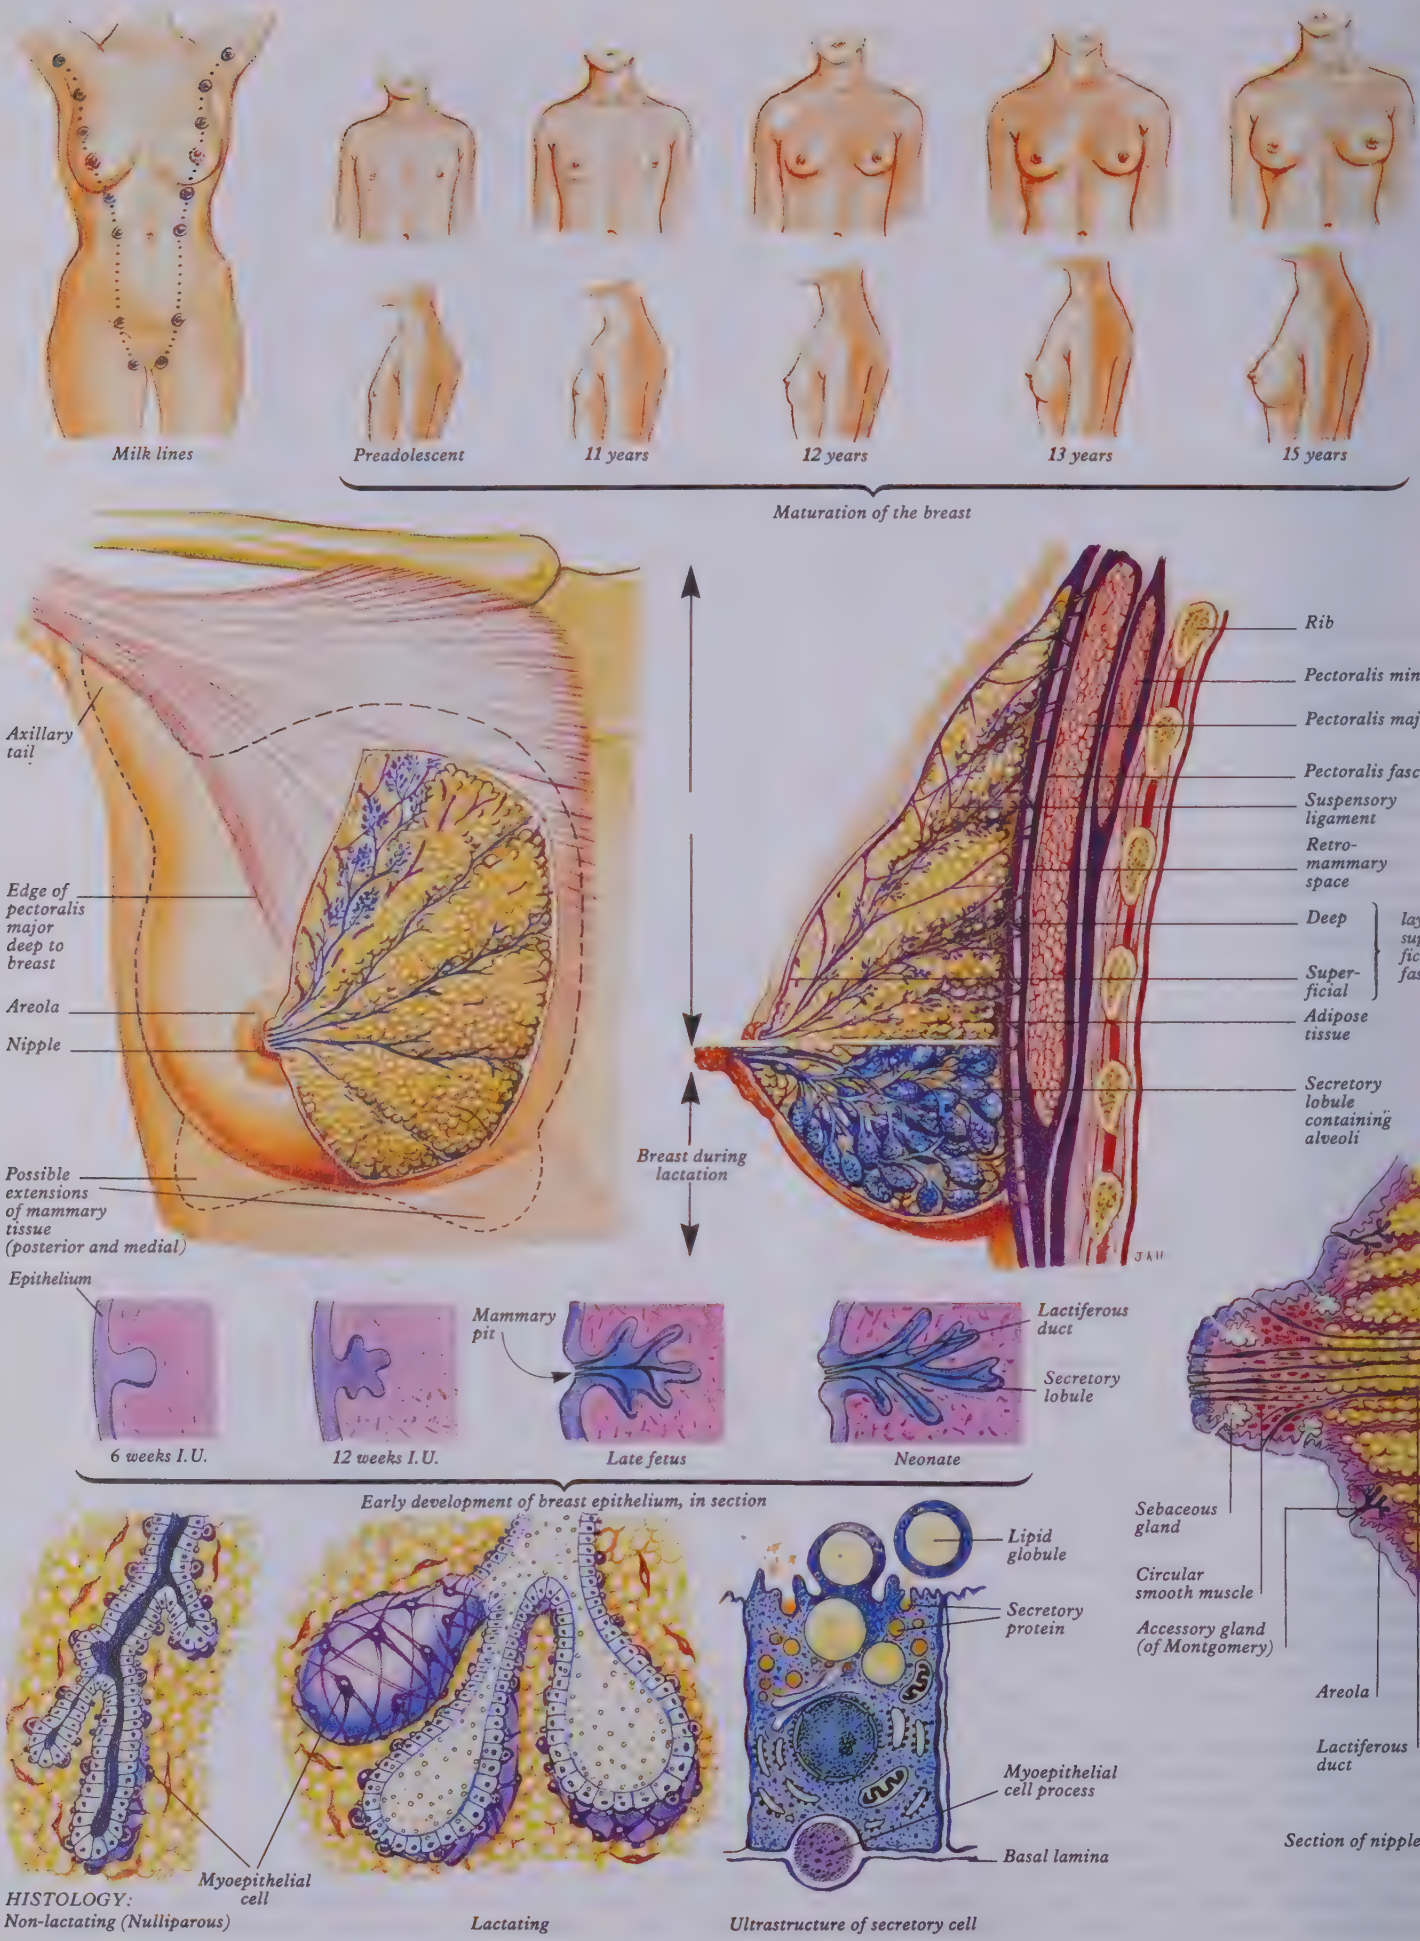
The greater vestibular glands (**8**.218), homologues of the male bulbo-urethral glands, are two small, round or oval reddish-yellow bodies, flanking the vaginal orifice, in contact with and often overlapped by the posterior end of the vestibular bulb. Each opens, by a duct of about 2 cm, in the groove between the hymen and a labium minus.

Vessels and nerves

The arterial blood supply, venous and lymph drainage and nerve supply of the female external genitalia resemble those of homologous structures in males. The arterial supply, from two external and one internal pudendal artery on each side, is massive. Hence, haemorrhage from vulval injuries may be severe. The sensory innervation of the anterior and posterior parts of the labium majus differ, as in the scrotum (p. 1432).

The Mammae or Mammary Glands

The mammae exist in both sexes, though they are rudimentary in males thoughout life. In females they are undeveloped before puberty but grow and differentiate considerably at and after puberty. They attain their greatest development during the later months of pregnancy and lactation. A mamma consists of glandular tissue (*mammary gland* proper), capable of secreting milk, and fibro-adipose tissue between its glandular lobes and lobules, together with blood and lymph vessels and nerves and covered by skin.



THE FEMALE MAMMA (8.219)

In young adult females, each breast is a rounded eminence lying within the superficial fascia chiefly anterior to the upper thorax but spreading laterally to a variable extent. Its shape varies greatly in individuals and races and at different ages, being hemispherical, conical, variably pendulous, piriform or thin and flattened. It is largely composed of adipose tissue, except during lactation; its consistency, shape and size primarily depend on this. In the lateral plane (**8**.106) its base extends vertically from the second to the sixth rib; at the level of the fourth costal cartilage it extends transversely from the parasternal region almost to the mid-axillary line. The superolateral quadrant is prolonged superolaterally towards the axilla, as the *axillary tail*, along the lower border of pectoralis major, sometimes passing through the deep fascia nearly as far as the pectoral group of axillary lymph nodes. Its deep aspect is slightly concave and is anterior to pectoralis major, serratus anterior, obliquus externus abdominis and its aponeurosis as it forms the anterior wall of the sheath of rectus abdominis. It is separated from these by the deep pectoral fascia, with superficially intervening loose connective tissue, the *retromammary (submammary) 'space'*, which allows the breast some degree of movement on the deep pectoral fascia. (Advanced mammary carcinoma may, by invasion, fix the breast to pectoralis major.) Occasionally, small projections of glandular tissue may pass through the deep fascia into the muscle in normal subjects. The *mammary papilla (nipple)*, the cylindrical or conical projection below the centre of the anterior mammary aspect, is commonly level with the fourth intercostal space in nulliparous females. It is pink or light brown or darker and is traversed by 15–20 lactiferous ducts, their minute orifices opening on to its wrinkled tip. The papilla contains many non-striated myocytes, their arrangement being largely circular; their contraction (when stimulated, e.g. by suckling) erects the papilla; other muscle fibres are longitudinal and may retract it. Occasionally the papilla may not evert during prenatal development (p. 177), remaining permanently retracted and so causing difficulty in suckling. Its base is encircled by a cutaneous discoidal area, the *areola*, rose-pink in nulliparous Caucasian females and usually strongly pigmented in more melanized races and individuals. In the second month of pregnancy the areola becomes larger and darker, dark brown in pregnancy, the depth of colour varying with complexion; the degree of pigmentation diminishes after lactation, but the areola never returns to its original hue. It contains many sebaceous *areolar glands*, much enlarged in pregnancy and lactation as subcutaneous *'tubercles'*, whose oily secretion is a protective lubricant during lactation. Some appear intermediate in structure between sebaceous and sweat glands; others (Montgomery's glands) are of the mammary type although small. There is no fat immediately beneath the skin of the areola and papilla.

Structure of the Breast

The mammary gland (**8**.219, 220A,B) contains (1) glandular tissue of the tubulo-alveolar type, (2) fibrous tissue connecting its lobes, (3) interlobar adipose tissue (Cowie 1974). Subcutaneous tissue encloses the gland (but not as a distinct capsule), sending in many septa to support its lobules. From its covering fascia fibrous processes extend to the skin and the papilla, being more developed over the upper part of the breast as *suspensory ligaments* (of Cooper). These may be contracted by fibrosis in carcinoma, causing retraction or pitting of the overlying skin. Normal mammary tissue is a pale red, firm, lobulated mass, antero-posteriorly flattened and thicker centrally than at its periphery. It has 15–20 lobes containing many lobules held together by loose connective tissue which supports blood vessels and ducts. The smallest lobules, when fully developed, consist of clusters of rounded alveoli opening into ductules which unite to form larger tributaries of the terminal *lactiferous ducts*; each of the latter drains a lobe and so are the same in number (15–20), converging to the areola and forming beneath it variable *lactiferous sinuses*, which may serve as reservoirs. (Some authorities, however, consider a lactiferous 'sinus' to be an artefact.) At the papillary base these narrow and pass straight to its summit, ending at still narrower orifices; they are surrounded by connective tissue containing longitudinal and transverse elastic fibres and lined by columnar epithelium, with an external layer of longitudinal myoepitheliocytes on a basal lamina. In larger ducts the epithelium has two or more layers, becoming, near the papillary openings, keratinizing stratified squamous. Mammary carcinoma is usually caused by neoplastic change in the ductual cells, forming tumours in the ductual tissues or infiltrating the surrounding connective tissue.

Mammary structure varies with *age*, *pregnancy* and *lactation*. (Prenatal development is described on p. 177.) At *birth* there are lactiferous ducts but no alveoli and *until puberty* little branching of the ducts occurs, slight mammary enlargement being due to growth of fibrous stroma and fat. *After puberty*, stimulated by ovarian oestrogens, the ducts develop branches whose ends form solid, spheroidal masses of granular polyhedral cells, which are potential alveoli. In the resting state the glandular epithelium is separated from the vascular stroma by a thin avascular zone of fibroblasts. This *'epithelio-stromal junction'* may control the passage of materials to the secretory cells (Ozzello 1974). Secreting alveoli appear only in pregnancy, when the ducts branch markedly, their ends enlarging as milk is secreted; this growth is due to the rising output of placental oestrogen and progesterone. Adipose tissue also increases and blood flow becomes richer. Secretory activity in alveolar cells augments progressively in the latter half of pregnancy. The secretion in late pregnancy and for a few days after parturition is different from the later milk and is known as *colostrum*; it contains many cytoplasmic fat globules and *colostral corpuscles*, whose nature is uncertain; some consider them to be the lining cells of primitive alveoli, which undergo fatty degeneration and are shed; others regard them as macrophages which engulf the small amounts of fat present in the secretion at this time. True milk secretion begins a few days after parturition due to a reduction of circulating oestrogen and progesterone, which appears to stimulate production of prolactin by the anterior hypophysis (Wolstenholme & Knight 1972 and p. 1451). Milk distends the alveoli, at first lined by a single layer of granular, short columnar cells with stellate myoepitheliocytes

near the basement membrane; the cells flatten as secretion increases. Fat droplets accumulate superficially in the cells before entering the alveolar lumen in apocrine fashion.

Alveolar cells vary in form and content according to their role in the mammary secretory cycle, being cuboidal in the resting state and columnar in lactation; as they distend with milk they may become cuboidal again, by stretching of the alveolar lining. Then, however, they are much distended by huge apical secretory vacuoles. When secreting milk their cytoplasm is basophilic and contains abundant granular endoplasmic reticulum, mitochondria, lysosomes and free ribosomes. Apical to the basal nucleus are a Golgi complex and large secretory vacuoles of two types; proteinaceous and lipid-containing. Protein vacuoles contain granules of micellar casein and other lactic proteins formed in the granular endoplasmic reticulum and passed to the Golgi apparatus to form larger vacuoles, eventually secreted in a merocrine manner. Lipid vacuoles do not traverse the Golgi apparatus, but accumulate apically, fusing into large 'milk vacuoles' up to 10 μm across, frequently protruding from the cell's surface before release. Lipid vacuoles are eventually discharged with a thin surround of cell membrane and cytoplasm (Saacke & Heald 1974, Hollmann 1974, Pitelka 1977, Tobon & Salazar 1975, Kesinger et al 1986). This may be considered *apocrine* secretion, since actual cytoplasm is lost, though not to a large extent.

Alveolar cells are joined apically by occluding tight junctions which prevent the passage of substances from the lumen into the intercellular spaces and vice versa; many desmosomes and communicating junctions also occur between cells (Pitelka et al 1973). In pregnant rats, other types of protein granule are synthesized as precursors of normal granules; these may appear in colostrum (Murad 1970).

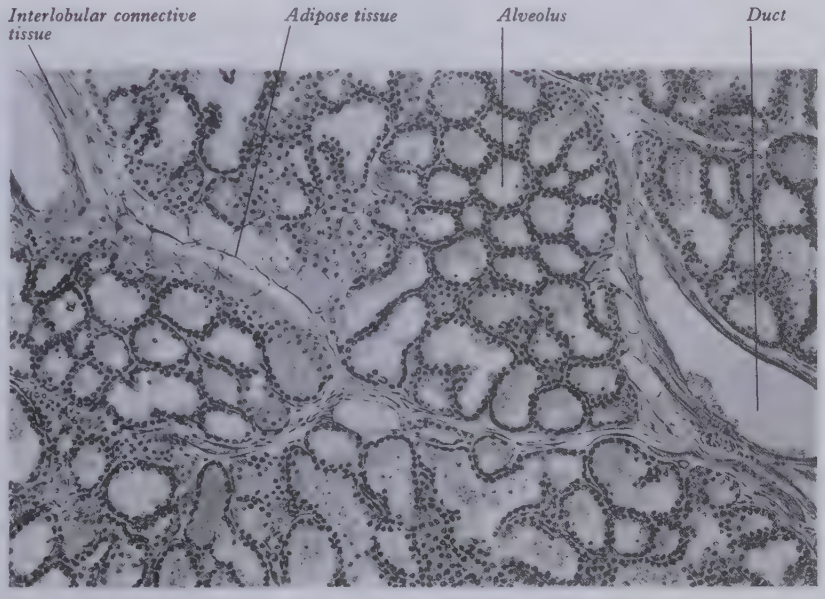
Lactation

Passage of milk from alveoli into and along the ducts may be aided by *myoepitheliocytes* (p. 55) located between the lining cells and basement membrane. Flow is initiated by suckling, which stimulates nerves abundant in the papilla and areola; such afferent impulses evoke secretion of oxytocin from the neurohypophysis, apparently stimulating contraction of the ductual myoepitheliocytes and non-striated myocytes. Without suckling, secretion of milk soon ceases. Oestrogens stimulate growth of ducts, while progesterone (from the corpus luteum) directly or indirectly stimulates alveolar formation at their ends. Formation of true secretory alveoli in pregnancy is due to the synergic action of oestrogens, progesterone (mainly placental) and hypophysial hormones (prolactin and growth hormone, which also maintain lactation). Commonly lactation continues for five or six months after birth, then progressively diminishes, infants usually being weaned at about nine months. When lactation stops, the glandular tissue returns to the 'resting' condition, remaining milk is absorbed and the alveoli shrink, many losing their lumina. Glandular tissue may fail to produce milk throughout pregnancy or secretion may cease within a few weeks of birth. After menopause, mammary glands atrophy, the alveolar cells and ducts degenerating, but a few ducts may remain (Ozzello 1974); the stroma becomes much less cellular and collagenous fibres decrease. The amount of fat varies. In neonates of both sexes, in the first week or two after birth, cells lining ducts may be stimulated by maternal oestrogens, via the placenta, to secrete a little fat-free fluid, sometimes termed 'witch's milk'.

Milk

Milk is a complex fluid, composed in humans of about 88% water, 7% lactose, 4% fat, 1% protein and various ions, notably calcium, sodium, potassium, phosphate and chloride. Vitamins and antibodies, mainly of the IgA (secretory) class are present, the latter being largely responsible for the sterility of milk during lactation (Jennesse 1974). The proteins are chiefly caseins and a lactalbumen; these, with lactose and several triglycerides, are synthesized from circulating precursors which enter the gland and are unique to it. *Colostral milk* is markedly different, poor in nutrients with an ionic composition like blood plasma. For details of lactation and human mammary structure see the review by Larson (1978).

The Male Mamma



The male mamma remains rudimentary. It is formed of small ducts (without alveoli) and a little supporting fibro-adipose tissue. Sometimes the 'ducts' are largely solid cellular cords. Slight temporary enlargement may occur at puberty. Generally the ducts do not extend beyond the areola, which, however, is well developed. The papilla and areola are relatively small.

Vessels and Nerves

The *arteries* supplying the mammary glands are from thoracic branches of the axillary and from the internal thoracic and intercostal arteries. The *veins* form an anastomotic *circulus venosus* at the papillary base. From this and from the glandular tissue, veins carry blood to the periphery to end in the axillary and internal thoracic veins. *Lymph vessels* are described on p. 847. The *nerves* are from the anterior and lateral cutaneous branches of the fourth to sixth thoracic spinal nerves, which also convey sympathetic fibres to the mamma; however secretory activities of the gland are

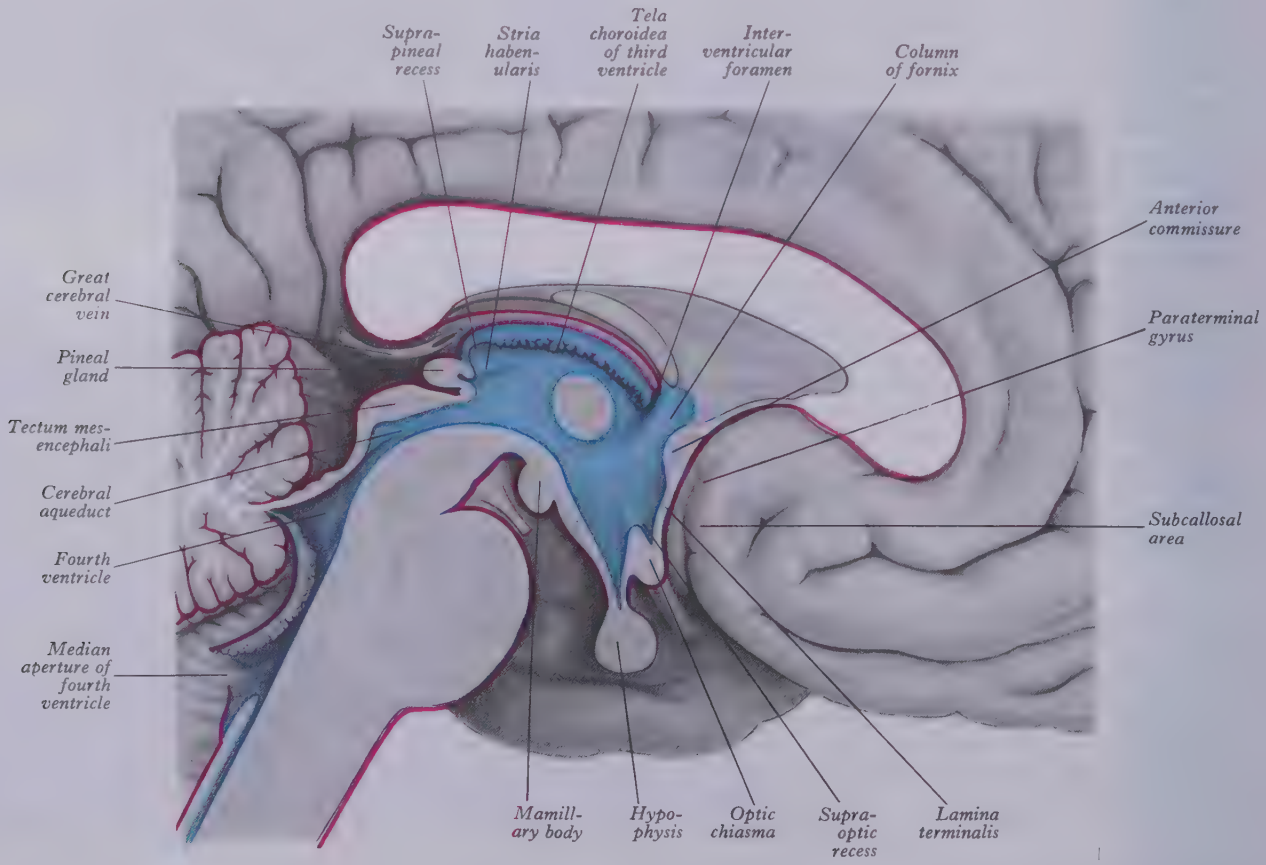
largely controlled by ovarian and hypophysial hormones. The papilla has a dense nervous plexus supplying many receptors, such as Meissner's corpuscles and Merkel's discs and also 'free' terminals; these are essential in signalling suckling to the central nervous system (vide supra).

Applied Anatomy

The papillary ducts are radially orientated and incisions should hence also be radial. An obstructed lactiferous duct may distend as a *galactocele*. Abscesses may occur between the septa in the glandular tissue, subcutaneously near the papilla or between gland and deep fascia anterior to the pectoralis major.



Supernumerary mammae (*polymastia*) or papillae (*polythelia*) occur in males and females, usually along a line extending from the axilla to the pubic region, the *milk line* (8.219). The male mamma may hypertrophy after puberty (*gynaecomastia*), usually due to imbalance between oestrogenic and androgenic hormones. (See pp. 1451, 1452, 1463 and 1472 for endocrine influences.)

THE ENDOCRINE SYSTEM

For a multicellular organism to survive and maintain its integrity in a varying, often adverse environment, regulatory mechanisms are vital. Metazoa have attained some freedom from the vagaries of the external environment (over which only the most advanced have much control, although this is only of a short-term nature) by developing the capacity to regulate, with varying success, the composition and properties of their immediate cellular environments which comprise intercellular or tissue fluid and, in vascularized metazoa, the fluid components of blood and lymph. The effective stabilization of these media is directly related to an organism's success and longevity.

Tissue fluid and plasma are stabilized by the co-ordinated regulatory activity of the autonomic and endocrine systems, the latter including the diffuse neuro-endocrine system (p. 1466) and the endocrine system proper. All operate by intercellular communication but differ in the mode and speed, and in the degree of localization of the effects produced. The *autonomic nervous system* utilizes conduction and neurotransmitter release to transmit information; it is swift and localized in the responses induced. The diffuse *neuro-endocrine system* uses only secretions, is slower and the induced responses are less localized, because the secretions e.g. neurotransmitters, can act on contiguous cells, on groups of nearby cells reached by diffusion (a paracrine secretion) or on distant cells via blood like a hormone. The *endocrine system* proper, comprising isolated or clustered cells and discrete ductless glands producing hormones (organic molecules transported by blood to distant effector cells), is even slower and less localized, though its effects are specific and often prolonged. These regulatory systems overlap in form and function, with a gradation from the neural autonomic system, through intermediate diffuse neuro-endocrine mechanisms to the endocrine system proper.

The close interrelationship of autonomic and endocrine systems, both structural and functional, is exemplified by the hypothalamus (p. 1007). This integrates both systems and is the major site at which their activities combine. Apart from its nervous functions the hypothalamus is also endocrine, producing by neurosecretion a wide range of peptide hormones including releasing and inhibiting factors which control the activity of the adenohypophysis, itself a major endocrine gland. Though conveniently considered separately, the autonomic, diffuse

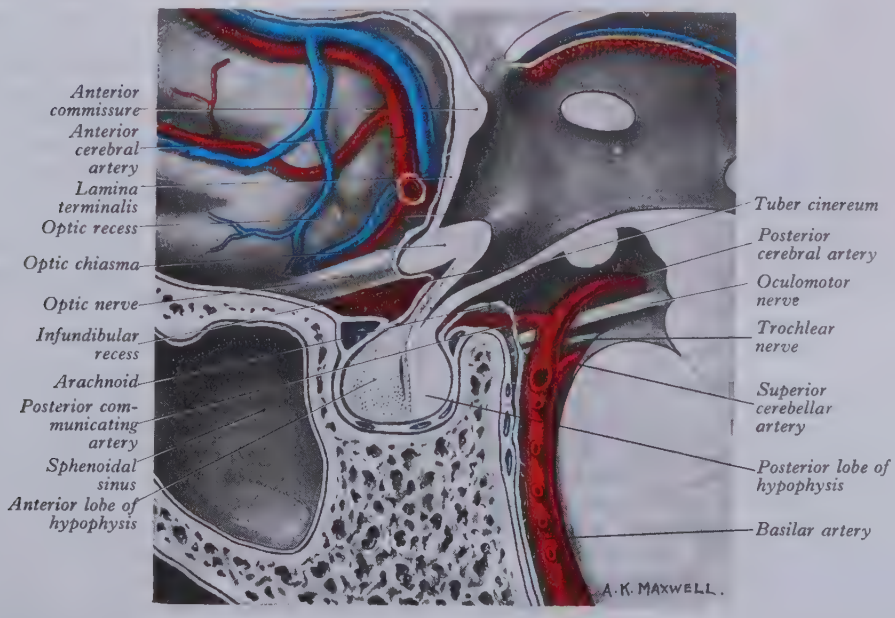
neuro-endocrine and endocrine systems are really a single neuro-endocrine regulator of the metabolic activities and internal environment of the organism, providing conditions in which it can function successfully.

There are, in addition to the endocrine glands and diffuse neuro-endocrine system described here, other hormone-producing cells which form minor components of other systems and are described with them. These include: pancreatic islets (p. 1383), gastro-entero-endocrine cells (p. 1466), certain thymic (p. 833) and renal (p. 1409) cells, pulmonary endocrine cells (p. 1278), interstitial testicular cells (p. 1428), interstitial, follicular and luteal ovarian cells (p. 1437) and, in pregnancy, placental cells (p. 156). Some cardiac myocytes, particularly in the walls of the atria, also have endocrine functions. In addition to these various cell types, it has become apparent over the last few years that many secretory substances which were hitherto thought to be exclusive to the endocrine glands also occur widely in the central nervous system, where they may act as neurotransmitters or neuromodulators (p. 887). The ability to synthesize and secrete such substances is therefore a very widespread activity, emphasizing the complex interdependence of the systems of chemical control throughout the body.

The Hypophysis Cerebri

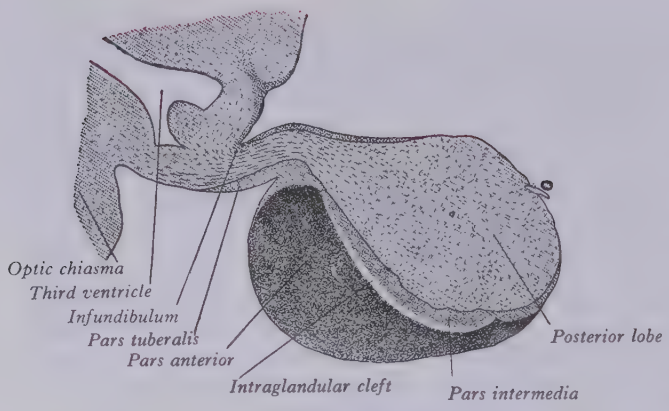
The hypophysis cerebri (pituitary gland, **8**.221–227) is a reddish-grey, ovoid body, about 12 mm in transverse and 8 mm in antero-posterior diameter and weighing about 500 mg. It is continuous with the infundibulum, a hollow, conical, inferior process from the tuber cinereum of the hypothalamus (p. 1007). It lies within the hypophysial fossa of the sphenoid, covered superiorly by a circular *diaphragma sellae* of dura mater; this is pierced centrally by an aperture for the infundibulum and separates the anterior superior aspect of the hypophysis from the optic chiasma (**8**.222). The hypophysis is flanked by the cavernous sinuses and their contained structures (p. 802). Inferiorly it is separated from the floor of its fossa by a venous sinus communicating with the circular sinus (p. 803). Meninges blend with the hypophysial capsule and are not separate layers.

The terminology of the hypophysial divisions and subdivisions are somewhat confused. The major division is into two regions, differing in origin, structure and function: one is a diencephalic down-growth connected with the hypothalamus; the other is an ectodermal derivative of the stomatodeum. These are respectively the *neurohypophysis* and *adenohypophysis*. Both include parts of the *infundibulum* (the older terms 'anterior' and 'posterior lobes' do not). The infundibulum has a central *infundibular stem*, containing neural hypophysial connections and continuous with the *median eminence* of the tuber cinereum (p. 1007). Thus, the term *neurohypophysis* includes the median eminence, infundibular stem and *neural lobe* or *pars posterior* and also an extension of the adenohypophysis, largely surrounding the neural infundibular stem, the *pars tuberalis* or *infundibularis*. The main mass of the adenohypophysis is divisible into the *pars anterior* (pars distalis) and *pars intermedia*, separated in fetal and early postnatal life by the hypophysial cleft, a vestige of Rathke's pouch (p. 231) from which it develops. Usually obliterated in childhood, it may persist in the form of cystic cavities often present near the adeno-neurohypophysial frontier and sometimes invading the neural lobe. The human pars intermedia is rudimentary; because it may also be partially displaced into the neural lobe, it has been included in the anterior *and* posterior parts by different observers. Apart from this equivocation, of little significance in view of the exiguous status of the human pars intermedia, the partes anterior et posterior (nervosa) may be equated with the anterior and posterior lobes. When the associated infundibular parts continuous with these lobes are included, the names adenohypophysis and neurohypophysis become appropriate. The terms will hence be used as follows:



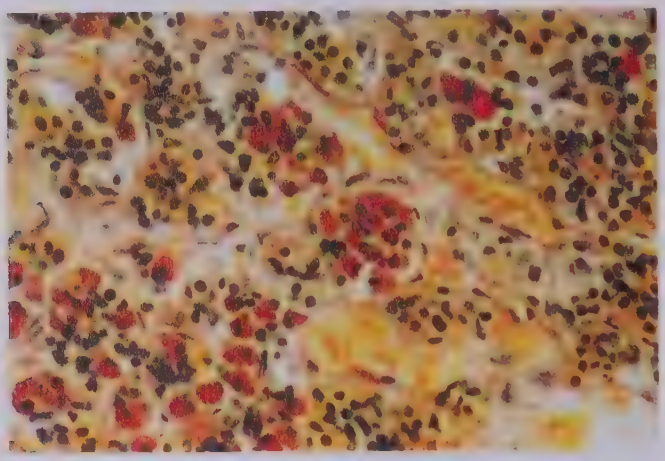
(1) *Neurohypophysis*: includes the pars posterior (pars nervosa, posterior or neural lobe), infundibular stem and median eminence.

(2) *Adenohypophysis*: includes the pars anterior (pars distalis or glandularis), pars intermedia and pars tuberalis.



The hypophysial divisions are shown in **8**.222, 223A, 227. They differ in the types and arrangement of cells and the details of their vascular and neural supplies. Studies of these structures have engendered a formidable literature, which will be summarized here only briefly.

The Adenohypophysis



The adenohypophysis (**8**.223, 224) is highly vascular and consists of epithelial cells of varying size and shape arranged in cords or irregular follicles, separated from each other by thin-walled vascular sinusoids and supported by a delicate skeleton of reticular tissue. At least seven hormones are synthesized and released by the adenohypophysis, most of them being *tropic*, such as: *somatotropin* (STH) involved in the control of body growth, *mammotropin* (*lactogenic hormone* LTH) stimulating growth and

secretion by the female breast, *adrenocorticotropin* (ACTH) governing the secretion of some adrenal cortical hormones, *thyrotropin* (TSH) stimulating thyroid activity, *follicle-stimulating hormone* (FSH) stimulating growth and secretion of oestrogens in the ovarian follicles and spermatogenesis in the testis, *interstitial-cell-stimulating hormone* (ICSH) activating androgen secretion by the testis, *luteinizing hormone* (LH), inducing progesterone secretion by the corpus luteum and *melanocyte-stimulating hormone* (MSH) increasing cutaneous pigmentation. Most of these hormones also have other complex metabolic effects.

CELL TYPES IN THE ADENOHYPOPHYSIS

The identities of endocrine cells secreting the different adenohypophysial hormones have been intensively sought by various staining techniques to distinguish between different cell types (Harris & Donovan 1966); earlier techniques used the simple criterion of the affinities of cells for acidic and basic dyes, such as orange-G and aldehyde fuchsin, respectively. Cells staining strongly were *chromophilic*, those with little affinity for dyes being *chromophobic*. Chromophilic cells were classed as *acidophils* (α-cells) or *basophils* (β-cells) for obvious reasons. Modifications using complex, multi-stage staining further distinguished many subcategories of cells, each with its own tinctorial nuance. Such techniques, applied particularly to experimental or pathological pituitary glands from individuals with known hormonal defects, were used to associate specific cell types with particular hormones. However, many uncertainties remained, due to difficulty in standardizing stains and in classifying endless minor variations in different individuals and species.

More recently, immunochemical methods have been applied (Nakane 1970) and immunofluorescence techniques have identified the sites of synthesis of individual hormones. Such methods, combined with electron microscopy and cell fractionation, have made it possible to consign all major hormones to particular cell types, although the terminology of older classifications has in part been retained. Ultrastructural studies of the normal human adenohypophysis are relatively scarce and much of our information has come from non-human primates. However, species differences do exist in the fine structural and dye-binding properties of cells of this kind. For detailed accounts of adenohypophysial structure, see Costoff (1977), Pelletier et al (1978), Bhatnagar (1983), Motta (1984) and Martin (1985).

The pars anterior contains the following cell varieties:

A. Chromophil Cells

1. *Acidophils (α cells)*

(*a*) *Somatotropes*. These are ovoid and usually grouped along sinusoids; they are the largest and most abundant class of adenohypophysial chromophils, secreting the protein somatotropin. They stain strongly with orange G, and ultrastructurally are seen to contain numerous electron-dense, spherical, secretory granules, 350–500 nm in diameter, and a well-developed Golgi complex but, in the secretory phase, relatively small amounts of granular endoplasmic reticulum; the nucleus is central. Cells of similar fine structure characterize human eosinophilic adenomata associated with acromegaly or giantism (Zambrano et al 1968).

(*b*) *Mammotropes*, secreting the polypeptide hormone prolactin, are dominant in pregnancy and hypertrophy during lactation. They are distinguished by their affinity to the dye erythrosin and also azocarmine. Their secretory granules are the largest in any hypophysial cell (over 600 nm in diameter) in pregnant and lactating females, although smaller (200 nm) and fewer in non-pregnant females and in males; the granules are evenly dense, ovoid or irregular, the latter form resulting from fusion. Excess granules fuse with lysosomes to form autophagic vacuoles which degrade unused granules. In active cells, granular endoplasmic reticulum and a Golgi complex are prominent.

2. *Basophils* (β cells)

(*a*) *Corticotropes*. The identification of the cells which secrete adrenocorticotropin (ACTH) was difficult to achieve until it was realized that a precursor molecule, pro-opio-melanocorticotropin, is cleaved into a number of different molecules including ACTH, beta lipotropin and beta-endorphin; the functions of the latter two substances in the pituitary are not known, although the opio-melanocorticotropin complex is also synthesized in neurons of the central nervous system and has neuromodulator functions there (p. 887). In humans, though not in some other species, this precursor is glycosylated, making the granules PAS-positive. They are also weakly basophilic. These cells are

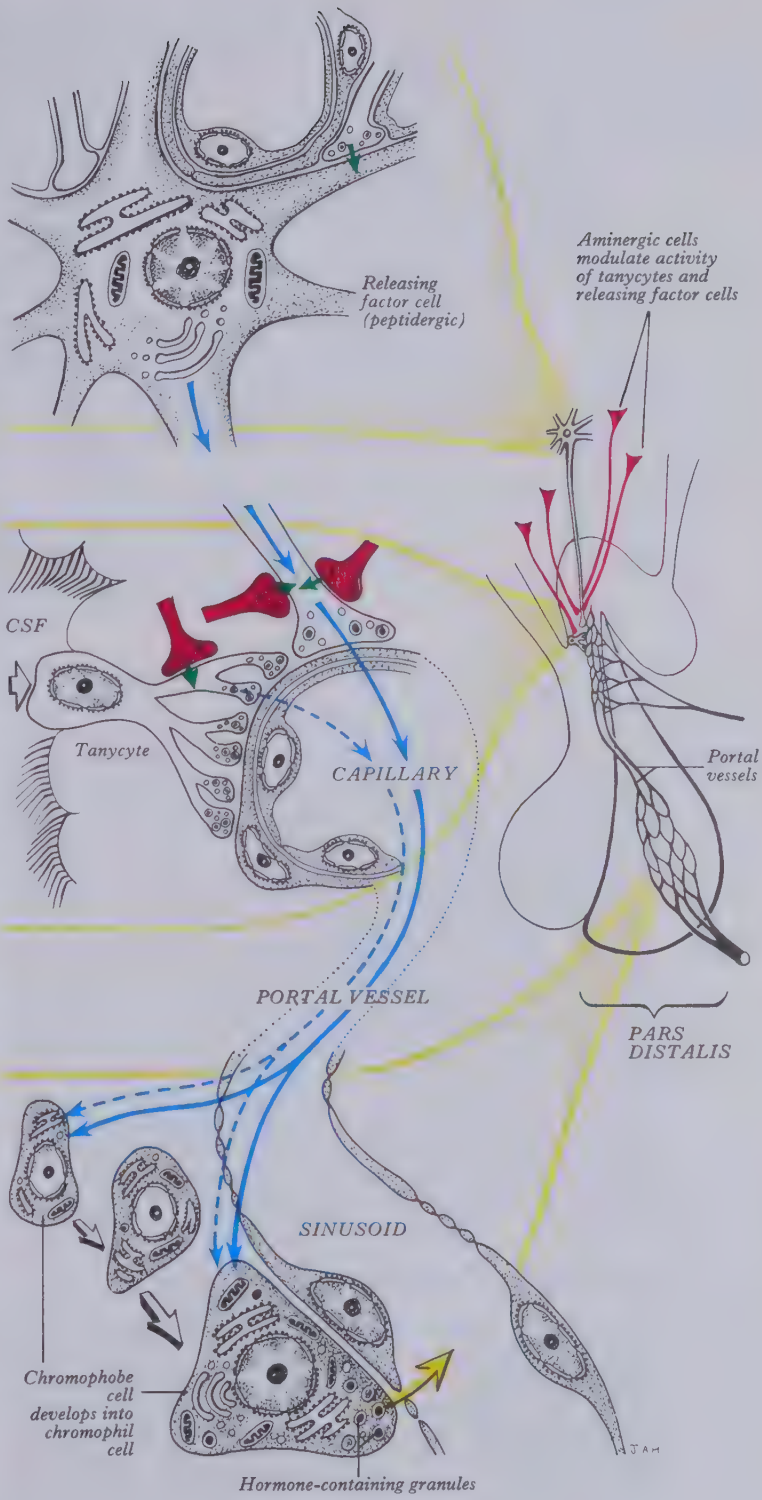
irregular in shape and have short dendritic processes which are inserted among other neighbouring cells. Their granules are also small (about 200 nm) and difficult to detect by light microscopy.

(*b*) *Thyrotropes* (beta-basophils) secrete TSH. They are elongate, polygonal and lie in clusters towards the adeno-hypophysial centre. They usually form cellular cords and are not in direct contact with sinusoids; they stain selectively with aldehyde fuchsin. Their granules, peripheral and irregular, are less electron-dense than in other basophils, being 100–150 nm in diameter and among the smallest granules in adenohypophysial cells.

(*c*) *Gonadotropes* (*delta-basophils*) are larger than thyrotrophs, are rounded and usually situated next to sinusoids; they have secretory granules with an affinity for the periodic acid/Schiff stain. In some cells, usually peripheral in the lobe, granules stain purple while in others, more central, they stain red, suggesting that the former secrete FSH and the latter LH or ICSH (Purves 1961). Electron microscopy of the rat adenohypophysis has distinguished two cell types (Kurosumi & Oota 1968); but immunocytochemical studies of Phifer et al (1973) in man and of Moriarity (1975) in rats suggest that FSH and LH may coincide in the same cell, within the same secretory granules. Gonadotrophs have pleomorphic nuclei and spherical granules about 200 nm in diameter which tend to gather in lines under the cell surface during secretory activity, a vesicular granular endoplasmic reticulum and a well-developed Golgi complex (von Lawzewitsch et al 1972).

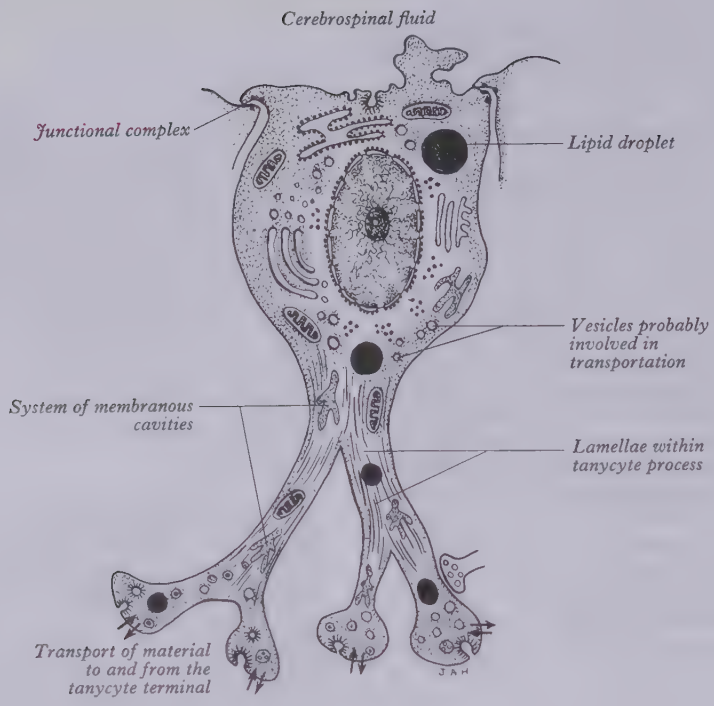
B. Chromophobe Cells

Chromophobe cells constitute the majority of the cells of the adenohypophysis (about half the population of epithelial cells) but, because of their small size and lack of reaction to routine stains, they are not a conspicuous feature of the pituitary. They appear to consist of a number of different types of cells, including degranulated secretory cells of the types described above, stem cells capable of giving rise to chromophils (the turnover of these cells has been described) and follicular cells containing numbers of lysosomes and forming cell clusters around cysts of various sizes; cysts are often present in the junctional area with the neurohypophysis and are filled with a PAS-positive substance of unknown significance.



The pars intermedia has many β-cells and follicles of chromophobe cells surrounding PAS-positive colloidal material, some of these being derived from pouches of the embryonic intrahypophysial cleft (of Rathke); in some species, where this pouch remains large, a ciliated lining epithelium has been noted.

Secretory cells of the pars intermedia have granules containing either α-endorphin or β-endorphin scattered uniformly (Bloom et al 1977, Guillerman 1978); these cells have been shown to contain various peptide hormones including ACTH and α-MSH (melanocyte-stimulating hormone), which are assigned to the APUD series (p. 1466), as are other adenohypophysial secretory cells. Endorphin, also occurring in the pars anterior, is localized here to peripheral granules in discrete groups of cells.



The pars tuberalis is remarkable for its large number of blood vessels, between which cords or balls of undifferentiated cells are admixed with some α- and β-cells.

The release of adenohypophysial hormones into the circulation appears to be by exocytosis of their vesicle contents into the perivascular spaces of the neighbouring sinusoids; these are lined by a fenestrated endothelium, facilitating diffusion into the blood. The signal for secretion is the liberation of releasing factors from neurons (McKelvy 1974) in the median eminence, nucleus infundibularis (arcuate nucleus) and other hypothalamic nuclei, into the upper capillary bed of the venous portal system which carries them to the adenohypophysis to act on its endocrine cells. These neurosecretory cells are *neuroendocrine transducers* (Wurtman 1970), receiving neural and hormonal signals and responding by secreting hormones, thus transducing one type of signal into another. The neurons which produce releasing factors are peptidergic, whereas neurons modulating endocrine activity are largely monoaminergic, making axosomatic or axo-axonic synapses with them.

Tanycytes (p. 894, 8.224, 225) may also control secretion, possibly transporting hormones from the cerebrospinal fluid to

8.224 Diagram illustrating the control systems which influence the hormonal output of the adenohypophysis. The small diagram on the right shows the ventral hypothalamus, median eminence and adenohypophysis (pars distalis) and their associated neurons and vasculature. On the left three zones are shown in greater details. The concatenation of events is as follows: under the influence of blood-borne factors and neural stimuli, the hypothalamic neuron shown above liberates specific releasing factors into capillaries of the median eminence. Modulation at this point is mediated by aminergic neurons and tanycytes. Onward transport of these factors through portal vessels is indicated by blue arrows. Stimulation and hormone production and release on the part of the adenohypophysial cell are also indicated.

8.225 The general ultrastructure of a tanycyte. (See text on pp. 894 and 1453 for explanatory details.)

capillaries of the portal system (Knigge 1976) and/or from hypothalamic neurons to the cerebrospinal fluid (Joseph & Knigge 1978). Tight junctions between them and ependymal cells (Brightman et al 1975), though rudimentary compared with those in the choroid plexus, impede movement of peptides and even some amino acids (Weindl & Joynt 1972), suggesting that materials such as releasing factors would need to cross the ependyma via, not between, the tanycytes. The endocytotic (presumably also exocytotic) activity of tanycytes appears to be under monoaminergic neuronal control (Kobayashi 1975, Nozaki et al 1975). Tanycytes in the walls of the ventricular recess appear suitable for the transport of releasing factors from neurosecretory cells to cerebrospinal fluid, because they traverse the arcuate nucleus, linked to its neurons by junctions permitting the passage of small molecules such as peptide hormones between cells which they unite (del Cerro & Knigge 1977). However, this possible involvement of tanycytes in the control of secretion by transport of releasing factors awaits verification.

The Neurohypophysis

The posterior hypophysial lobe is a downgrowth from the diencephalic floor, and in early fetal life contains a cavity continuous with the third ventricle, which in some animals, e.g. cats, persists. The posterior lobe, infundibular stem and median eminence are often grouped as the *neurohypophysis* (vide supra and consult Harris 1955, Heller & Clark 1962, Scharrer & Scharrer 1963, Gabe 1966, Donovan 1970, Knowles 1974).

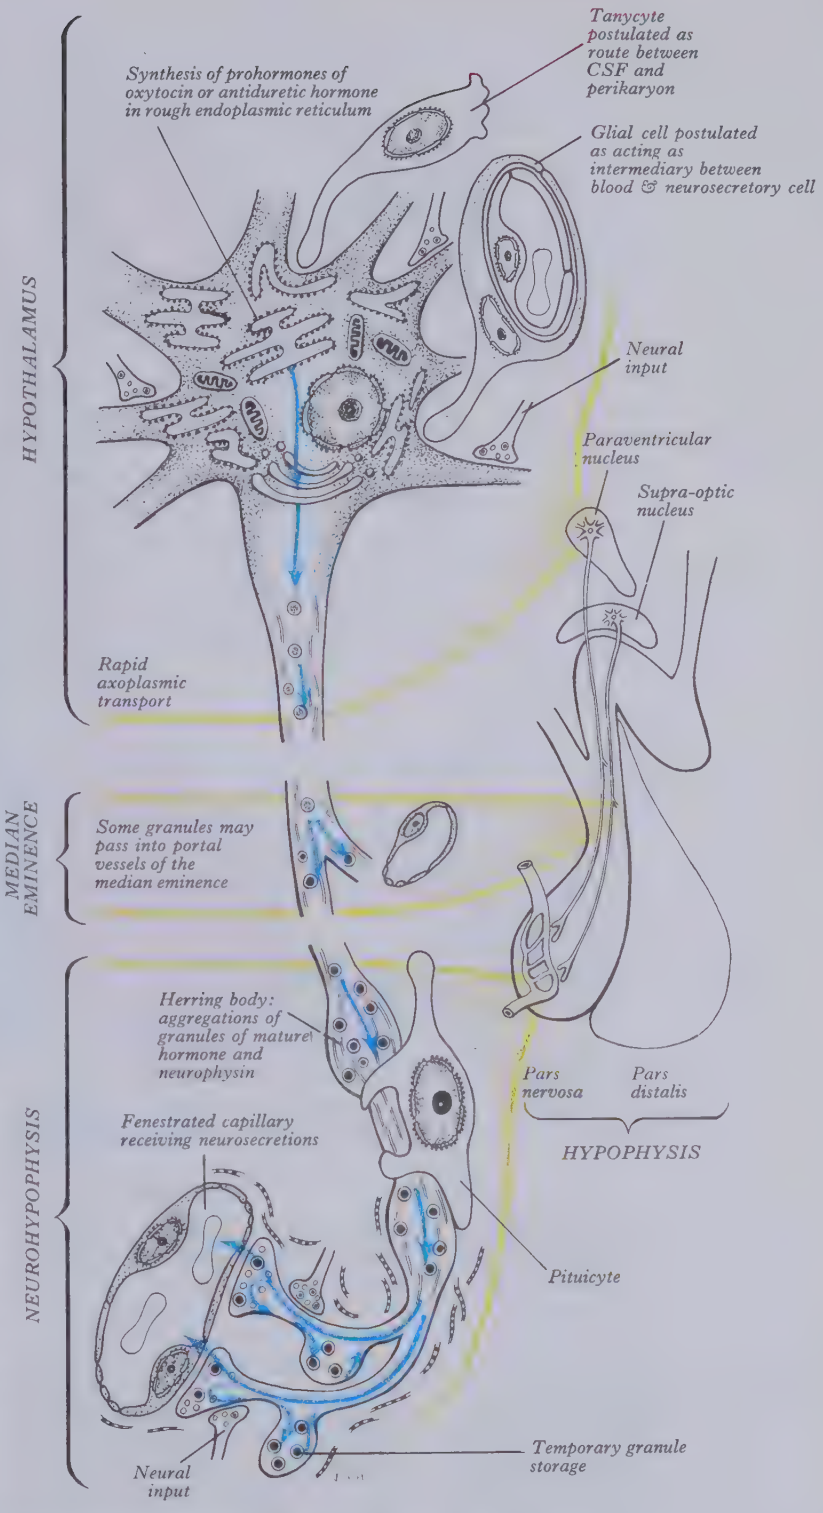
Axons arising from groups of hypothalamic neurons (supraoptic and para-ventricular nuclei, etc.) terminate in the neurohypophysis; some are short, ending in the median eminence and infundibular stem among the superior capillary beds of the venous portal circulation, possibly providing neural control of adenohypophysial function (vide infra). Longer axons pass to the main neurohypophysis thereby forming the neurosecretory hypothalamohypophysial tract (p. 1009), terminating near the sinusoids. The hormones concerned are *vasopressin (antidiuretic hormone,* ADH) controlling reabsorption of water by renal tubules (p. 1406) and *oxytocin* which promotes the contraction of uterine and mammary non-striated muscle. Their sites of production have been described (p. 1009); from their neuronal perikarya they traverse axons of the tract for release at nerve terminals. Ligation of the tract causes proximal damming of secretion granules, whose high glycoprotein content facilitates PAS staining. The active hormones are simple polypeptides, elaborated and transported in cells with a glycoprotein, *neurophysin*; after release into the circulation this association is broken, the hormone being carried to its cellular targets by plasma glycoproteins.

Other substances demonstrated in these endings include met-enkephalin (co-localized with vasopressin) and cck (p. 891) (with oxytocin).

The neurohypophysis contains thin, non-myelinated nerve fibres and associated cells; these are the terminal ramifications of the hypothalamohypophysial tract. Proximally, in the infundibulum, the fibres are ensheathed by typical astrocytes but near the posterior lobe *pituicytes* appear, dendritic cells of variable appearance, often with long processes running parallel to adjacent axons. Pituicytes constitute most of the non-excitable tissue in the neurohypophysis. Cytoplasmic processes of many pituicytes end on or near the walls of adjacent capillaries and sinusoids between nerve terminals. Axons end in perivascular spaces and, though they approach close to the walls of sinusoids, they remain separated from them by two basal laminae, one applied to the nerve endings and the other to the external surface of the endothelial cells. Fine collagen fibres often exist between the two. The cytoplasm of endothelial cells is generally extremely attenuated and has regular fenestrations which facilitate the passage of hormones into the bloodstream (8.226).

Three types of nerve terminal are described in the posterior hypophysial lobe: (1) terminal axonal swellings adjacent to the sinusoids, in which are large (200–300 nm), dense vesicles containing hormones bound to glycoproteins, and also small (40–60 nm), clear, spherical vesicles; (2) peri-axonal endings with small (80 nm) dense-cored vesicles, like those containing catecholamine in sympathetic nerve endings (p. 905); (3) peri-axonal endings containing small (40–60 nm), clear, spherical vesicles forming synapses with large hormone-containing endings (Bargmann 1966). Interactions between these diverse terminals are not clear. The hormones are probably released by exocytosis from endings with large dense vesicles. Excitation or inhibition of release is mediated by excitation of hormone-containing endings by action potentials carried along the same axon.

Vessels of the Hypophysis

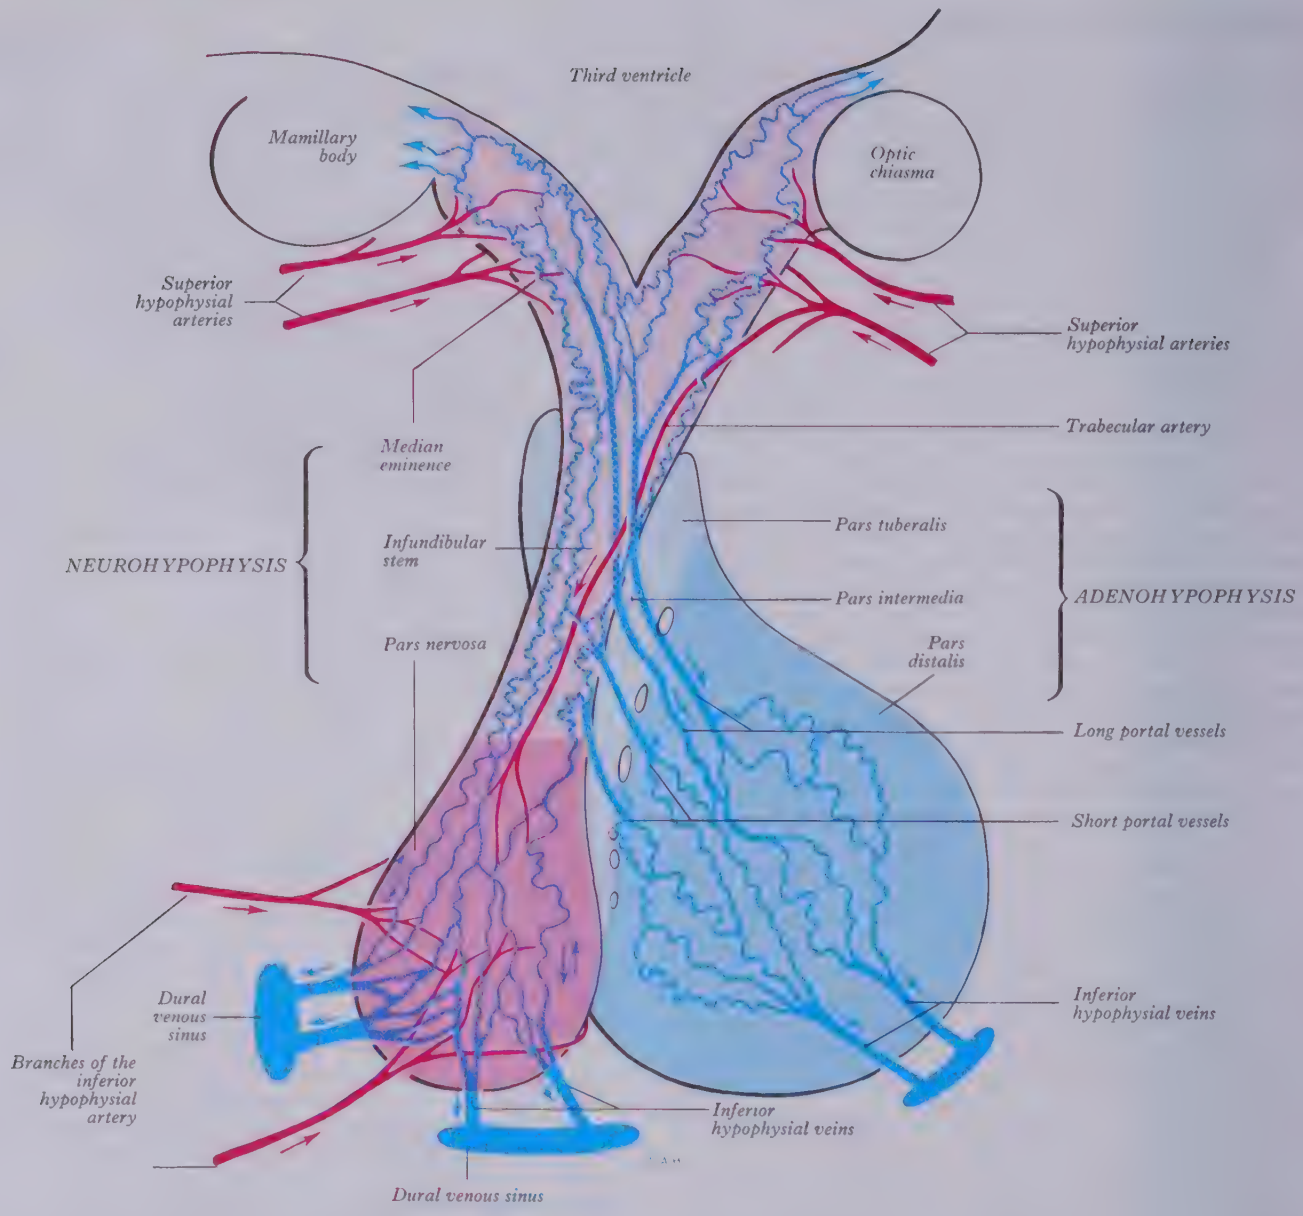


These have been studied by injection with neoprene latex and Berlin blue; also by staining erythrocytes (Popa & Fielding 1930 a, b, Green & Harris 1949, Xuereb et al 1954 a, b, Stanfield 1960) and examination by scanning electron microscopy of corrosion casts to determine details of angio-architecture of the median eminence and the vascular connections in and between the neurohypophysis and adenohypophysis (Page & Bergland 1977).

The *arteries* of the hypophysis arise from the internal carotids via a single *inferior* and several *superior hypophysial arteries* on each side, the former coming from the cavernous part of the internal carotid, the latter from its supra-clinoid part and from the anterior and posterior cerebral arteries. The inferior hypophysial arteries divide into medial and lateral branches which anastomose across the midline to form an infundibular *arterial ring*. From this fine branches enter the neurohypophysis, supplying its capillary bed. The superior hypophysial arteries supply the median eminence, upper infundibulum and, via *arteries of the trabeculae*, its lower part. A confluent capillary net, extending through the neurohypophysis (median eminence, infundibular stem and pars nervosa), is supplied by both sets of hypophysial vessels. *Reversal* of flow can occur in cerebral capillary beds lying between the two supplies (Gillilan 1974) and has been suggested in the neurohypophysial network (Page & Bergland 1977).

The arteries of the median eminence and infundibulum end in characteristic sprays of capillaries, which are most complex in the upper infundibulum. In the median eminence these are an *external* or '*mantle*' *plexus* (Green 1951) and an *internal* or '*deep*' *plexus* (Duvernoy 1972); the external plexus, fed by the superior hypophysial arteries, is continuous with the infundibular plexus and is drained by *long portal vessels* descending to the pars anterior; the internal plexus projects within the external plexus which is supplied by it and is continuous posteriorly with the infundibular capillary bed and, like the external plexus, is drained by *long portal vessels*. *Short portal vessels* run from the lower infundibulum to the pars anterior. Both types of portal vessel open into vascular sinusoids lying between the secretory cords in the adenohypophysis, providing most of its blood; there is no direct arterial supply (Wislocki & King 1936). The *portal system* is considered to carry hormone-releasing factors, probably elaborated in parvocellular groups of hypothalamic neurons to control the secretory cycles of cells in the pars anterior, supply of which is not clear; it appears to be avascular in corrosion casts (Page & Bergland 1977).

The venous drainage of the neurohypophysis is by three possible routes: (1) to the adenohypophysis via long and short portal vessels; (2) via the large inferior hypophysial veins into the dural venous sinuses; (3) to the hypothalamus via capillaries passing to the median eminence. The venous drainage carries hypophysial hormones from the gland to their targets and also facilitates feedback control of secretion. In contrast, the venous drainage of the adenohypophysis appears restricted. Few vessels connect it directly to the systemic veins so the routes by which blood leaves remain obscure. If flow in the short portal veins running between the adeno- and neurohypophysis were reversible (Adams et al 1969), these portal vessels could constitute drainage channels; adenohypophysial hormones could enter the neuro-hypophysial capillaries before reaching the systemic veins, providing a 'short feedback' loop postulated from the evidence of endocrinology. The reversed flow in neurohypophysial capillaries (from neurohypophysis to hypothalamus, according to Torok 1954) could be a vascular route for neurohypophysial hormones to the ventricular tanycytes and hence to the cerebrospinal fluid. The demonstration of neurohypophysial hormones in the cerebrospinal fluid (Robinson & Zimmerman 1973) and of releasing factors there and in tanycytes (Knigge & Joseph 1974) strengthens this hypothesis. Cushing's original (1912) suggestion that the neurohypophysis secretes into the third ventricle may yet be confirmed.

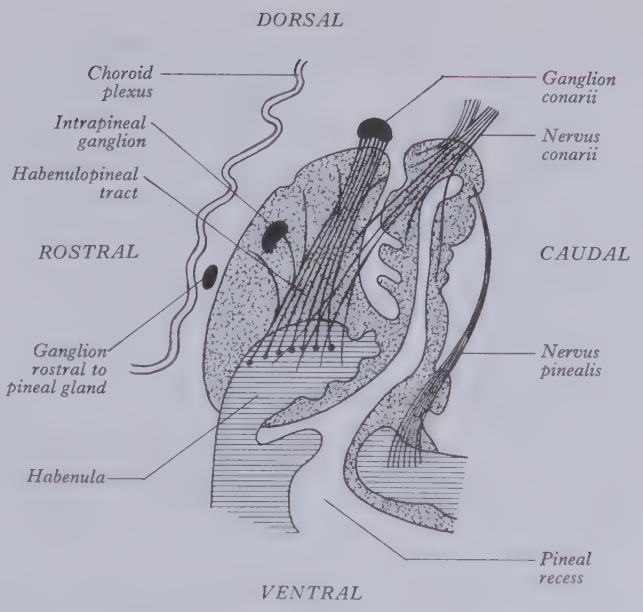


This model of hypophysial blood supply has far-reaching implications; instead of the median eminence being the final common pathway for neural control of the adenohypophysis (Harris 1947), the entire neurohypophysis may be involved; its capillary bed may selectively 'determine the destination of both hypothalamic and pituitary secretions, conveying some to the glandular pituitary, others to distant target organs and yet others to the brain' (Page & Bergland 1977).

8.226 Diagram summarizing the control systems which influence the production of neurohypophysial hormones.

THE PHARYNGEAL HYPOPHYSIS

This small collection of adenohypophysial tissue lies in the mucoperiosteum of the human nasopharyngeal roof (Boyd 1956) as in many other mammals (McGrath 1974). By 28 weeks in utero it is well vascularized and capable of secretion, receiving blood from the systemic vessels of the nasopharyngeal roof. At this stage



8.227 Diagram summarizing the vasculature of the hypothalamic median eminence, infundibulum and the rest of the hypophysis cerebri. (See text for a detailed account and possible significances.)

it is covered posteriorly by fibrous tissue but in the second half of fetal life this is replaced by venous sinuses and a trans-sphenoidal portal venous system develops, bringing it under the same hypothalamic control as the cranial adenohypophysial tissue (McGrath 1978). The peripheral vascularity of the pharngeal hypophysis persists until about the fifth year; the organ is then reinvested by fibrous tissue and presumed to be again controlled by factors present in systemic blood. Though it does not change in size after birth in males, in females it becomes temporarily smaller, returning to natal volume during the fifth decade (McGrath 1971), when once again it may be controlled via a trans-sphenoidal extension of the hypothalamo-hypophysial portal venous system. The human pharyngeal hypophysis may be a reserve of potential adenohypophysial tissue which may be stimulated, particularly in females, to synthesize and secrete adenohypophysial hormones in middle age, when intracranial adenohypophysial tissue is beginning to fail.

The Pineal Gland

The pineal gland or *epiphysis cerebi* (**8**.221), a small, piriform, reddish-grey organ, occupies a depression between the superior colliculi. (For classic reviews see Gladstone & Wakeley 1940, Kappers 1960, Wolfe et al 1962, Kappers & Schade 1965, Wurtman et al 1968, Wolstenholme & Knight 1971.) It is inferior to the splenium of the corpus callosum, separated from it by the tela choroidea of the third ventricle and its cerebral veins and enveloped by the tela's lower layer, which is reflected thence to the tectum (**8**.221). The gland is about 8 mm in length; its base, directed anteriorly, is attached by a *peduncle* dividing into inferior and superior laminae, separated by the *pineal recess* of the third ventricle (**8**.221), and respectively containing the posterior (p. 1005) and habenular (p. 1006) commissures. Aberrant commissural fibres may invade the gland but do not terminate near parenchymal cells. Nerve fibres enter its dorsolateral aspects from the tentorium cerebelli as a single or paired *nervus conarii*, which is subendothelial in the wall of the straight sinus (p. 801), its fibres derived from neurons of the superior cervical ganglia. These fibres are adrenergic sympathetic elements associated with blood vessels and parenchymal cells (Kappers 1960, Wolfe et al 1962). Bjorklund et al (1972) have shown in rats that postganglionic sympathetic fibres from the *nervus conarii* reach neurons in the habenular nuclei, from which some fibres of the *habenulopineal tract* (p. 1006) may start. Møller (1978) reported that, in human

fetuses, fibres of this tract reach the *ganglion conarii* (Pastori ganglion) at the pineal apex (**8**.228); the neurons of origin of these fibres need verification. Møller (1978, 1979) has also reported an unpaired nerve containing non-myelinated fibres and bipolar neurons with axosomatic and axodendritic synapses, the *nervus pinealis*, in human fetuses; it is in the subarachnoid space near the median plane just caudal to the pineal, connecting it to the posterior commissure. It is ephemeral, presumed to degenerate late in intrauterine life and its function is uncertain; but since it is presumed to be homologous with the sensory pineal nerve of fish and amphibians (Møller 1978), whose pineal complexes contain photoreceptors, it might transmit light-generated impulses. Though in some mammals (e.g. neonatal rats) pinealocytes transiently resemble photoreceptors (Zimmerman & Tsi 1975), those in human fetuses do not. The human fetal nervus pinealis may be involved in pineal differentiation. At present it can only be regarded as a phylogenetic vestige; its loss may be associated with evolution of the pineal as a secretory rather than photoreceptive organ. Møller (1978) has also described a ganglion, presumed to be parasympathetic, rostral to the pineal gland and near the choroid plexus of the third ventricle. An anterior *intrapineal ganglion* has also been found (**8**.228).

8.228 Diagram showing the principal neural pathways which have been described in connection with the human fetal pineal gland (epiphysis cerebri).

STRUCTURE OF THE PINEAL GLAND

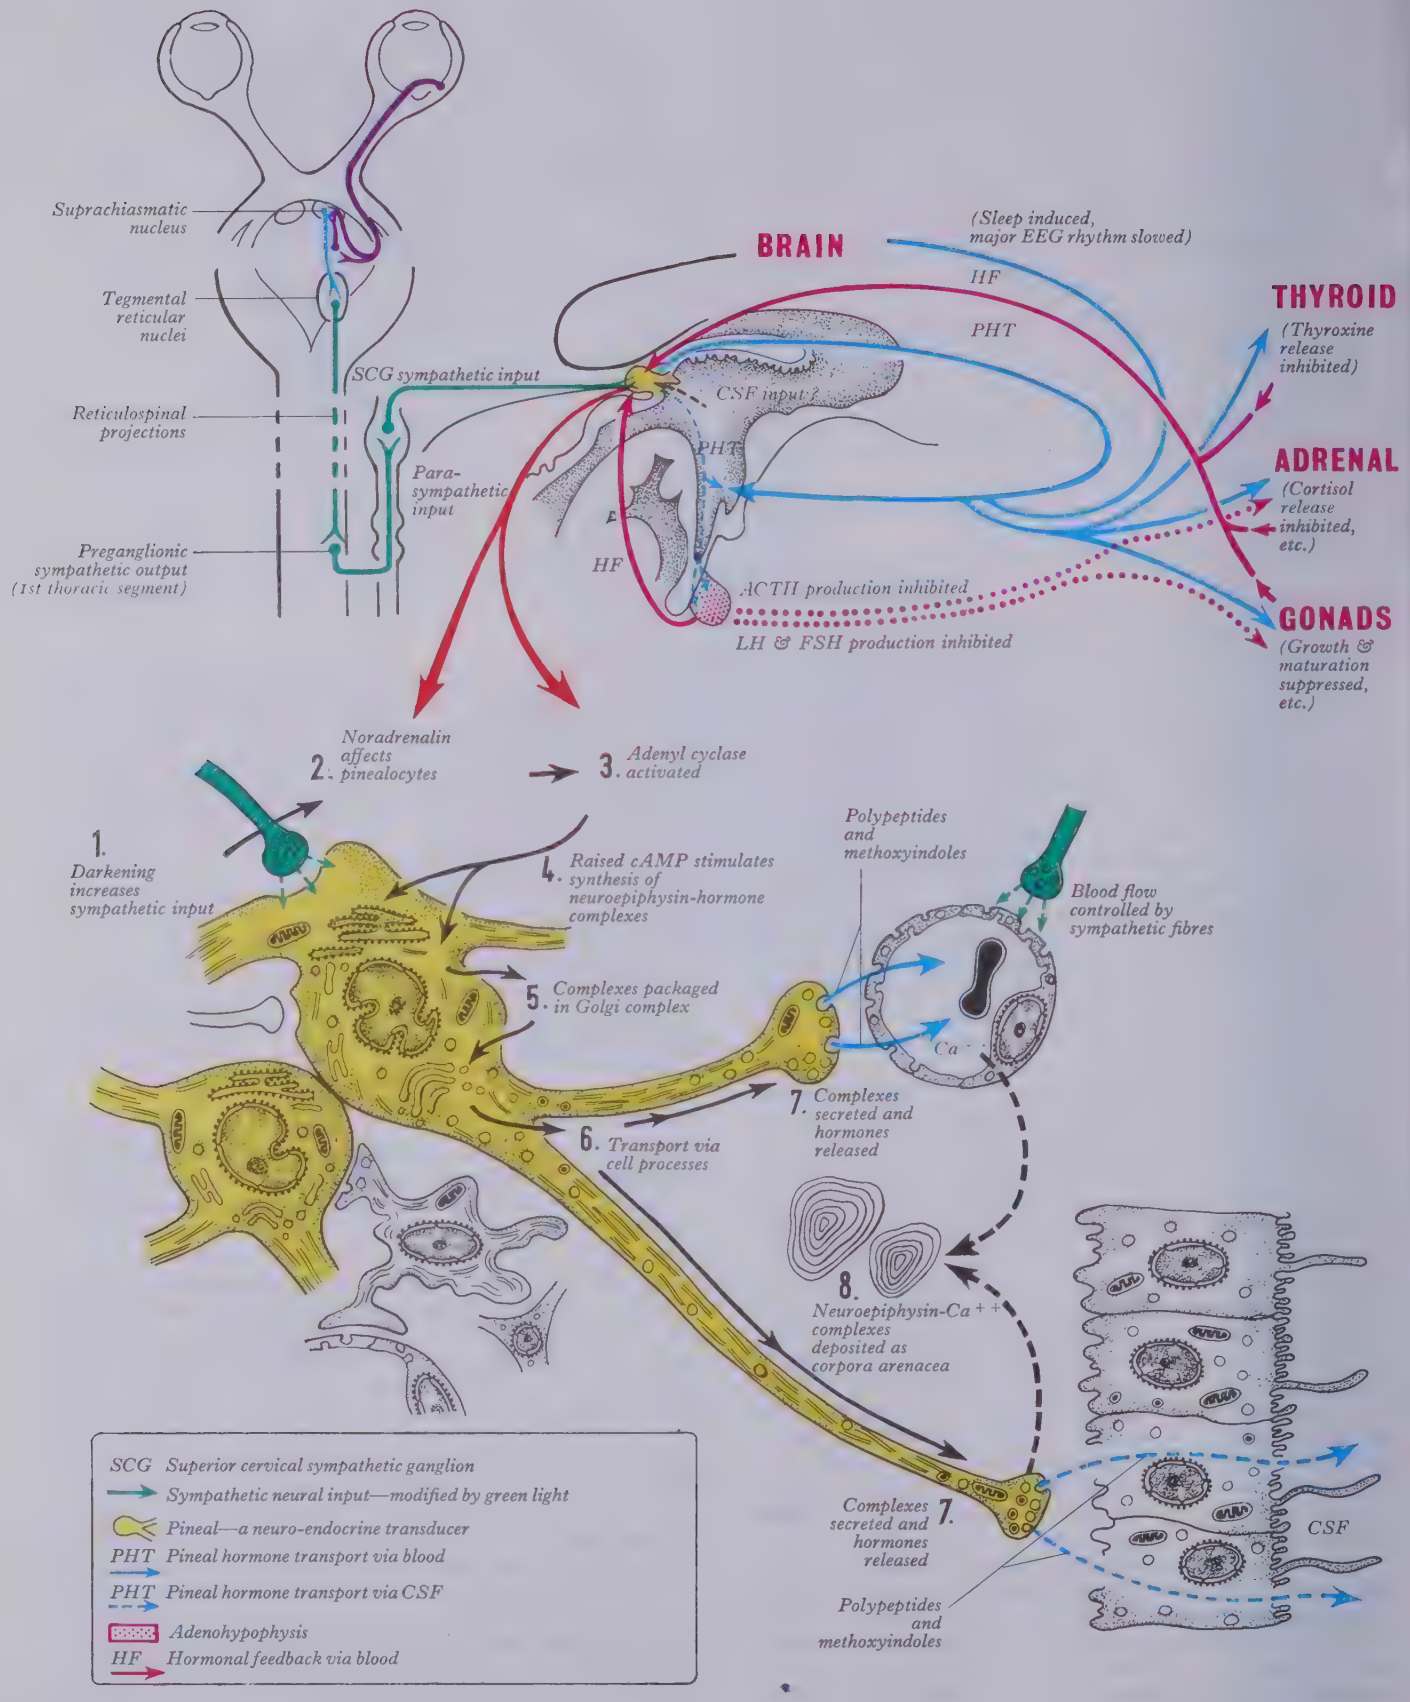
The pineal gland contains cords and follicles of pinealocytes and neuroglial cells among which ramify many blood vessels and nerves. Septa extend into it from the surrounding pia mater.

Pinealocytes form the pineal parenchyma. Extending from each cell body, with a spherical, oval or lobulated nucleus, are one or more tortuous basophilic processes, containing parallel microtubules (Knight et al 1973) which end in expanded terminal buds near capillaries or, less frequently, ependymal cells of the pineal recess. The terminal buds contain granular endoplasmic reticulum, mitochondria and electron-dense cored vesicles, which store monoamines and polypeptide hormones (Sheridan & Sladek 1975), release of which appears to require sympathetic innervation. Lukaszyk & Reiter (1975) have proposed that the polypeptide hormones (which they consider could be produced by pineal neuroglia and neurons) combine with specific protein carriers, termed *neuro-epiphysins* to distinguish them from hypophysial neurophysins. They are released by exocytosis, together with fragments of vesicular membrane, the latter forming exocytotic debris. When released the complex is believed to dissociate, hormones being exchanged for calcium ions. The calcium-carrier complex so formed is, in the pineal, deposited concentrically around exocytotic debris as *corpora arenacea* or '*brain sand*' (**8**.229, 230). It is often supposed that the pineal atrophies with age, corpora arenacea being a sign of atrophy; on the contrary, these corpuscles may indicate continued secretion. Wildi & Frauchiger (1965) found no evidence of pineal degeneration in the elderly.

Pinealocytes contain both granular and agranular endoplasmic reticulum, with extensive Golgi complexes, lipid droplets and numerous mitochondria, according with secretory function. An unusual organelle (groups of microtubules and perforated lamellae) sometimes occurs near granular endoplasmic reticulum and lipid droplets. Termed '*canaliculate lamellar bodies*' by Lin (1967) and McNeil (1977), '*annulate lamellae*' by Friere & Cardinali (1975) and '*mikrotubuli*' by Gusek (1976), they may be involved in secretion (McNeil 1977) but their function remains uncertain.

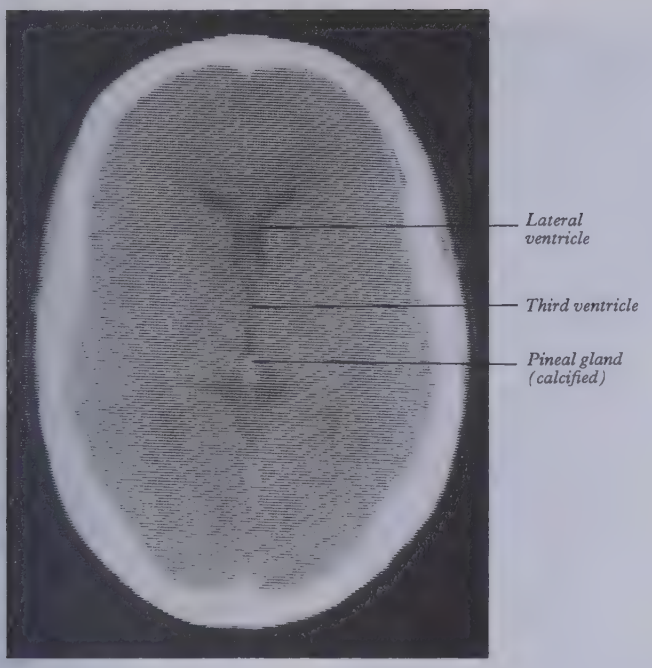
Pinealocytes of some mammals contain synaptic ribbons, perhaps involved in transmission; vesicles near them contain neurotransmitters such as gamma-amino-butyric acid (Krstic 1976). These ribbons may arise from microtubular sheaths and in turn from centrioles (Karasek 1976). Similar organelles occur in mammalian retinal photoreceptors and simpler submammalian photoreceptors, supporting the theory that mammalian pinealocytes are derived from photoreceptors (Kappers 1976, Relkin 1976). Transient similarities between pinealocytes and retinal photoreceptors in neonatal rats lend further support to this concept (Zimmerman & Tso 1975).

The ultrastructure of human fetal pinealocytes indicates their secretory function in early intrauterine life (Møller 1974). As in adults, they contain all the appropriate organelles, together with abundant microfilaments, microtubules and a few cilia with a 9 + 0 microtubular pattern, the latter also associated with secretory cells in other endocrine glands, such as the hypophysis (Barnes 1961, Andersen et al 1970). Fetal pinealocytes have gap junctions, desmosomes and 'intermediate-like junctions' (Møller 1976); the first are for electrotonic coupling between adjacent cells enabling group activity, the others of an adhesive nature. Synaptic ribbons do not appear in human fetal pinealocytes.



Neuroglial cells, partially separating the pinealocytes, are like astrocytes and in the pineal stalk many have extensive longitudinal processes, composing most of the stalk. Ultrastructurally they display numerous filaments extending throughout their processes.

Vessels and Nerves



Pineal *capillaries* are lined by thin, sometimes fenestrated, endothelial cells, with a tenuous external basal lamina, sometimes incomplete. The non-myelinated autonomic *nerve fibres* are mostly noradrenergic, with dense-cored vesicles in terminal and preterminal expansions. Arising in the superior cervical ganglion they penetrate the pineal either via perivascular spaces or through the nervi conarii (vide supra) or else by the leptomeningeal pineal surface. They either terminate in perivascular spaces between the pinealocytes or synapse with them. Other nerve fibres in the stalk are of uncertain origin but habenular nuclei are strongly mooted as their source.

FUNCTIONS OF THE PINEAL GLAND

Once considered to be a phylogenetic relic, a vestige of a dorsal third eye and of little functional significance, the mammalian pineal is now accepted as an endocrine gland of major regulatory importance, modifying the activity of: the adenohypophysis, neurohypophysis, endocrine pancreas, parathyroids, adrenal cortex, adrenal medulla and gonads (De Vries & Kappers 1971, Klein 1978, Haulica & Coculescu 1981, Reiter 1983, 1984, 1985, 1987, Malendowicz 1985). Its effects are largely inhibitory: indoleamine and polypeptide hormones secreted by pinealocytes are believed to reduce synthesis and release of hormones of the pars anterior, e.g. by direct action on its secretory cells and indirectly by inhibiting production of hypothalamic releasing factors.

8.229 Diagrammatic review of current hypotheses regarding the control and effects of pineal function. (See text for details.)

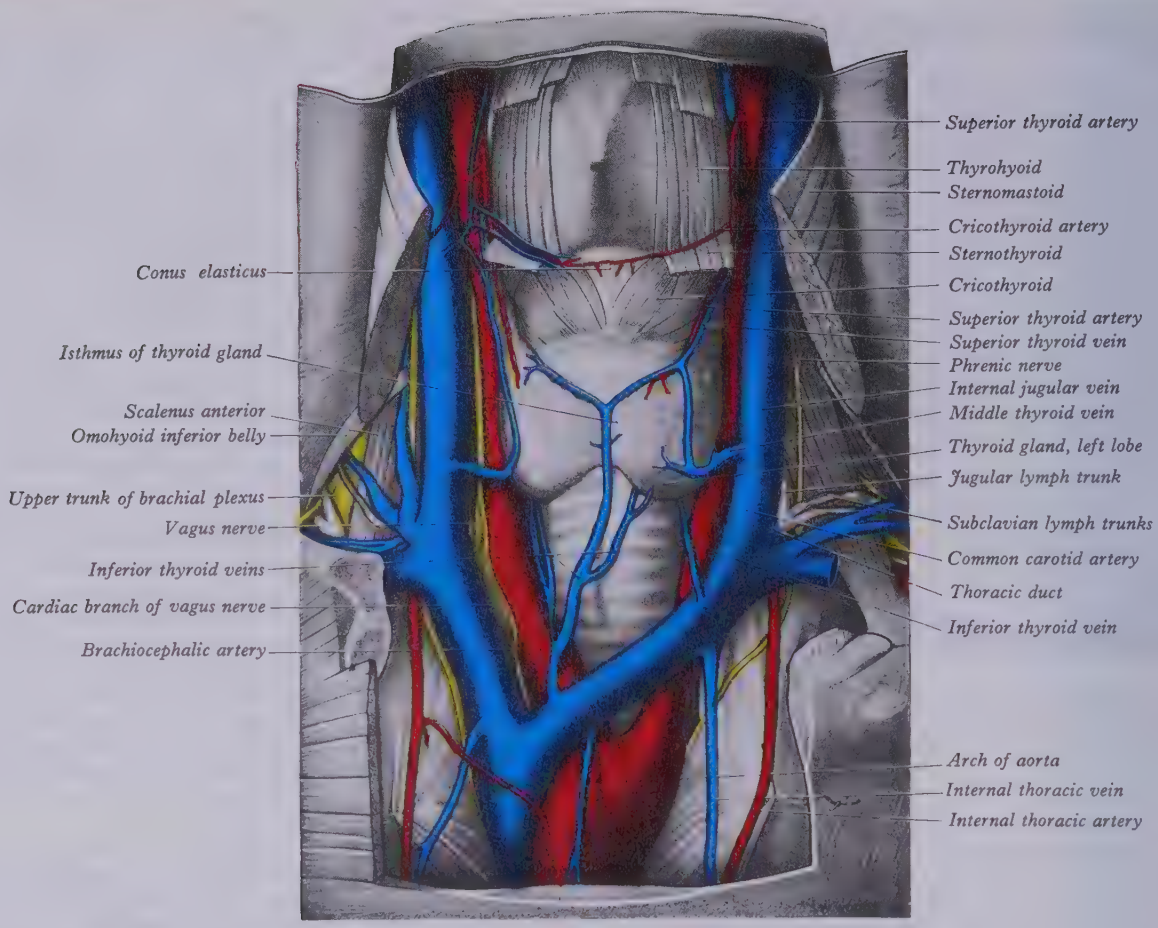
8.230 Computed tomogram of the head in the horizontal plane at the level of the pineal gland. Supplied by Shaun Gallagher, Guy's Hospital; photography by Sarah Smith, UMDS, Guy's Hospital Campus, London.

Pineal secretions may reach their target cells via cerebrospinal fluid (Sheridan et al 1969, Knight et al 1973) or the bloodstream.

Some pineal indole-amines, including melatonin and enzymes for their biosynthesis (e.g. serotonin N-acetyltransferase) show circadian rhythms in concentration and activity in many mammalian pineal glands. In rats there may be an *endogenous circadian oscillator* in the suprachiasmatic nucleus (hypothalamus), whose intrinsic rhythmicity governs cyclical pineal behaviour (Klein 1978). Photic stimuli, in particular intensity changes of yellow-green light acting on rhodopsinoid retinal pigment, seem to be involved in this rhythm (Cardinali et al 1971, Minneman et al 1974), the pineal being most *active* in *darkness*. With the visual pathway and pineal sympathetic supply intact, exposure to *light* after several hours of darkness *depresses* pineal activity (Klein & Weller 1972). Suprachiasmatic neurons are supplied directly by axons of retinal ganglion cells, allowing response to changes in illumination (Nishino et al 1976). In rats, the path from the suprachiasmatic nucleus to the pineal gland is claimed to include the tegmental nuclei and the upper thoracic spinal intermediolateral column (Saper et al 1976); preganglionic sympathetic fibres from the latter are said to reach the superior cervical ganglia, from which post-ganglionic fibres can be traced to the pinealocytes. Release of catecholamines from these fibres causes a receptor-mediated increase in the production of cyclic AMP in pinealocytes, evoking a 70- to 100-fold increase in serotonin N-acetyltransferase activity, which regulates daily changes in melatonin production and hence its plasma levels. Interest has centred on sympathetic innervation; the role of its parasympathetic supply is as yet unknown. These hypothecations are summarized in 8.229. Evidence has been found of a circadian rhythm in *human* pineal activity, in changes of plasma melatonin levels (Vaughan et al 1976). As in other mammals, the level rises during darkness, falling during the day. Whether the control mechanisms demonstrated in other animals also operate in man is unresolved.

The Thyroid Gland

The thyroid gland (8.231), brownish-red and highly vascular, is placed anteriorly in the lower neck, level with the fifth cervical to the first thoracic vertebrae. Ensheathed by the pretracheal layer of deep cervical fascia, it has right and left lobes connected by a narrow, median *isthmus*. Its weight is usually about 25 g but varies, being slightly heavier in females, and enlarging during menstruation and pregnancy.



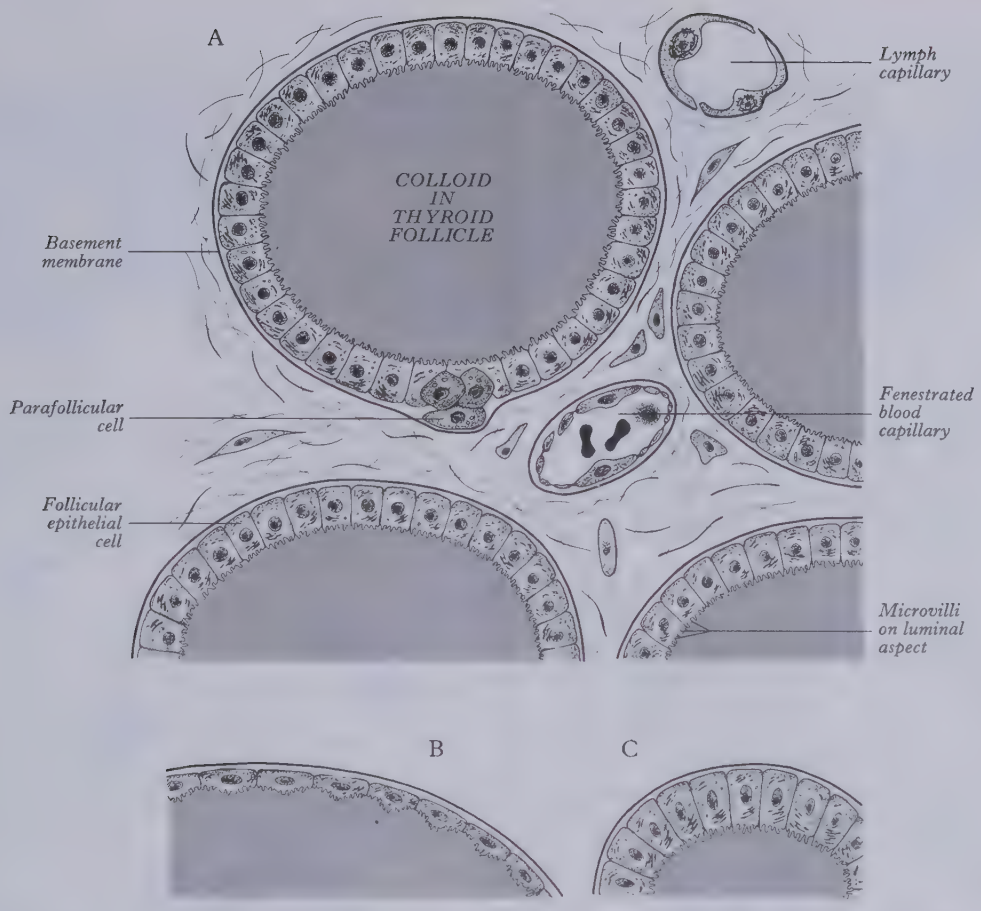
The lobes are approximately conical; their ascending apices diverge laterally to the level of the oblique lines on the laminae of the thyroid cartilages; their bases are level with the fourth or fifth tracheal cartilages. Each lobe is about 5 cm long, its greatest transverse and anteroposterior extents being about 3 cm and 2 cm respectively. Its *posteromedial aspect* is attached to the side of the cricoid cartilage by a *lateral thyroid ligament* (p. 1118). The *lateral (superficial) surface* is convex and covered by the sternothyroid, whose attachment to the oblique thyroid line prevents the upper pole of the gland from extending onto the thyrohyoid muscle. More anteriorly are the sternohyoid and superior belly of omohyoid, overlapped inferiorly by the anterior border of sternocleidomastoid. The *medial surface* is adapted to the larynx and trachea, contacting at its superior pole the inferior pharyngeal constrictor and the posterior part of the cricothyroid, which separate it from the posterior part of the thyroid lamina and the side of the cricoid cartilage. The external laryngeal nerve is medial to this part of the gland, on its way to the cricothyroid. Below the trachea, and posterior to this, the recurrent laryngeal nerve (p. 1118) and oesophagus (closer on the left) are medial relations. The *posterolateral surface* is next to the carotid sheath, overlapping the common carotid artery. The thin *anterior border*, near the anterior branch of the superior thyroid artery, slants down medially. The rounded *posterior border* is related below to the inferior thyroid artery and its anastomosis with the posterior branch of the superior thyroid artery. The parathyroid glands are usually related to this border (p. 1463), whose lower end on the left is near the thoracic duct.

The isthmus connects the lobe's lower parts; it measures about 1.25 cm transversely and vertically and is usually anterior to the second and third tracheal cartilages, though often higher or sometimes lower; its site and size vary greatly. Pretracheal fascia separates it from the sternothyroid muscles; more superficially are the sternohyoids, anterior jugular veins, fascia and skin. The superior thyroid arteries anastomose along its upper border; at the lower border the inferior thyroid veins leave the gland. Occasionally the isthmus is absent.

A conical *pyramidal lobe* often ascends towards the hyoid bone from the isthmus or the adjacent part of either lobe (more often the left). It is occasionally detached or in two or more parts. A fibrous or fibromuscular band, the *levator of the thyroid gland*, sometimes descends from the hyoid body to the isthmus or pyramidal lobe. Small detached masses of thyroid tissue may occur above the lobes or isthmus as *accessory thyroid glands*. Vestiges of the thyroglossal duct (p. 229) may persist between the isthmus and the lingual foramen caecum, sometimes as accessory nodules or cysts of thyroid tissue near the midline or even in the tongue.

STRUCTURE AND FUNCTIONS

The gland has a thin capsule of connective tissue, whose extensions divide it into masses of irregular form and size. The parenchyma derives mainly from the endoderm of the thyroglossal duct (p. 229), usually a transient embryonic structure extending between the gland and the tongue. From its distal end solid epithelial cords and sheets branch and lumina filled with yellow, viscid colloid appear in them. This endodermal epithelium is generally considered to develop into *separate* follicles, approximately spherical and about 0.02–0.9 mm in diameter, each with a central colloid core surrounded by a simple epithelium and basal lamina. But three-dimensional reconstructions of mature thyroid glands show that follicles are typically aggregated, with a common epithelium bordering several colloid masses and linking follicles together (Isler et al 1968). Solid cell nests have also been described (Harach 1985). The colloid, staining pink with eosin, contains an iodinated glycoprotein, iodothyroglobulin, a precursor of the thyroid hormones, tri-iodothyronine (T_3) and tetra-iodothyronine or thyroxine (T_4), and a product of the follicular epithelial cells. Aggregated follicles nestle in a delicate connective



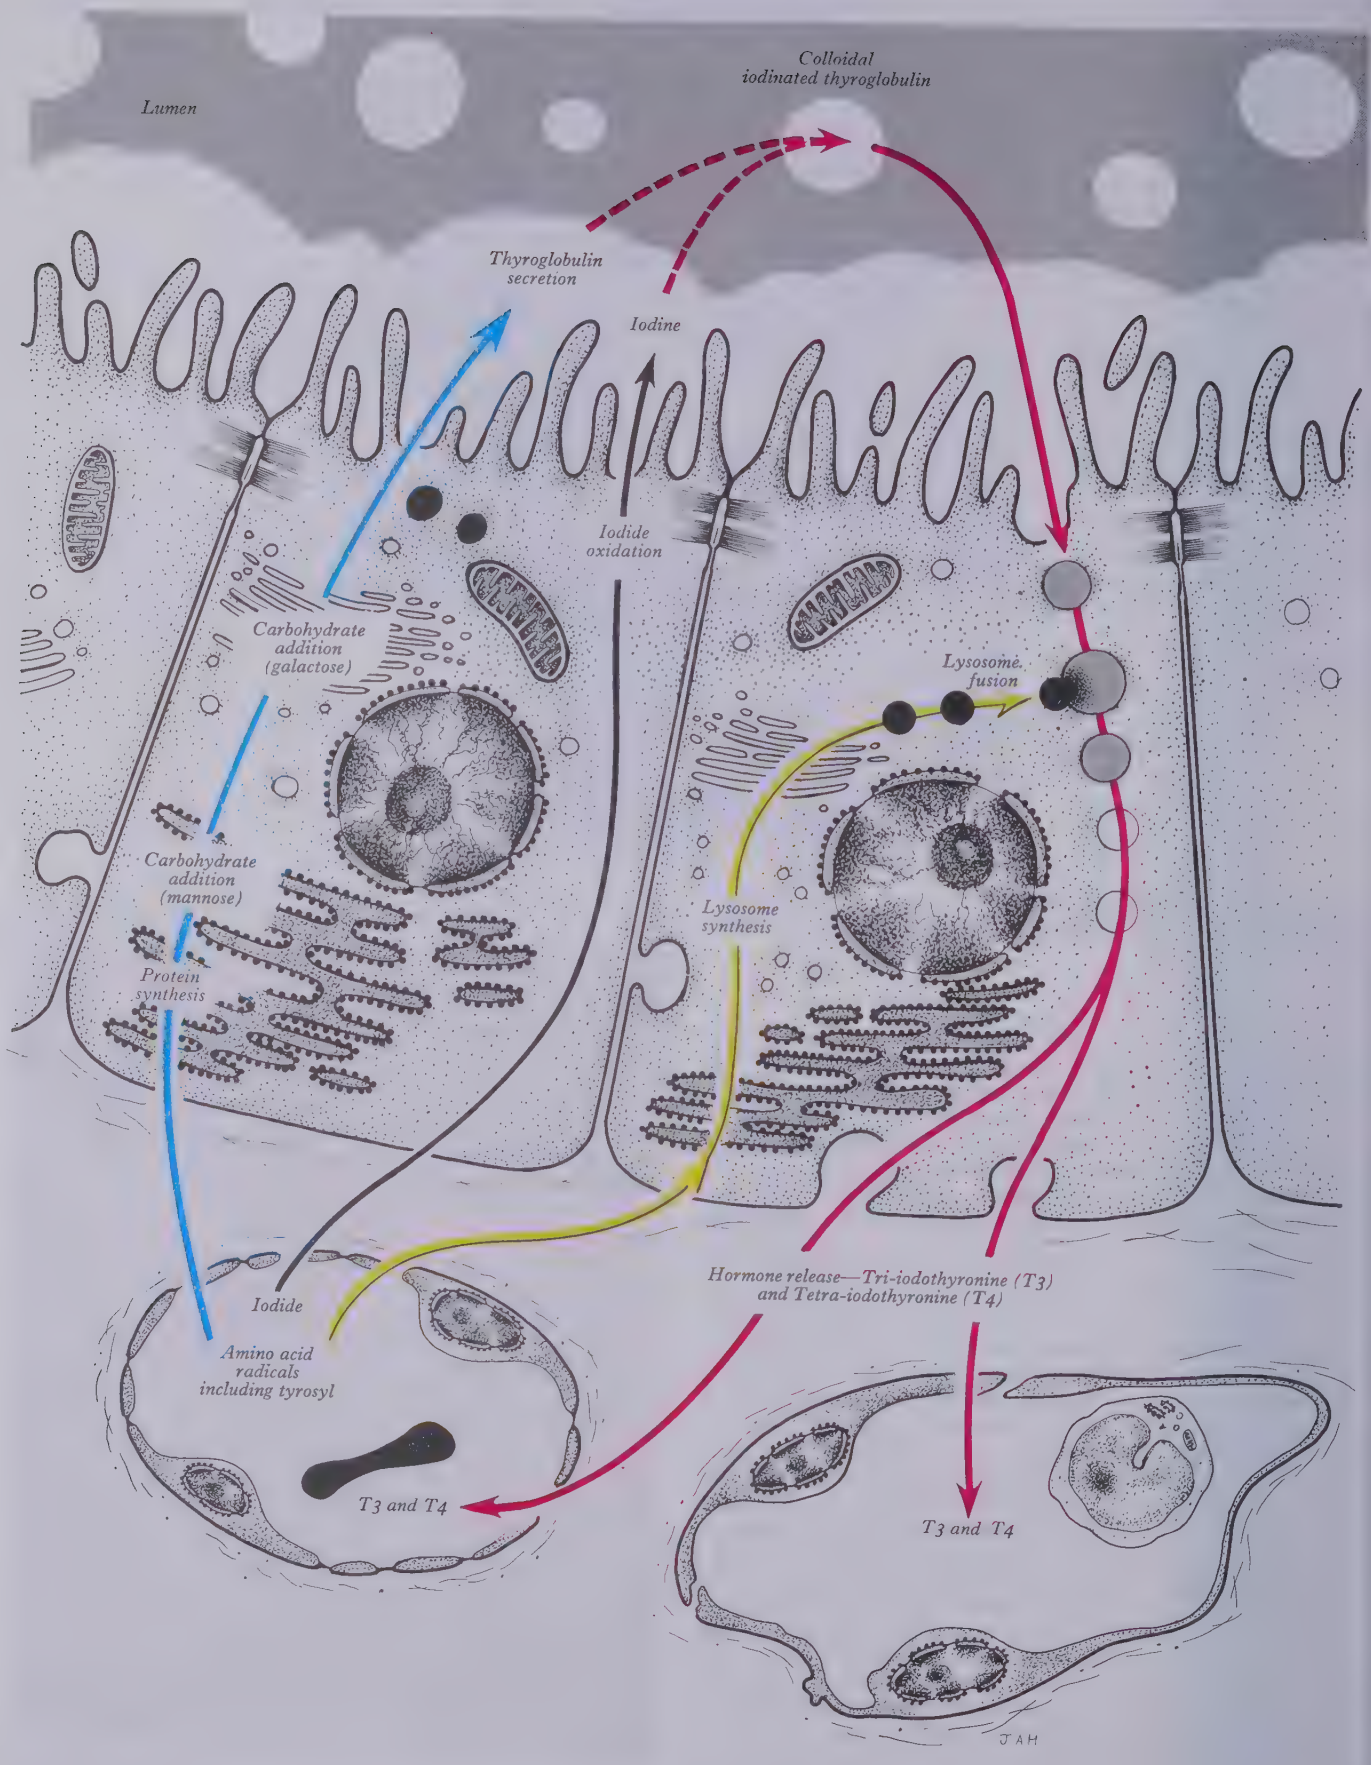
8.231 The thyroid gland and its environs. The manubrium sterni and the sternal ends of the clavicles and first costal cartilages have been removed and the pleural sac and lung have been retracted on each side.

tissue stroma, surrounded by dense plexuses of fenestrated capillaries, extensive lymphatic networks and sympathetic nerve fibres which supply the arterioles and capillaries, some nerve fibres ending close to the follicular epithelial cells (Melander et al 1975, Melander 1977).

Thyroid parenchyma contains a second, parafollicular type: 'light', 'clear' or C cells, producing the peptide hormone thyrocalcitonin. C cells, an APUD element (p. 1446), are derived from the ultimobranchial bodies (p. 229). They are a minor component but improved techniques (Solcia et al 1968, 1969) suggest that in some species they have been underestimated; e.g. in dogs Kameda (1971, 1976) found a ratio of 30–90 parafollicular to 100 follicular cells. Branched tubules containing desquamated cells may occur; like C cells, these are ultimobranchial in origin (Halmi 1978). Other cells, some ciliated, have been described in rodent thyroid glands (Wollman & Neve 1971).

Follicular cells proper vary from squamous to columnar, depending on their activity, mainly controlled by circulating hypophysial thyrotropin (TSH) (8.232), in the absence of which the follicular cells are squamous and 'resting', luminal colloid being abundant and reflecting increased storage of iodinated thyroglobulin. The secretion of TSH leads to endocytosis of colloidal droplets at the luminal aspects of follicular cells, cavities appearing in the luminal colloid near the epithelium. Prolonged high levels of circulating TSH induce follicular hypertrophy and even hyperplasia, with progressive resorption of colloid and increased stromal vascularity.

Follicular cells have a striking ultrastructural and functional polarity: when activated by TSH, or possibly adrenergic nerve terminals (vide infra), they engage in apical synthesis and luminal exocytosis of thyroglobulin, with basally directed thyroglobulin endocytosis, degradation and liberation of thyroid hormones (T_3 and T_4) into the blood capillaries. This polarized dual function is indicated by the arrangement of their organelles. To form a continuous wall around each mass of colloidal thyroglobulin, the follicular cells are linked by apical junctional complexes and have their bases resting on a basal lamina (8.232, 233). Each cell has a basal nucleus, prominent granular endoplasmic reticulum and supranuclear Golgi complex, the last named being particularly prominent in TSH-activated cells. Apical to the Golgi complex and derived from it, secretory vesicles transport glycoprotein, assembled by serial activity of the granular endoplasmic reticulum and the Golgi complex, to the apical plasmalemma for luminal release by exocytosis. Iodine required to complete thyroglobulin formation enters the follicular cells basally by active transport from the blood capillaries across the basal plasmalemma; labelled iodide rapidly appears in the lumina (Wolff 1964) and is oxidized to iodine, mainly by thyroid peroxidase in the apical plasmalemma (Taurog 1970). Iodine is then attached to the tyrosyl groups of the secreted glycoprotein manufactured by the follicular cells. to form mono- and di-iodotyrosyls. These are then coupled into iodothyronyl groups (thyroid hormones in peptide linkage) to complete the formation of iodinated thyroglobulin, the precursor of thyroid hormones (Bjorkman & Ekholm 1973, Robbins et al 1974, Haeberli et al 1975). In follicular cells endogenous peroxidase occurs in perinuclear cisternae, granular endoplasmic reticulum, Golgi complex, apical vesicles, apical plasmalemma and particularly on microvilli (Strum & Karnovsky 1970); but it is likely that only in the apical plasmalemma is it involved in iodide oxidation, its distribution indicating its route to this site. Apical microvilli, numerous but short in resting cells (Wetzel et al 1965), elongate and often branch on stimulation by TSH, which also provokes extension of cytoplasmic processes into the luminal colloid; these fuse around portions of the colloid



8.232 Diagrams of thyroid follicular structure. A. Normal structure under average physiological conditions. B. 'Resting' state. C. Highly active state. (See text for details.)

and take it into the cell. After colloid endocytosis, lysosomes, located basally in the resting state, migrate towards the lumen to fuse with the intracellular droplets of colloid, forming secondary lysosomes or phagolysosomes, which return to the cell's base. During this period the colloid gradually disappears as acid proteases and peptidases in the phagolysosomes degrade the iodinated thyroglobulin, releasing the thyroid hormones T_3 and T_4, which pass basally for release, leaving the gland mainly via the blood capillaries and lymphatics. More numerous precursor molecules, such as 3-mono-iodotyrosine and 3,5-di-iodotyrosine, are de-iodinated by a dehalogenase; the released iodine migrates apically to be recycled in the iodination of newly synthesized thyroglobulin molecules. Microtubules and microfilaments are probably involved in thyroid hormone secretion (Wolff & Williams 1973); treatment with colchicine and cytochalasin B (interfering respectively with microtubule and microfilament activity) inhibits TSH and dibutyryl cAMP-induced secretion. Some iodinated thyroglobulin escapes intact from the follicles and can be radio-immunoassayed in blood, probably reaching it via the lymphatic vessels. Follicular activity in thyroglobulin synthesis and thyroid hormone release is illustrated in **8**.233. Greer & Haibach (1974), DeGroot & Niepomniszcse (1977) and Taurog (1978) provide detailed accounts of these processes.

Of the two thyroid hormones tri-iodothyronine is probably the main stimulator of cellular metabolic rate, its action being very powerful and immediate, whereas tetra-iodothyronine (*thyroxine*) is powerful but less rapid. Over-production of both causes *thyrotoxicosis* (exophthalmic goitre); hyposecretion in adults produces *myxoedema* and in infants *cretinism*. Their synthesis and release are mainly controlled by adenohypophysial thyrotropic hormone (TSH). However, in *Graves' disease*, antibodies to human thyroid-stimulating immunoglobulin (HTSI) bind to TSH-receptor sites in the follicular

cells, interfering with this control and causing excessive hormone production (Werner 1978). Thyroid hormones increase the sensitivity of tissues to adrenalin and noradrenalin. Recent advances in understanding the action of the thyroid hormones at the cellular level have been reviewed by Oppenheimer et al (1987).

Although follicular activity is mainly controlled by circulating TSH, evidence in several mammals, including mankind, suggests a direct sympathetic influence on follicular cells, separately from sympathetic control of the gland's circulation (Melander 1978). Fluorescence histochemistry and electron autoradiography have demonstrated adrenergic terminals near blood vessels and follicular cells. In mice, with TSH secretion eliminated to avoid indirect effects on thyroid secretion, unilateral sympathetic stimulation evokes secretion of the thyroid hormones only in those regions supplied by the stimulated nerve (Melander et al 1972). Studies of human thyroid tissue in vitro also suggest that noradrenalin directly induces follicular changes associated with hormone secretion, including colloid droplet formation and lysosome migration (Melander 1978). In vitro investigations on isolated calf's thyroid cells show that catecholamines can enhance the incorporation of iodine and synthesis of hormones (Melander et al 1973), effects abolished in vivo and in vitro by drugs which block adrenergic receptors (Melander 1970, Maayan & Ingbar 1978) but which do not affect the ability of cells to respond to TSH. Therefore catecholamines and TSH interact with different receptors in follicular cells and can act independently, however, with similar effects. Both activate adenyl cyclase, increasing the formation of cyclic-AMP, which augments hormonal release (Melander 1978). Although anatomicophysiological evidence leaves little doubt that follicular cells and their vessels have direct sympathetic innervation, its effect on thyroid secretion is uncertain. TSH may be a greater influence in sustained regulation; the link between the nervous system and follicular cells may mediate rapid, transient responses to external influences.

Parafollicular ('C') cells, an APUD type (p. 1466), occur singly or in small groups, close to the outer follicular borders but within the follicular basement membrane. Often partly insinuated between adjacent follicular cells, they do not reach the follicular lumen; they are oval or polyhedral and larger than follicular cells. Grouping is sometimes more marked, e.g. in canine thyroid glands, and when perfused with fixative for electron microscopy, where folliculoid groups of such cells appear with expanded central extracellular spaces, perhaps storing hormone. Parafollicular, unlike follicular, cells have no apparent nerve supply; their cytoplasm has numerous membrane-bound secretory granules, probably containing a stored form of thyrocalcitonin, as supported by immunocytochemical studies (Pearse 1966, Wolfe et al 1974). As befits cells engaged in making exportable protein, they contain granular endoplasmic reticulum varying with the level of activity, obvious Golgi complexes, many mitochondria and free ribosomes. The oval nucleus is generally eccentric and has a smooth or slightly irregular membrane.

The main factor controlling release of thyrocalcitonin is usually said to be the concentration of serum calcium; a rise of this in blood perfusing the thyroid gland stimulates thyrocalcitonin secretion, while hypocalcaemia suppresses it, there being a reciprocal relation between secretion of thyrocalcitonin and parathyroid hormone (**8**.234A). Thyrocalcitonin regulates calcium metabolism in many species, largely by suppressing bone resorption, but its human role is uncertain; difficulties arise in detecting thyrocalcitonin in human plasma even by sensitive radio-immunoassay; no pathological condition has been associated with thyrocalcitonin deficiency (O'Riordan 1978).

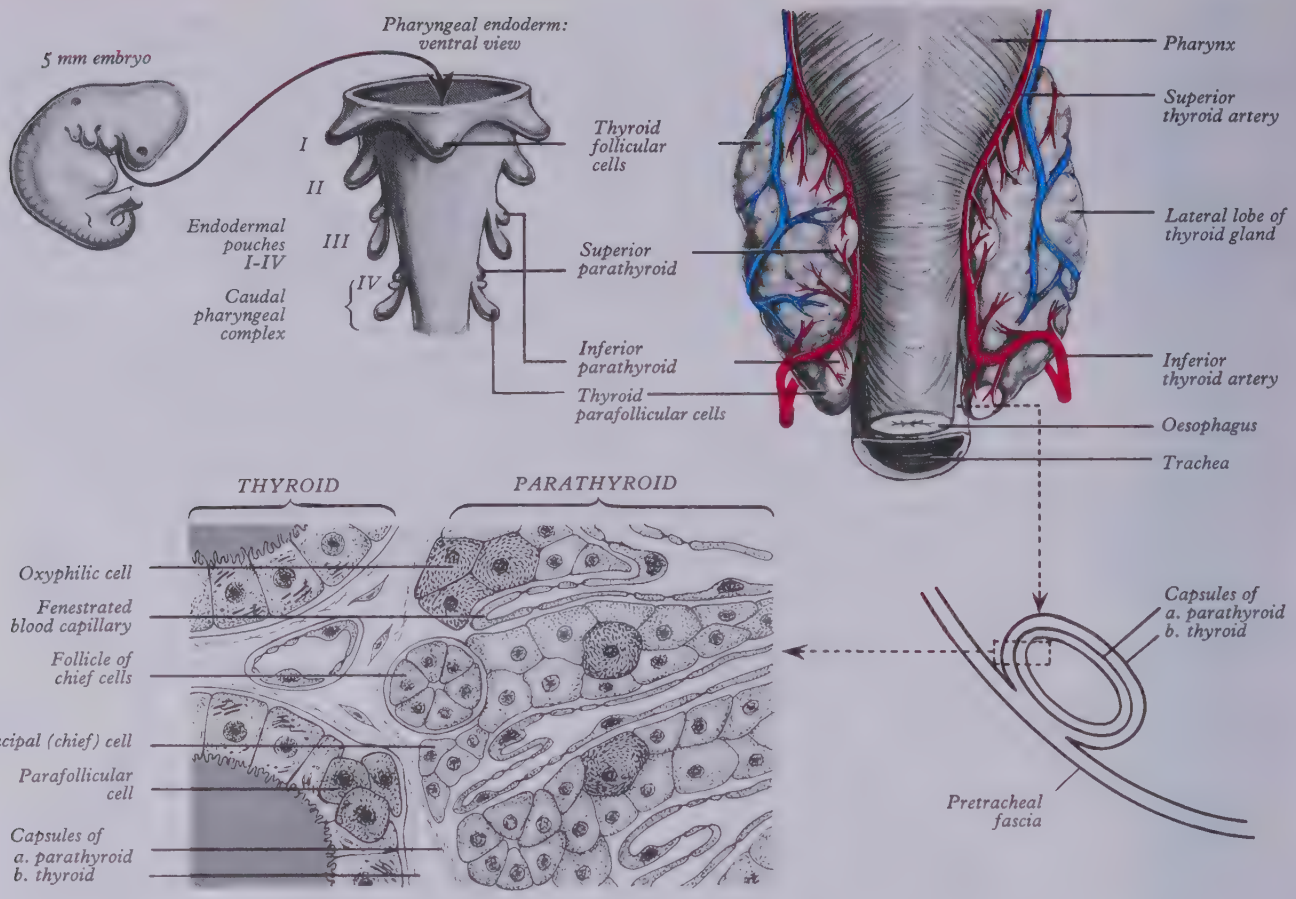
Vessels and Nerves

The *arteries* supplying the gland are the superior (p. 736) and inferior thyroid (p. 755) and sometimes an *arteria thyroidea ima* from the brachiocephalic trunk or aortic arch. The arteries are remarkably large with frequent anastomoses on and in the gland. The *veins* form a plexus on its surface and in front of the trachea; from this plexus superior, middle and inferior thyroid veins arise: the first two end in the internal jugular, the inferior in the left brachio-cephalic vein. A dense blood capillary plexus surrounds the follicles, between their epithelium and the endothelium of lymph capillaries, which also surround much of the follicular peripheries. *Lymph vessels* run in the interlobular connective tissue, often around arteries; they communicate with a capsular network, may contain colloid material and end in the thoracic and right lymphatic ducts. The *nerves* are derived from the superior, middle and inferior cervical sympathetic ganglia.

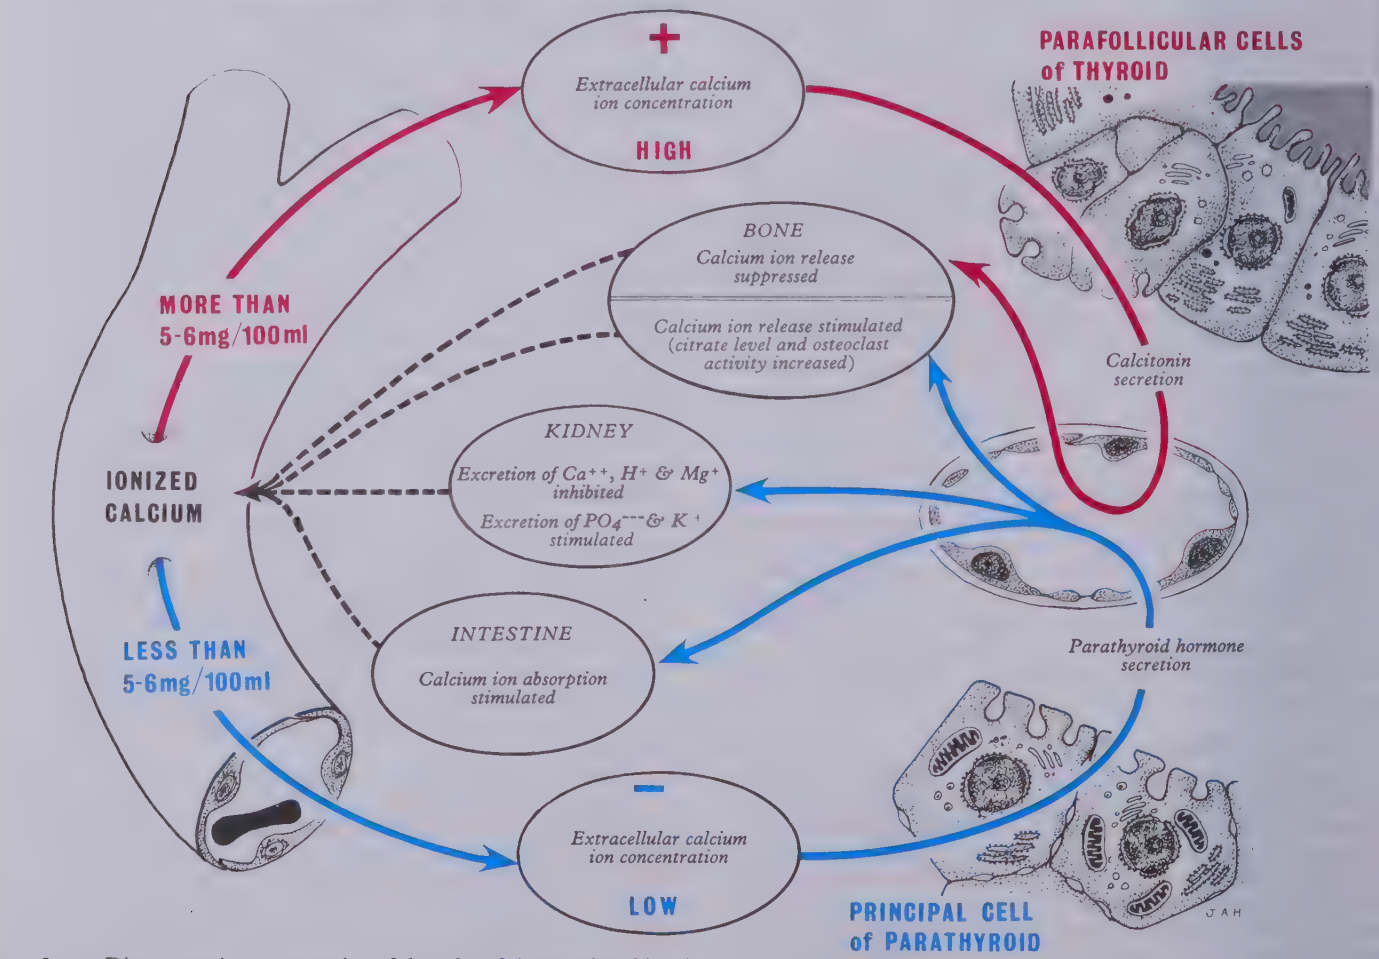
Applied Anatomy

Apart from variable enlargement during menstruation and pregnancy, any thyroid swelling is a *goitre*, which may press on related structures. Symptoms are most commonly due to pressure on the trachea or on the recurrent laryngeal nerves. These nerves and therefore the laryngeal muscles supplied by them, may be affected by pressure or damaged in thyroidectomy; if the external laryngeal nerve or the cricothyroid muscle (which is supplied by it and tenses the vocal folds) are damaged, the voice becomes incapable of varying pitch and is slightly tremulous (Harries 1955).

Partial thyroidectomy is often necessary in hyperthryoidism and thyroid enlargement. Enough is removed to relieve symptoms; except in malignant disease it is not entirely removed, since this leads to myxoedema. During tying of the inferior thyroid artery, the proximity of the recurrent laryngeal nerve (pp. 755, 1118) is a hazard. Temporary aphonia sometimes follows mere bruising of the nerve; complete division reduces the voice to a whisper. In partial thyroidectomy the posterior parts of both lobes are left intact to preserve the parathyroid glands.

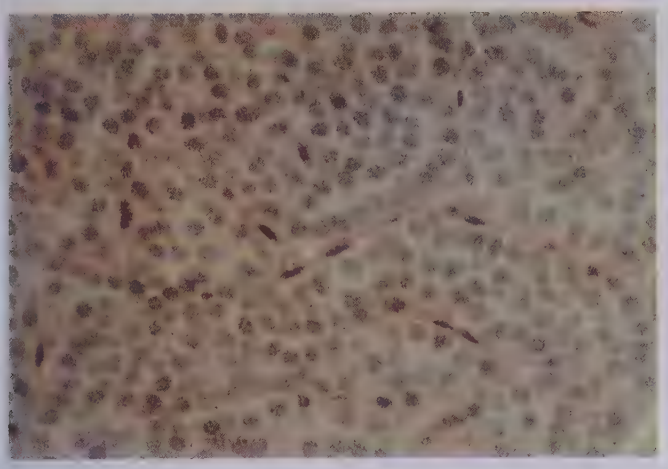


The Parathyroid Glands



The parathyroid glands (**8**.234) are small, yellowish-brown, ovoid or lentiform structures, usually lying between the posterior lobar borders of the thyroid gland and its capsule. They are commonly about 6 mm long, 3–4 mm across, and 1–2 mm from back to front, each weighing about 50 mg. Usually there are two on each side, superior and inferior. The anastomotic connection between the superior and inferior thyroid arteries along the posterior thyroid border (p. 755) usually passes very close to the parathyroids.

The superior parathyroid glands are more constant in site than the inferior and are usually midway along the posterior thyroid borders but sometimes higher. The *inferior pair* (Walton 1931, Gilmour 1938, Murley & Peters 1961) may be: (1) within the fascial thyroid sheath, below the inferior thyroid arteries and near the inferior lobar poles; (2) outside the sheath, immediately above an inferior thyroid artery; or (3) in the thyroid gland near its inferior pole. These variations are surgically important; a tumour of the inferior parathyroid, if in position (1), may descend along the inferior thyroid veins anterior to the trachea into the superior mediastinum, whereas if in position (2) it may extend posteroinferiorly behind the oesophagus into the posterior mediastinum. The superior parathyroids are usually dorsal, the inferior ventral, to the recurrent laryngeal nerves (Pyrtek & Painter 1964).



The glands develop from endoderm in the pharyngeal pouches (p. 229), the inferior from the third and therefore referred to as *parathyroids III*, the superior from the fourth and termed *parathyroids IV*. An inferior parathyroid is connected in early development with the diverticulum of the third pouch, which forms the thymus and is carried with it in its caudal migration. Normally the inferior parathyroids migrate only to the inferior thyroid poles but may descend with the thymus into the thorax or not descend at all, remaining above their normal level near the carotid bifurcation. Parathyroid glands vary in number; there may be only three or many minute parathyroid islands scattered in connective tissue near the usual sites (Hintzsche 1937, Vail & Coller 1967).

Structure (**8**.234B). Each parathyroid has a thin connective tissue capsule with intraglandular septa but lacking lobules. In childhood, the gland consists of wide, irregular, interconnecting columns of *chief cells* or *principal cells*, responsible throughout life for the synthesis and secretion of parathyroid hormone (parathormone); three types of chief cell, *light*, *dark* and *clear*, can be distinguished by the depth of cytoplasmic staining; by light microscopy their cytoplasm appears homogeneous. Between the columns of cells is a dense plexus of sinusoidal capillaries, via which the

8.234B Section through a parathyroid gland showing densely-packed chief cells and capillaries (rabbit). Haematoxylin and eosin. Magnification × 800.

hormone leaves the gland. Their ultrastructure was reviewed by Capen in 1975. Human chief cells differ according to the level of their activity (Munger & Roth 1963). *Active* chief cells have large Golgi complexes with numerous vesicles and small membrane-bound granules, the latter probably being prosecretory; secretory granules are rare, cytoplasmic glycogen sparse, much of the cytoplasm being occupied by flat sacs of granular endoplasmic reticulum in parallel arrays. In contrast *inactive* chief cells contain small Golgi complexes with only a few grouped vesicles and membrane-bound secretory granules; glycogen and many lipofuscin granules abound but sacs of granular endoplasmic reticulum are rare and dispersed. In normal human parathyroid gland inactive chief cells outnumber active in ratio of 3–5:1.

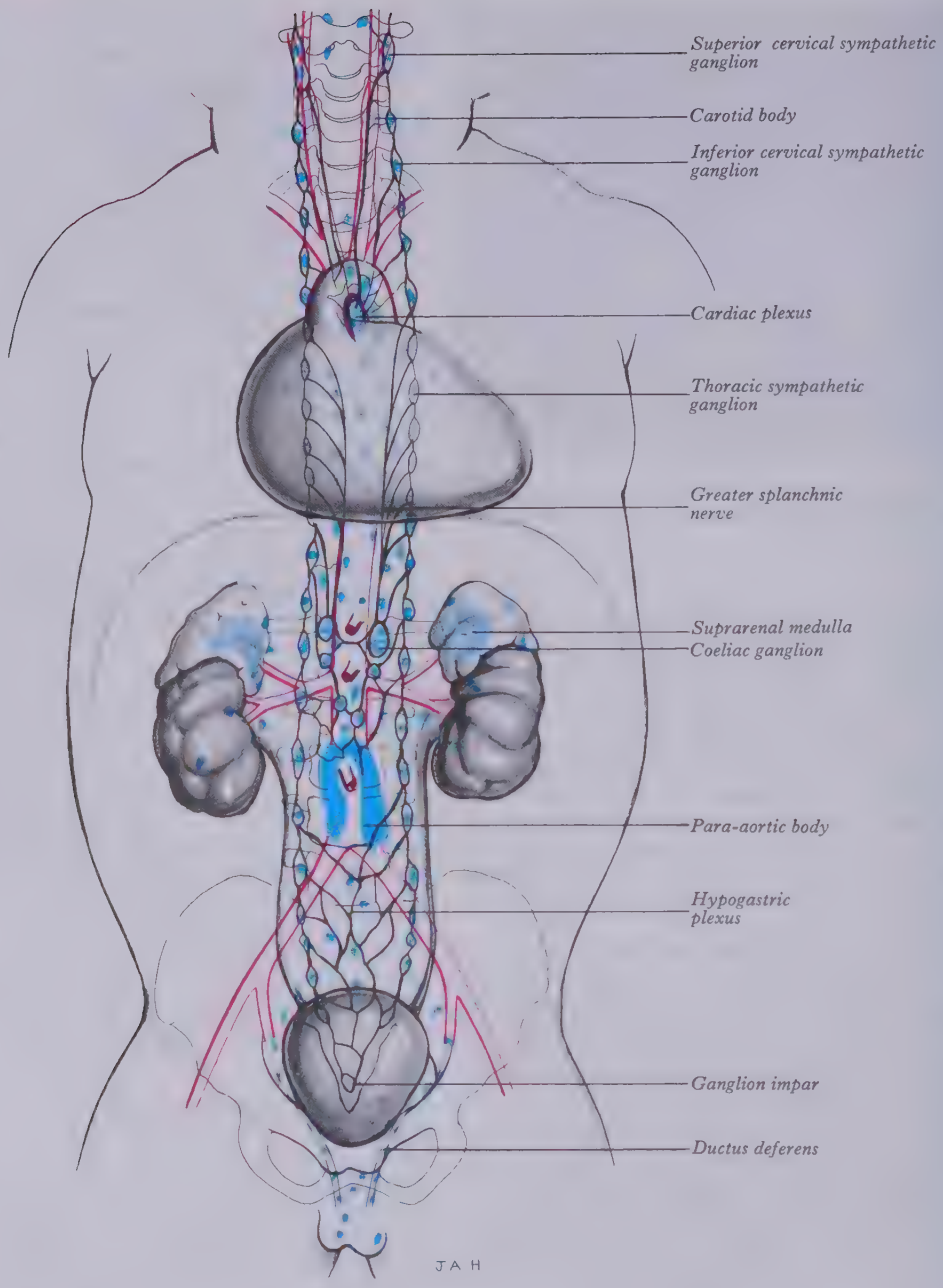
Active chief cells synthesize, assemble and secrete parathyroid hormone. It is assumed that the dense-cored, membrane-bound granules in the chief cells of all mammals contain parathyroid hormone, though this awaits proof (Capen & Roth 1973). During secretion the granules first become peripheral and then, under appropriate stimulus (vide infra), their membranes fuse with the plasmalemma to release their contents, presumably parathyroid hormone. Involution continues, with increased lysosomal activity and reduction of Golgi complexes and granular endoplasmic reticulum; glycogen accumulates again; lipofuschin granules form and the cells enter a phase of temporary inaction. In contrast to the thyroid, where activity of adjacent cells is synchronized, each parathyroid chief cell appears to pass through its secretory cycle independently (Roth & Capen 1974).

A second cell type, the *oxyphil (eosinophil)* cell, appears just before puberty and multiplies with age (Roth 1962). Only in man, macaque monkey and cattle have such cells been noted. They are larger than chief cells and contain more cytoplasm which by light microscopy appears granular and which stains deeply with eosin; the nucleus is smaller and more darkly staining than in chief cells. Ultrastructural observations (Munger & Roth 1963, Gaillard et al 1965, Roth & Capen 1974, Capen 1975) show that 'granules' seen by light microscopy are actually mitochondria, extremely numerous, tightly packed and often bizarre in form. The cytoplasm also contains a few sacs of granular endoplasmic reticulum, some glycogen and, rarely, small Golgi complexes. No secretory granules have been reported. These features suggest that oxyphil cells are not involved in hormone synthesis or secretion, though abundant mitochondria suggest a high metabolic activity. Their role remains to be determined. The arrangement of chief and oxyphil cells in parathyroid glands is shown in 8.234A.

Parathyroid hormone (PTH), a single-chain polypeptide of 84 amino acid residues (Potts et al 1971), is concerned with control of the level and distribution of calcium and phosphorus (8.234). Two other hormones, namely calcitonin (p. 302) and 1,25-hydroxycholecalciferol, are also involved, the latter produced by the sequential action of hepatic and renal cells on vitamin D (O'Riordan 1978). Hormonal control of calcium metabolism has been described in detail by Copp & Talmage (1978). Secretion of PTH is dependent on the level of calcium ions in the blood traversing the parathyroid glands. PTH acts upon osteocytes and osteoclasts, its rapid initial effect being to increase the rate of release of calcium from bone into blood, apparently by stimulation of osteocytic osteolysis (Belanger 1969, see also p. 303). It also has a delayed effect if a high level of secretion is maintained, stimulating internal bone remodelling by promoting osteoclast activity; changes in the membrane potential of osteoclasts may be involved in the latter (Mears 1971). PTH also affects renal ion transport (Puschett 1978), increasing excretion of phosphate, sodium and potassium and decreasing that of calcium. It may also affect intestinal transport of calcium. 1,25-hydroxy-cholecalciferol, production of which is regulated by PTH, shares many of these effects and may 'modulate' PTH action (O'Riordan 1978). How PTH affects target cells is not clear; adenyl cyclase activation and consequent rise in intracellular cAMP appear to be involved (Chase & Aurbach 1967, Chabardes et al 1975).

Vessels and Nerves

The glands have a rich blood supply from the *inferior thyroid arteries* or from anastomoses between the superior and inferior vessels. *Lymph* vessels are numerous and associated with those of the thyroid and thymus glands. The *nerve supply* is sympathetic, either direct from the superior or middle cervical ganglia or via a plexus in the fascia on posterior lobar aspects. The nerves are not secretomotor but probably vasomotor; parathyroid activity is controlled by variation in blood calcium level: inhibited by a rise, stimulated by a fall.



Applied Anatomy

If all parathyroid tissue is removed, body muscles show convulsive spasms (*tetany*); since respiratory and laryngeal muscles are involved, death ensues. Tetany is due to a fall in blood calcium. Excess of parathyroid secretion, due to tumours, causes the removal of calcium ions from bones, which soften, a condition of *generalized osteitis fibrosa*. Calcium ions leak from the bones into the blood (hypercalcaemia), are excreted in urine and may calcify in the renal tubules, with resultant fatal renal disease.

The Chromaffin System

Chromaffin cells (phaeochromocytes) are classically defined as derived from neuro-ectoderm, innervated by preganglionic sympathetic nerve fibres and capable of synthesizing and secreting catecholamines (dopamine, noradrenalin or adrenalin), storing enough to give an intense yellow-brown coloration, the *positive chromaffin reaction*, when treated with aqueous solutions of chromium salts, particularly potassium dichromate (Coupland 1965). Groups of such cells, associated topographically and functionally with the sympathetic nervous system, comprise the *chromaffin system* which includes: (1) medullae of the suprarenal glands, (2) para-aortic bodies, (3) paraganglia proper, (4) certain cells of the carotid bodies and (5) small groups of cells irregularly dispersed among the paravertebral sympathetic ganglia, splanchnic nerves and prevertebral autonomic plexuses; they may, therefore, be related to: the heart, liver, kidney, ureter, prostate, epididymis, ovary, etc. Distribution of the main components in newborn infants is shown in a diagram in 8.235.

Three main groups of cells give positive chromaffin reactions (Coupland 1976): (1) *true chromaffin cells*, as defined above, (2) *enterochromaffin cells* in epithelial tissue lining the gastrointestinal and respiratory tracts (p. 1466) and (3) *amine-storing mast cells* in the connective tissues of the gut, pancreas and liver. Ultrastructural similarity of (1) and (2) and the ability of all three groups to decarboxylate amino acids (p. 1466), observations that other non-chromaffin cells, in the gastrointestinal and respiratory tracts, pancreas and other endocrine glands are alike in both ultrastructure and amino-acid uptake and the discovery of paraneurons with many features of chromaffin cells in sympathetic ganglia (p. 1157), all undermine the rationale of continuing to restrict the term 'chromaffin system' to 'true' chromaffin cells. It may be

8.235 The principal aggregations of 'classic' chromaffin tissue in the human neonatal child. The aggregates in stippled blue lie deep to overlying structures.

more appropriate now to consider it as part of a diffuse neuro-endocrine system (vide infra).

The Diffuse Neuro-endocrine System

Feyrter (1938) drew attention to isolated groups of hormone-secreting cells not restricted to accepted endocrine glands and widely scattered in many tissues. Terming such elements *clear cells*, he noted their prominence in the gut and pancreas. These are now classified as types of 'APUD' cells (Pearse 1966,1980), the acronym being derived from their amine-handling properties (*a*mine *p*recursor *u*ptake and *d*ecarboxylation). Most APUD cells synthesize related peptides which act as *hormones* or *neurotransmitters*, though in others a main secretion is an *amine* of similar action. Collectively APUD cells are a 'system' more extensive than envisaged by Feyrter, including chromaffin cells (vide supra), SIF cells (p. 1157), peptide-producing cells of the hypothalamus (p. 1009), hypophysis (p. 1453), pineal (p. 1457), parathyroids (supra) and placenta, the Kulchitsky cells in the lungs (p. 1282), the myoendocrine cells of the cardiac atria (Forssmann & Girardier 1979, Forssmann et al 1983) and ventricles (Cantin et al 1987). Over 40 different cell types (see accompanying table) have been categorized as APUD cells and included in what has been described as the *diffuse neuro-endocrine system* (Pearse & Polak 1978). The myoendocrine cells of the heart differ from the others in being modified myocytes. These cells are listed in the accompanying table.

In 1966 Pearse described common cytochemical features in cells making peptide hormones and most notably in those which produce biogenic amines (adrenalin, noradrenalin, dopamine, 5-hydroxy-tryptamine, etc.) He suggested that uptake of 5-hydroxy-tryptophan (5-HTP) and its decarboxylation to 5-hydroxytryptamine (5-HT) might be linked to peptide hormone production in general. From this concept the designation 'APUD' cell arose (Pearse 1968). Pearse (1977) also suggested

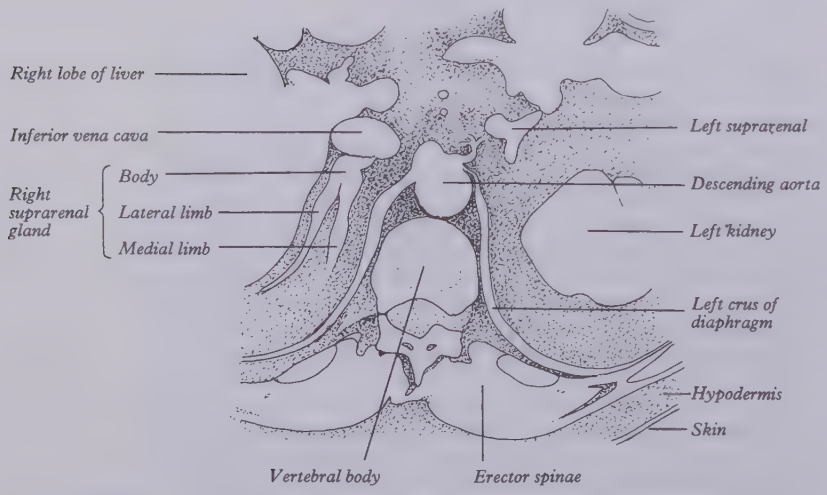
that all APUD cells were derived from 'neuroendocrine-programmed cells of the ectoblast' but there is now experimental evidence that many APUD cells (e.g. GEP endocrine cells, p. 1466) develop from other sources (Le Douarin 1978) and may be endodermal in origin (Andrew et al 1982). Other cells, e.g. the myoendocrine cells of the heart (Forssmann et al 1983), may be of mesodermal origin but can be grouped with the other cells of the neuro-endocrine system because of their similarities as producers of peptide hormones. Pearse considered APUD cells to be a third division of the nervous system, third-line effectors which support, modify or amplify the actions of neurons in the autonomic and somatic divisions. Their effects are slower in onset and longer in duration than those of the autonomic cells, which in turn have a similar functional relation to the faster somatic neurons. Secretions of APUD cells (diffuse neuro-endocrine system) may act upon *contiguous* cells, on *groups of adjacent* cells or on *distant* cells by transport in blood; they may thus be considered intermediate between the locally-acting transmitters produced by neurons and remote-acting endocrine secretions. Such a diffuse neuro-endocrine system complements and co-ordinates the nervous and endocrine systems, *all three* interacting to provide a precise mechanism for homeostatic control. For a critical review of the APUD concept, see Andrew (1982). It must be added that, as already stated (p. 809), the central nervous system also shares in many of the transmitters elaborated by APUD cells, further blurring the distinctions between neural and endocrine systems.

Deviations in the relative levels of secretions of different cells in this diffuse neuroendocrine system may cause disorders currently described as psychosomatic (Pearse & Polak 1978) or frankly psychotic (Webster 1978). If this proves true, the growing understanding of this system may improve their treatment.



The Suprarenal (Adrenal) Glands

The suprarenal glands (**8**.113, 237, 238), two small yellowish bodies, flat anteroposteriorly, are situated one immediately anterosuperior to each superior renal pole. Surrounded by connective tissue containing much perinephric fat (p. 1399), they are enclosed in renal fascia but separated from the kidneys by fibrous tissue. Each has a cortical zone rich in lipids but with *no* chromaffin tissue and an internal medulla staining deeply with chromic salts. Small masses of identical cortical suprarenal tissue occur often near the main gland and elsewhere as '*cortical bodies*'. Ontogenetically, phylogenetically, structurally and functionally, cortex and medulla are distinct, despite their forming a single organ.

The right gland is an irregular tetrahedron, the left semilunar and usually larger and more superior in level. Each in adults measures about 50 mm vertically, 30 mm transversely, and 10 mm in the anteroposterior dimension, weighing about 5 g. (the medulla being about one-tenth of the total weight). At birth the gland is about one-third the size of a kidney (**8**.171, 235) but in adults only a thirtieth. This change in ratio is not only due to renal growth but also to postnatal suprarenal diminution due to involution of the fetal cortex (p. 201). By the end of the second month the weight of the suprarenal is reduced to one-half. In the latter half of the second year it begins to increase, gradually regaining its natal weight around puberty, after which its weight increases little in adult life.

8.236B Diagram illustrating the major features demonstrated in **8**.236A.

RELATIONS OF THE SUPRARENAL GLAND

The right suprarenal gland (**8**.125) is posterior to the inferior vena cava and right hepatic lobe and anterior to the diaphragm and superior pole of the right kidney. It is shaped like an irregular tetrahedron. Its *base*, inferior, adjoins the anteromedial aspect of the right superior renal pole, often overlapping the upper part of the right kidney's medial border. Its *anterolateral surface* has a medial, narrow, vertical area, uncovered by peritoneum and posterior to the inferior vena cava, and a lateral triangular area in contact with the liver, devoid of peritoneum; above this it is in contact with the inferomedial angle of the bare area of the liver. Its inferior part may be covered by peritoneum, reflected on to it from the inferior layer of the coronary ligament; the duodenum may overlap this area. Below the apex, near the anterior border of the gland, is a short sulcal hilum where the right suprarenal vein emerges to join the inferior vena cava. The *posterior surface* is divided into upper and lower areas by a curved transverse ridge: its upper area, slightly convex, rests on the diaphragm; the lower, concave, contacts the superior pole and adjacent anterior surface of the right kidney. The thin *medial border* of the gland is related to the right coeliac ganglion, which is medial to it below, and to the right inferior phrenic artery, coursing superolaterally on the right crus of the diaphragm.

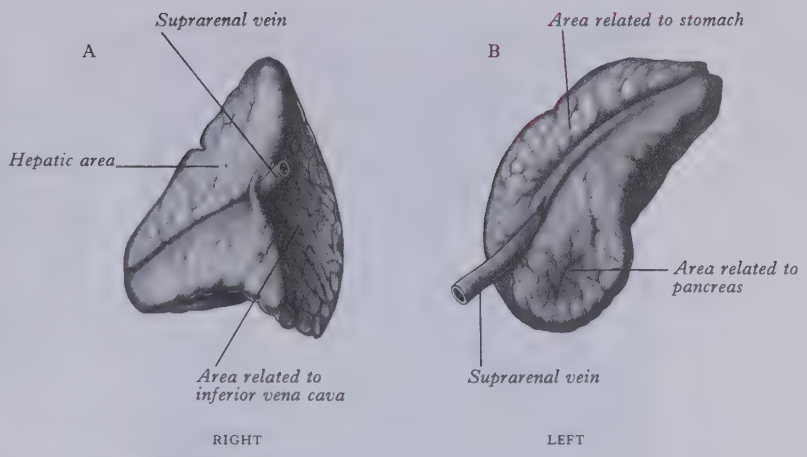
The left suprarenal gland (**8**.125) is crescentic, its concavity being adapted to the medial side of the superior pole of the left kidney. It is medially convex, laterally concave; its superior border is sharp, the inferior rounded. Its *anterior surface* has a superior area covered by peritoneum of the omental bursa, which separates it from the cardiac end of the stomach and sometimes from the posterior pole of the spleen; also an inferior area, not covered by peritoneum, in contact with the pancreas and splenic artery. The hilum faces ventrocaudally on the lower anterior surface; from it a left suprarenal vein emerges to join the left renal vein. Its *posterior surface* is divided by a ridge into a lateral area adjoining the kidney and a smaller medial one in contact with the diaphragm's left crus. The convex *medial border* is related to the left coeliac ganglion, which is inferomedial, and to the left inferior phrenic and left gastric arteries, which ascend on the left crus.

Small **accessory suprarenal glands**, sometimes composed only of cortical tissue, often occur in the areolar tissue near the main organ and sometimes in the spermatic cord, epididymis and broad ligament of the uterus.

STRUCTURE OF THE SUPRARENAL GLANDS

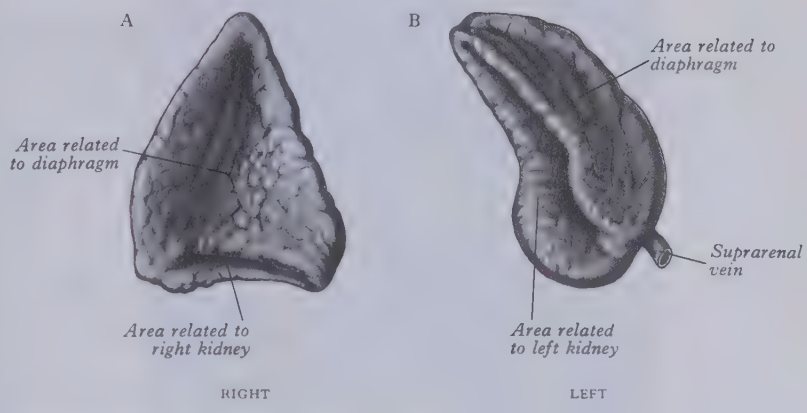
A sectioned suprarenal gland (**8**.239) reveals an outer *cortex*, yellow in colour and forming the main mass, and a thin *medulla*, forming about one-tenth of the gland, dark red or pearly grey depending on its content of blood. The medulla is completely enclosed by cortex, except at its hilum. The gland has a thick, collagenous capsule, which sends variably deep trabeculae into the cortex; the capsule contains a rich arterial plexus supplying branches to the gland.

The suprarenal cortex (**8**.240, 241) shows three cellular zones: the *zonae glomerulosa, fasciculata* and *reticularis*. The outer, subcapsular, *zona glomerulosa* consists of small polyhedral cells in rounded groups or curved columns with deeply staining nuclei, scanty basophilic cytoplasm and a few lipid droplets. Ultrastructurally (Lever 1955, Long & Jones 1967, Bloodworth & Powers 1968, Shelton & Jones 1971) the cytoplasm displays many microtubules, long mitochondria and abundant agranular endoplasmic reticulum, the latter being typical of cells elsewhere which synthesize steroids (vide infra). In humans the zona glomerulosa is poorly developed; deep to it the broader *zona fasciculata* consists of large polyhedral basophilic cells arranged in straight columns, two cells wide, with parallel fenestrated venous sinusoids between them. The cells contain many lipid droplets



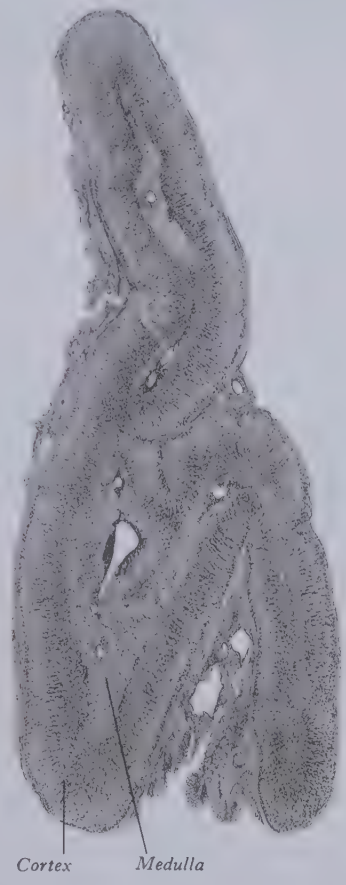
and large amounts of phospholipids, fats, fatty acids and cholesterol embedded in complex agranular endoplasmic reticulum. Mitochondria are typically spherical with tubular cristae; the Golgi complex is extensive. The innermost part of the cortex, the *zona reticularis*, consists of branching, interconnected columns of round cells whose cytoplasm contains much agranular endoplasmic reticulum, many lysosomes and pigment bodies which may indicate degeneration. Some consider that glomerulosar cells, particularly those more deeply set, proliferate continuously, some of the new cells migrating through the zona fasciculata to the reticularis in which they may degenerate and disappear. Autoradiography indicates that most proliferation occurs in the zona glomerulosa and outer reticularis but mitoses also appear in other cortical regions (Reiter & Hoffman 1967). There is, however, little ultrastructural evidence of cell death in the zona reticularis.

The deeper part of the zona fasciculata widens in pregnancy (Whiteley & Stoner 1957) and in women of childbearing age in summer (MacKinnon & MacKinnon 1958). Cortical atrophy in old males is greatest in the same region of this zone and least at its periphery (MacKinnon & MacKinnon 1960). Cortical cells produce several hormones and the cells of the zonae fasciculata and reticularis are also rich in *ascorbic acid (vitamin C)*. Cells in the zona glomerulosa produce *aldesterone*, which affects electrolyte and water balance; cells in the zona fasciculata produce hormones maintaining carbohydrate balance (glucocorticoids), e.g. *cortisol (hydrocortisone)*; cells in the zona reticularis may produce sex hormones (*progesterone*, *oestrogens* and *androgens*). The cortex is essential to life; complete removal is lethal, without replacement therapy. It also exerts considerable control over lymphocytes and lymphoid tissue (p. 838); increase in secretion of corticosteroids can result in a marked reduction in lymphocytes numbers. In some mammals the cortex shows cycles of hypertrophy and regression during the oestrous cycle. Between the cortical cells are sinusoids, into which branches from the capsular arterial plexus and cortical arteries largely open. Some arteries traverse the cortex to supply the medullary sinusoids. Cortical sinusoids discharge into medullary sinusoids. Sinusoidal endotheliocytes are phagocytic and belong to the macrophage (mononuclear phagocyte) system (p. 669).



Suprarenal development is described on p. 201. The relatively large size of the neonatal suprarenal gland is due to its very thick *fetal cortex* (Johannisson 1968), the *definitive cortex* being a thin peripheral zone. Around birth the fetal cortex begins to regress and largely disappears in a few weeks thereafter. Too rapid a cortical involution may be complicated by fatal haemorrhage. This transient fetal cortex occurs only in anthropoids. There is no proof that it produces androgenic hormones. It is poorly developed in anencephalic fetuses. It does not represent the X zone (androgenic), occurring e.g. in young mice as a zone around the medulla (Jones 1957).

The suprarenal medulla is composed of groups and columns of *chromaffin cells (phaeochromocytes)* separated by wide venous sinusoids. Single or small groups of neurons occur in the medulla.



Chromaffin cells synthesize and expel noradrenalin and adrenalin into the venous sinusoids; release is under preganglionic sympathetic control (see Coupland 1965a for review). In some mammals these hormones have been identified in two distinct types of cell (Yates et al 1962), cells storing noradrenalin being more peripheral than those storing adrenalin. All cells, which are large and columnar, form single rows along the venous sinusoids. Cell bases and nuclei are distal from the sinusoids, adjoining expanded extracellular spaces, in which the nerve terminals synapse with the chromaffin cells. These may form follicles but not like those in thyroid tissue (Al-Lami 1970). The cytoplasm is basophilic, showing well-developed granular endoplasmic reticulum, mitochondria, Golgi complex and many vesicles, indicating a high metabolic activity (Al-Lami 1970, Coupland 1965b). In noradrenalin-storing cells the vesicles are typically round or ellipsoidal and, after treatment with aldehyde and osmium, highly electron-dense. In adrenalin-storing cells, treated alike, the vesicles are paler (Coupland et al 1964), often with a clear zone between the granular contents and membrane. In the human suprarenal, cells with both types of vesicle have been

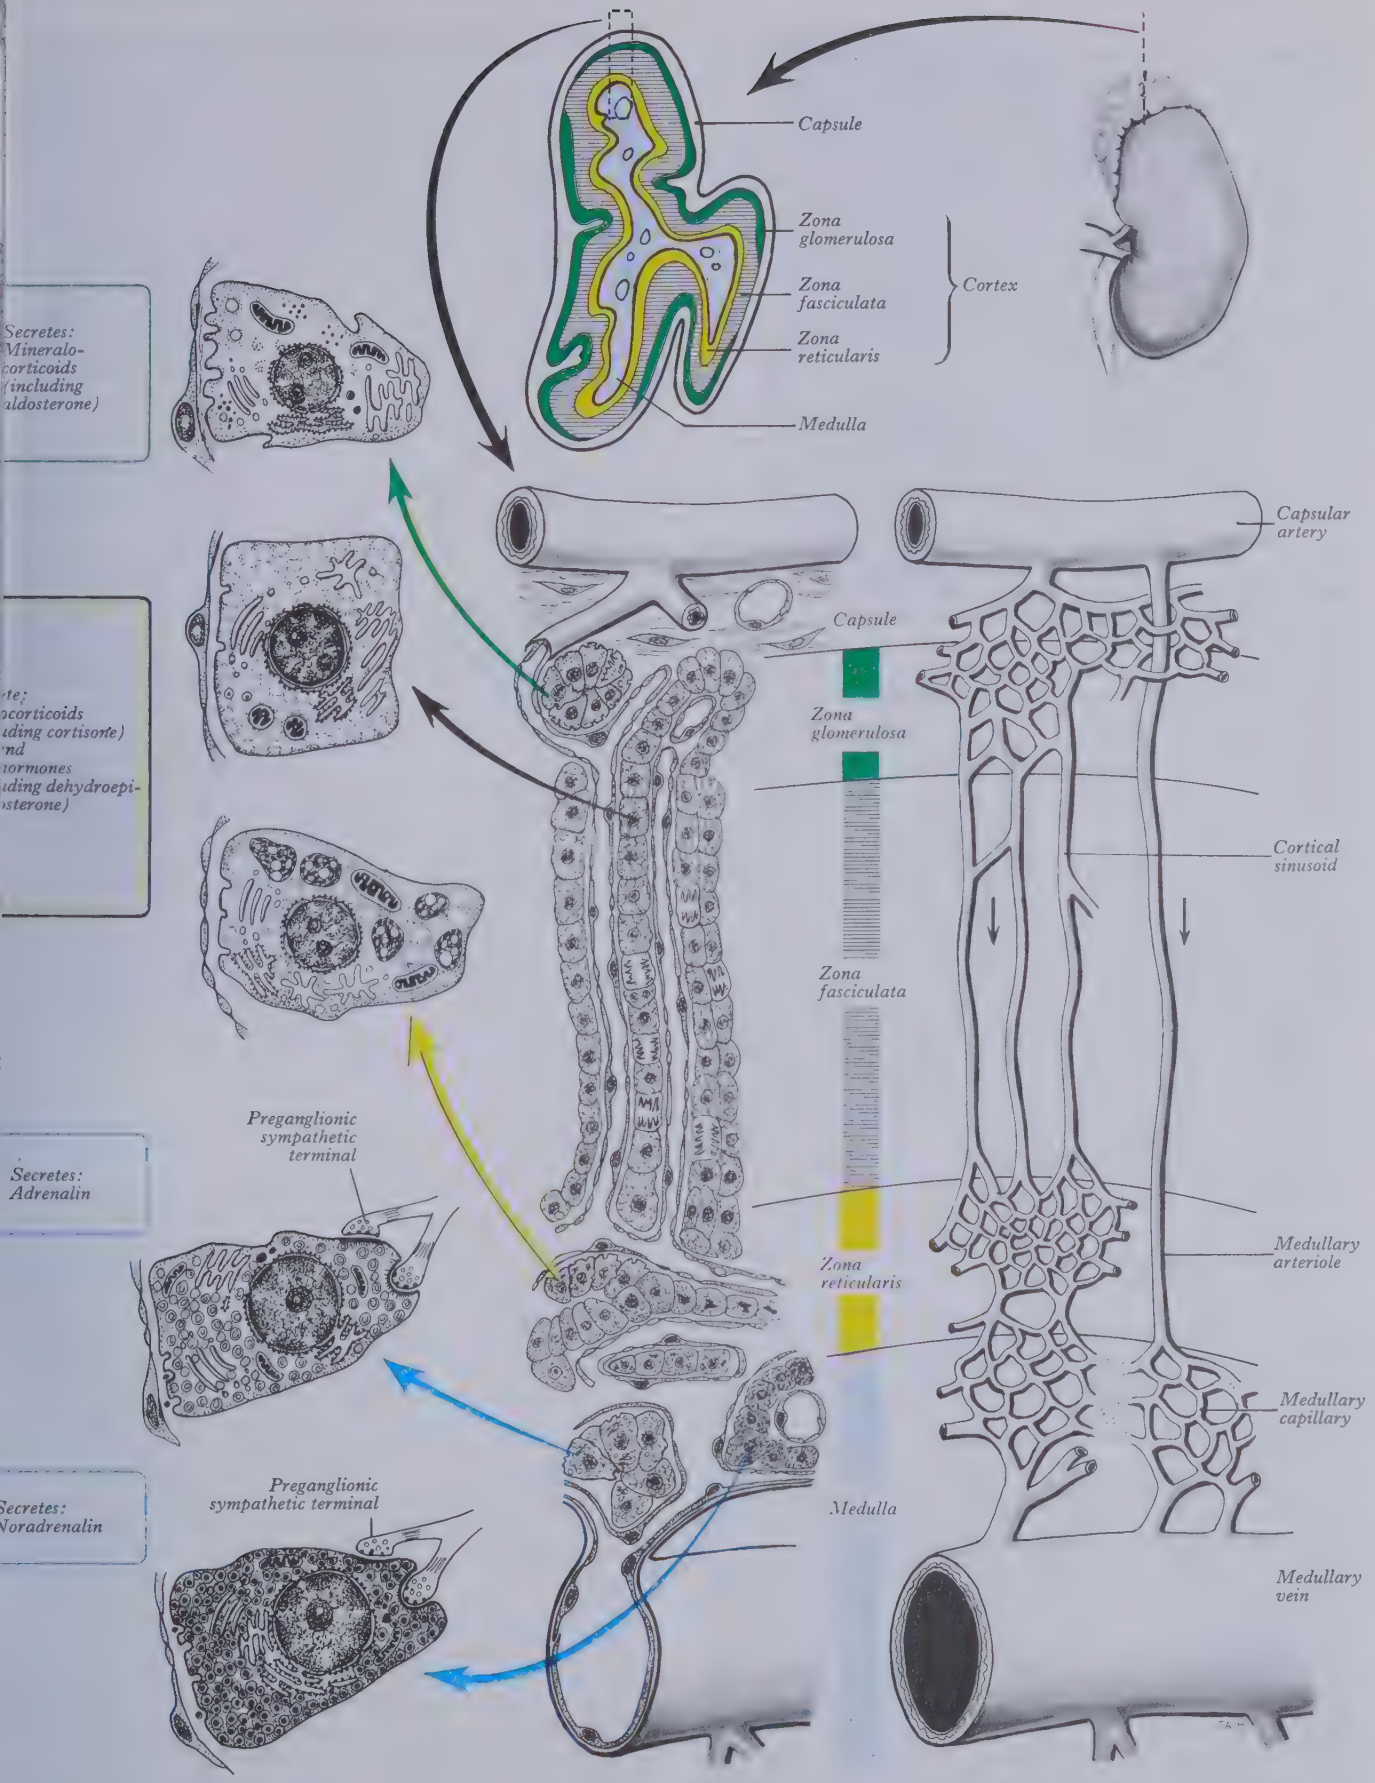
reported (Brown et al 1970) indicating that adrenalin and noradrenalin may both appear in the same cell. Vesicle contents are released at the cell apices into the perivascular spaces, entering the circulation through the fenestrated endothelium of venous sinusoids (Elfvin 1965, Al-Lami 1969).

The sinusoids drain to the hilar suprarenal vein. Normally, little adrenalin or noradrenalin is released but in fear, anger and stress secretion is augmented. Noradrenalin produces cardiac acceleration, vasoconstriction, raised blood pressure, etc., while adrenalin has a marked effect on carbohydrate metabolism. Unlike its cortex, the suprarenal medulla is not essential to life; removal has no clear effect. Medullary chromaffin cells develop in and migrate from the neural crests (sympatho-chromaffin tissue, p. 201). The chromaffin reaction (brown staining of granules by potassium bichromate, due to oxidation of adrenalin and noradrenalin) is positive from the fifth fetal month but adrenalin appears as early as the third (Keene & Hewer 1927).



Interaction between Cortex and Medulla

Only in mammals is the suprarenal chromaffin tissue almost enclosed by cortex. In elasmobranchs (e.g. dogfish) cortical tissue forms paired *inter-renal bodies*, chromaffin tissue being separate in segmental masses close to the sympathetic ganglia. In amphibia and birds, cords of chromaffin and cortical cells are intimately associated but a true medulla is not formed (Coupland 1965a). The proximity of cortical to chromaffin tissue may be associated with the formation of adrenalin by methylation of noradrenalin (vide infra).

Vessels and Nerves

The suprarenal gland is very vascular and is supplied by three groups of *arteries* (the superior, middle and inferior suprarenal) from the inferior phrenic, abdominal aorta and renal artery respectively (Harrison & Hoey 1960). Most suprarenal branches ramify over the capsule before entering the gland to form a subcapsular plexus, from which fenestrated sinusoids pass around clustered glomerulosal cells and between columns in the zona fasciculata to a deep plexus in the zona reticularis. From this venules pass between medullary chromaffin cells to medullary veins, which they enter between prominent longitudinal bundles of muscle fibres; these appear to regulate flow through a 'dam' at the corticomedullary junction, i.e. the internal aspect of the zona reticularis (Dobbie & Symington 1966). Since this would also control flow through the other zones, it could also control, in part, the availability of ACTH to their secretory cells (Griffiths & Cameron 1975).

Some relatively large arteries bypass the above route by going direct to the medulla, giving it a dual supply (8.241). Blood reaching it indirectly via the cortical sinusoids probably contains enough glucocorticoid hormone to maintain the synthesis of phenylethanolamine-N-methyl-transferase for synthesis of adrenalin from noradrenalin, whereas blood arriving by the direct non-cortical route does not. Whether medullary chromaffin cells can make adrenalin or noradrenalin depends on this enzyme and may be determined by the blood supply (Wurtman & Pohorecky 1971). Changes in relative blood flow via the two routes could thus have profound consequences.

8.241 The suprarenal gland, displaying its gross sectional appearance, histology, vasculature and ultrastructure. Brief functional summaries are appended.

Medullary veins emerge from the hilum to form a *suprarenal* vein, draining to the inferior vena cava (right side) and left renal vein.

The *lymph* vessels end in lateral aortic nodes (p. 854).

The *nerves*, which are exceedingly numerous, are mainly myelinated preganglionic sympathetic fibres (p. 1165) distributed to the medullary chromaffin cells. Suprarenal cortical activities are largely controlled by hypophysial adrenocorticotropic hormone (ACTH).

Applied Anatomy

Various clinical conditions due to lesions of the suprarenal cortex or medulla are attributable to the effects of excess or deficiency of secretions in the parts of the gland affected.

Atrophy (usually tuberculous) of the suprarenal cortex, with consequent insufficiency of cortical secretion, results in Addison's disease, typified by muscular weakness, low blood pressure, anaemia, cutaneous pigmentation, changes in electrolytic and fluid balance, and terminal circulatory and renal failure. Excessive cortical secretion, due to tumours or hyperplasia, produces various effects: (1) In adults, Cushing's syndrome may result, typified by obesity, excessive hairiness of the face and trunk, diabetes mellitus, impotence and hypogonadism in males and amenorrhoea in females. (2) In women, masculinization (virilism) may occur due to excess of androgenic hormones or (3) in men, feminization, particularly mammary development. (4) Children may show precocious body growth and development of the external genital organs, with early menstruation in girls. (5) In the female fetus, cortical hyperplasia between the third and fourth months leads to female pseudohermaphroditism, the excess androgen interfering with differentiation of the urogenital sinus; the urethra and vagina open into a persistent urogenital sinus, the clitoris enlarges and the external genital organs resemble the male's. In the male fetus cortical hyperplasia causes excessive external genital development.

Bilateral removal of the suprarenal glands is a treatment for some inoperable disseminated mammary or prostatic carcinomata, when the malignant changes are considered to be dependent on androgens or oestrogens. Tumours of the suprarenal gland's medulla and the para-aortic bodies (phaeochromocytomata) may cause excessive secretion of adrenalin and noradrenalin, producing attacks of palpitations, excessive sweating, pallor, hypertension, headaches and, if of long duration, retinitis and renal vascular changes.

The suprarenal glands can be demonstrated radiologically by air injected into perirenal fat.

The Paraganglia

Paraganglia (Zuckerkandl 1901, Kohn 1903) are extra-suprarenal aggregations of chromaffin tissue (p. 1465, 8.235), distributed near or in the autonomic nervous system (Coupland 1965a, Mascorro & Yates 1971, Hervonen et al 1978a). Cells like those in paraganglia proper (which adjoin various autonomic ganglia) also occur in the sympathetic ganglia as *small, intensely fluorescent* (SIF) *cells* (Williams et al 1975), in the walls of various viscera and in a variety of retroperitoneal and mediastinal sites (Ramsdale et al 1972, Hervonen et al 1976, Hervonen et al 1978b). All are neuro-ectodermal and can synthesize and store catecholamines but their functions differ with location: intraneural cells act as interneurons (p. 865), the remainder as sources of endocrine secretions including a tryptophanic protein and catecholamines (Hervonen et al 1978a). This dispersed array of extra-adrenal chromaffin tissue, often dubbed the *paraganglion system* (Mascorro & Yates 1975), is prominent in fetuses as the main source of catecholamines while the adrenal medulla is still developing (West et al 1955, Kovrishko 1964). Though many paraganglia degenerate soon after birth (Coupland 1965a), the specific fluorescent histochemical technique for the detection of catecholamines (Eranko 1967) has located many persistent, often minute, paraganglia in adult human and other mammals, contradicting the earlier assumption of general postnatal involution of paraganglia.

Paraganglia contain two typical varieties of cell: *type I* or granule-containing and *type II* or satellite cells (Mascorro & Yates 1975). Type I have a large nucleus, long mitochondria, some granular endoplasmic reticulum, well-developed Golgi complexes, glycogen deposits, numerous membrane-bound, electron-dense granules containing catecholamines and possibly the tryptophanic protein mentioned above, features which together with their neuro-ectodermal origin place them in the APUD category (Pearse 1969, Pearse & Polak 1974). By their cytoplasmic density, type I cells can be classified as 'light' or 'dark', though 'dark' cells are widely considered to be a fixation artefact (Mugnaini 1965, Benedeczky & Smith 1972) and both types may be stages in a secretory cycle. Type II cells lack cytoplasmic granules and their processes envelop type I cells partially or completely.

Type I cells of paraganglia receive a 'preganglionic' sympathetic innervation (Mascorro & Yates 1974) like the adrenal medullary chromaffin cells (Cummings 1969). The non-myelinated nerve fibres are largely separated from type I cells by Schwann cell cytoplasm and cytoplasmic projections of the type II cells, approximating only at synapses. Presynaptic endings contain mitochondria, glycogen granules and many synaptic vesicles, mostly electron-lucent, though some have electron-dense cores. In vagal paraganglia such endings may be cholinergic and efferent (Chen & Yates 1970). Nerve fibres containing vasoactive intestinal polypeptide are present in human fetal abdominal paraganglia (Hervonen et al 1985).

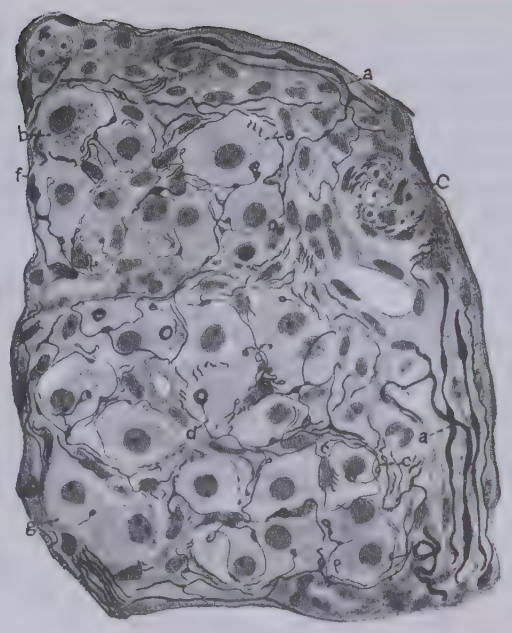
Paraganglia are well-vascularized and their secretory type I cells are usually next to one or more fenestrated capillaries, often with only basal lamina intervening, although sometimes fine collagen fibres and cytoplasmic processes of type II cells are present. Thus little obstructs the passage of hormones from type I cells to blood (Mascorro & Yates 1975).Evidence suggests that paraganglia are endocrine organs producing catecholamines and proteins and storing them as cytoplasmic granules until stimulated to release them. In addition to having a remote endocrine effect, these secretions may exert local paracrine action on nearby cells. Paraganglia comprise a dispersed system which throughout life may by the source of catecholamines additional to the suprarenal medulla and thus collectively having considerable metabolic importance (vide infra).

The Para-Aortic Bodies

Developing progressively during fetal life these attain maximum size in the first three postnatal years, when the largest are two brownish bodies about 1 cm long, flanking the abdominal aorta and usually united anterior to it by a horizontal mass immediately above the inferior mesenteric artery (8.235). They thus form an inverted crescentic or H-shaped arrangement, intimately related to the intermesenteric and superior hypogastric plexuses. Their constituent cells disperse and atrophy and by 14 years they may have completely disintegrated (Coupland 1965a). When well-developed, they are masses of polygonal chromaffin cells embedded in wide-meshed capillary plexuses and secreting noradrenalin. In fetuses chromaffin bodies are also widespread in the abdominal and pelvic prevertebral sympathetic plexuses, reaching a maximum size between the fifth and eighth fetal months and surviving in adults mainly near the coeliac and superior mesenteric arteries and as microscopic collections of cells persisting in the lower parts of the intermesenteric plexus.

Although chromaffin cells in sympathetic ganglia, as noted, may act as interneurons, those elsewhere are endocrine and probably support the suprarenal medulla as sources of catecholamines (Chen et al 1976), particularly in pre- and early postnatal life, when the suprarenal medulla and autonomic nervous system are immature (West et al 1953). This is supported by Coupland & Weakley (1970), who observed that extra-suprarenal chromaffin cells resemble those in the suprarenal medulla. Ultrastructural evidence shows that in rats chromaffin cells in nodes of the solar plexus have processes extending beyond their glial cells towards the capillaries, into which their catecholamines pass (Levkova & Kakabadze 1977).

The Carotid Bodies (Glomera Carotica)



The two carotid bodies are reddish-brown, ellipsoid and lie near the carotid sinuses in the neck (p. 734). Each is 5–7 mm in height and 2.5–4 mm in width and either posterior to the carotid bifurcation or between the start of its branches, being attached to or sometimes partly embedded in their adventitia. Occasionally it is a group of separate nodules. Aberrant 'miniglomera', microstructurally similar but with diameters of 600 μm or less, may appear in the adventitia and adipose tissue near the carotid sinus in human cadavers (Garfia 1980). Each glomus is innervated by glossopharyngeal carotid branches, including the *carotid sinus nerve*, and by a *plexus* of glossopharyngeal, vagal and sympathetic components (pp. 1113, 1158). Its abundant blood supply is derived from the adjacent external carotid rami.

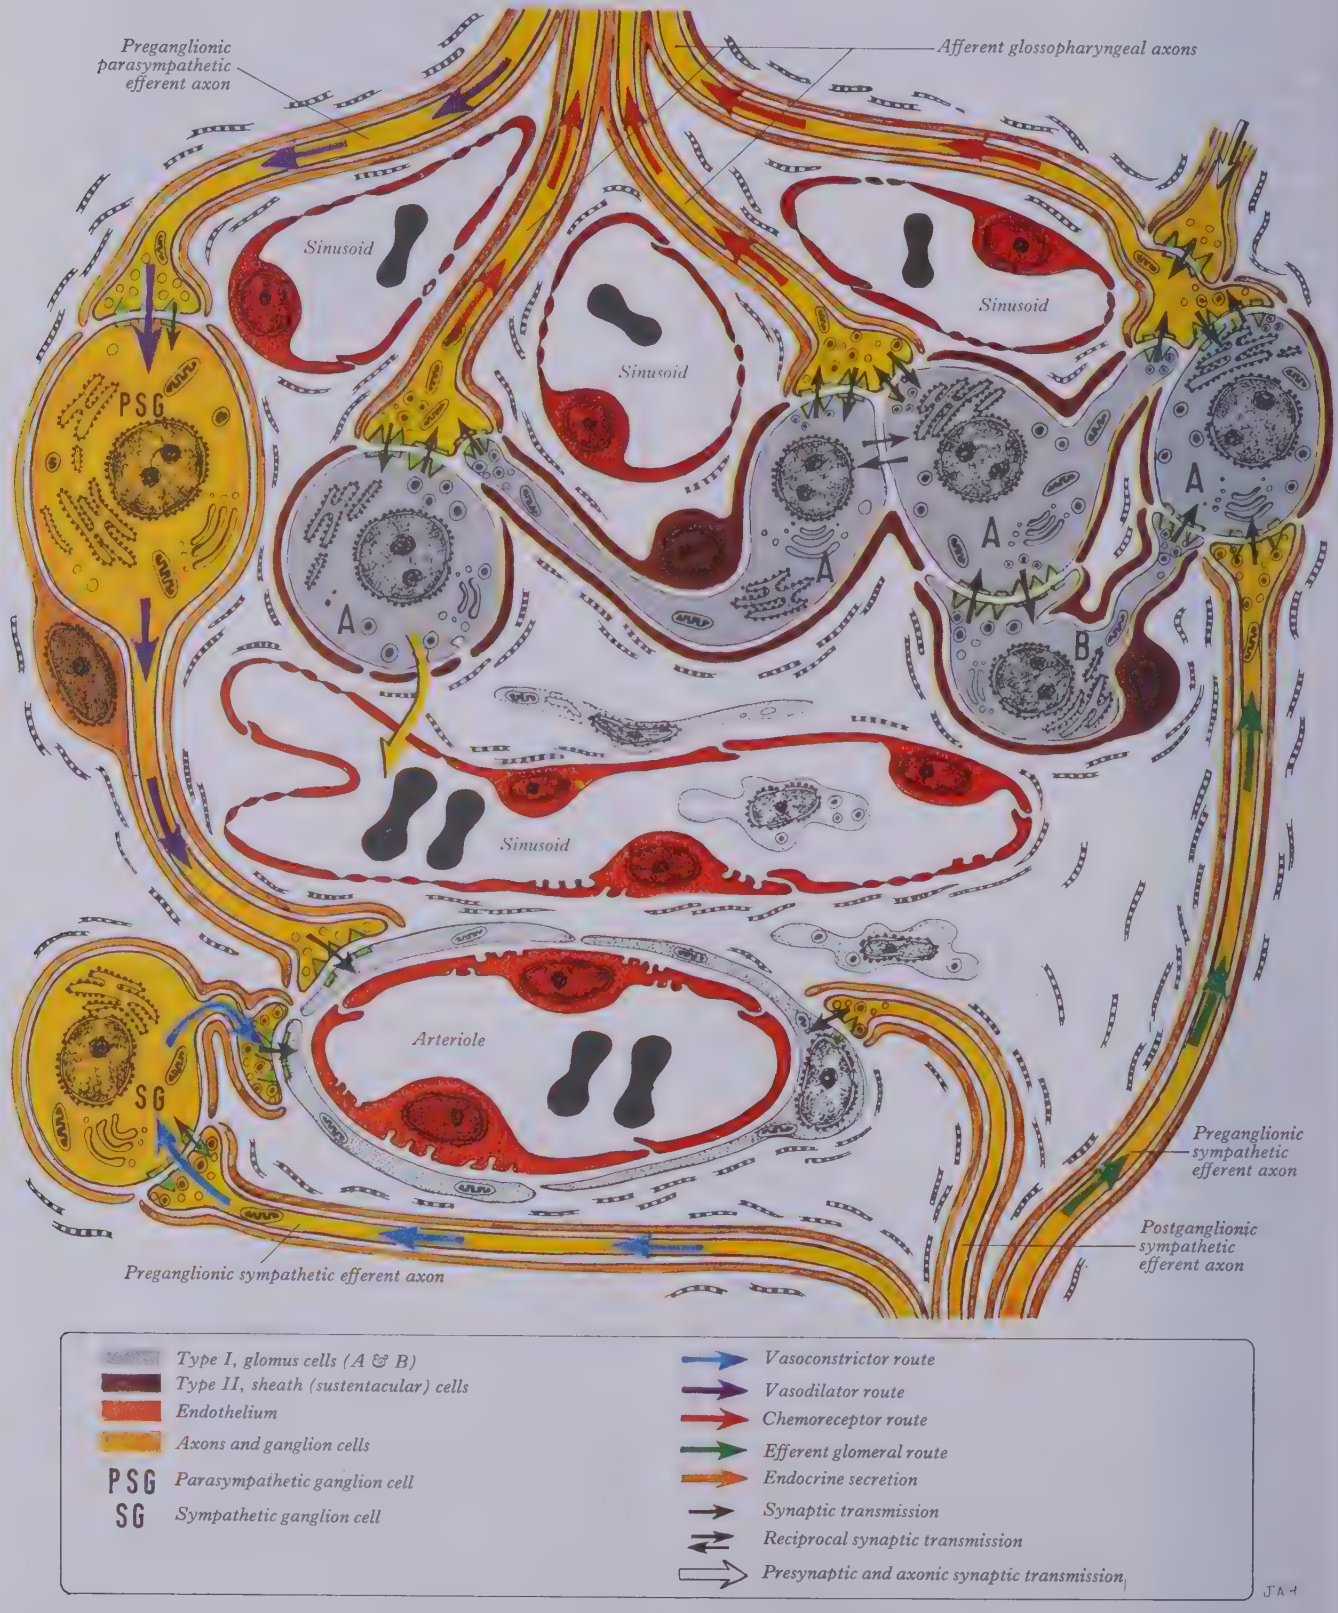
Structure and Function

The carotid glomus is an *arterial chemoreceptor*. When stimulated by hypoxia, hypercapnia or increased hydrogen ion concentration, it elicits reflex increase in the rate and volume of ventilation via connections with brain-stem respiratory centres. Although this main role is certain, which of its components are chemoreceptors is obscure (Chen et al 1976). It may also be *endocrine*; its *glomus cells* (vide infra) are in the APUD series (p. 1466), which has been extended to include virtually all cells specialized for peptide hormone production (Pearse 1976); but no specific peptide hormone has yet been assigned to them. A suggested controlling role in erythropoiesis (Tramezzani et al 1971) has been disproved (Paulo et al 1973).

The glomus has a fibrous capsule whose septa lobulate it, each lobule being a collection of epithelioid '*glomus*' (type I) cells enveloped by *sustentacular (type II) cells* (**8**.242) and separating the former from extensive anastomoses of fenestrated sinusoids. Between sustentacular cells and the sinusoidal endothelium are nonmyelinated nerve fibres, neurolemmocytes, attenuated processes of fibrocytes and collagen fibres (Chen et al 1976). Many of the nerve fibres are afferent, passing between the sustentacular to synapse with the 'glomus' (glomeral) cells. Preganglionic efferent fibres reach a sparse population of parasympathetic and sympathetic *ganglion cells*; these fibres are derived from the carotid sinus and sympathetic nerves (McDonald & Mitchell 1975), while the ganglion cells are either separate or in small groups near the body's surface. Axons proceed from the ganglion cells to local blood vessels, the parasympathetic efferent fibres probably being vasodilatory (Biscoe et al 1969) and the sympathetic ones vasoconstrictor (Purves 1970).

Glomeral cells (**8**.243), more numerous than sustentacular cells, are moderately large, with much cytoplasm and a few dendritic processes extending into intercellular spaces. Membrane-bound, electron-dense granules adjoin the Golgi apparatus and plasma membrane. Fusions of the limiting membranes of the granules and plasma membranes have been seen (Hansen 1977). Glomeral cells store dopamine (Kobayashi 1969), some other neurotransmitters (Fidone et al 1988) and the protein 'glomin' (Pearse 1969), presumably in their granules. They are accepted as chromaffin (Böck & Gorgas 1976) but a positive chromaffin response can be detected only ultrastructurally. They have also been regarded as paraneurons (Fujita 1976). Granular endoplasmic reticulum is not abundant but arrangements resembling neuronal Nissl substance have been described in human glomeral cells (Bock et al 1970). In rats, two types of glomeral cell are recognized (MacDonald & Mitchell 1975): type A have larger, more numerous electron-dense granules than type B and usually a smooth, globular contour with a few short dendrites; type B cells are more irregular with several long thin processes. Nerve endings seldom synapse with type B cells but at least two kinds of fibre synapse with type A, over 95% being *chemo-afferent axons* leaving in the carotid sinus nerve, their cell bodies being in the sensory glossopharyngeal ganglia. Less than 5% are *preganglionic efferent axons* from the cervical sympathetic trunk, entering the glomus with post-ganglionic axons from the superior cervical sympathetic ganglion. No efferent glossopharyngeal axons appear to synapse with glomeral cells but some are preganglionic to parasympathetic ganglion cells. In rabbits ultrastructurally

8.242 A section of the carotid body, showing nerve fibres distributed to the cells (de Castro): a, myelinated fibre dividing into two fine branches; b, cell closely surrounded by nerve fibrils; c, section of a small nerve, composed of several myelinated fibres; f, a nerve fibril apparently ending within the cytoplasm of a cell; g, a nerve fibril ending between the cells.



efferent fibres of uncertain origin, presumed inhibitory, synapse with the chemo-afferent axons (Verna 1975). Among 'afferent' nerve endings some are presynaptic to type A glomeral cells, others postsynaptic and some form *reciprocal synapses* with them. Such synapses have also been found between glomeral cells (McDonald & Mitchell 1975); they are dendrodendritic (Reese & Shepherd 1972). Similar connections occur in the central nervous system (pp. 888, 885) but not hitherto in the *peripheral*. Various neural circuits described in the glomus of rats and rabbits (McDonald & Mitchell 1975, Verna 1975, Fidone et al 1988) are shown in **8**.243. Human details are awaited with interest.

Ultrastructural and neurophysiological evidence ascribes at least three functions to glomeral cells. Firstly, they release neurotransmitters in response to hypoxia (Eyzaguire et al 1972) and may be *sensory*. Secondly, in ultrastructure they are like APUD cells (Pearse 1969) and may be *effector cells*, modifying the sensitivity of chemoreceptive nerve endings by variable release of dopamine (Biscoe et al 1970). Thirdly, having a synaptic input and output, a gliaform sheath and dendritic processes, they may act as *interneurons* (McDonald & Mitchell 1975). Involvement in several functions, as postulated above, is reminiscent of the presumed phylogenetic progenitor neuronal cell.

As stated above there is no consensus on which carotid glomeral cell is a chemoreceptor; *glomeral cells* (Lever et al 1959, Eyzaguire et al 1972), *afferent nerve terminals* (McDonald & Mitchell 1975) and *sustentacular cells* (Mills & Jöbsis 1972) have all been favoured. McDonald & Mitchell (1975) hypothecate co-operation between afferent axons and glomeral cells, proposing that: (1) afferent nerve endings, connected with glomeral cells by reciprocal synapses, are the true chemoreceptors; (2) glomeral cells are dopaminergic interneurons which modify the sensitivity of the chemoreceptive endings; (3) the reciprocal synapses between the glomeral cells and the afferent axons may form an inhibitory feedback, the glomerular cells inhibiting the activities of the axons with dopamine, the axons releasing an excitatory transmitter when stimulated, e.g. by hypoxia; (4) preganglionic sympathetic neurons may decrease chemoreception by evoking dopamine release from glomeral cells; and (5) synaptic interconnections between adjacent glomeral cells could mediate reciprocation. Another hypothesis (Mills & Jöbsis 1972), implicating sustentacular cells, suggests that hypoxia may affect these cells, initiating 'firing' of adjacent 'free' afferent nerve

endings; glomeral cells, with their efferent sympathetic innervation, could be part of a feedback modifying the activity of the afferent axons. Half the cytochrome (a_3) of the glomus has a low affinity for oxygen and appears to be located in sustentacular cell mitochondria, which would make such cells sensitive to hypoxia, cytochrome remaining reduced in oxygen shortage and depressing oxidative metabolism. This might make them release e.g. potassium, activating adjacent afferent axons whose many mitochondria, containing a cytochrome a_3 with a high affinity for oxygen, might sustain normal function even in hypoxia. It is interesting to speculate on the role of local haemodynamic control in such a monitoring system.

The carotid glomus develops from mesenchyme in the third pharyngeal arch (Boyd 1937), as a condensation around its artery; its nerve supply is mainly glossopharyngeal, the nerve being of that arch.

8.243 The cellular, neural and vascular architecture of the carotid body. Functional pathways are indicated. (Consult text for detailed discussion.)

Other small bodies, resembling carotid glomera, occur near the arteries of the fourth and sixth pharyngeal arches and hence near the aortic arch, ductus arteriosus and right subclavian artery and are supplied by the vagus nerve. They are also considered to be chemoreceptors.

The Tympanic Body

The tympanic body (*jugular glomus*) is ovoid, about 0.5 mm long and 0.25 mm broad, and occurs in the adventitia of the upper part of the superior bulb of the internal jugular vein. It is similar in structure to the carotid body, with presumably a similar function (Guild 1941, Kjaegaard 1944,1973). It may be present in two or more parts near the glossopharyngeal tympanic branch or vagal auricular branch, within their canals in the petrous temporal bone. Tumours of these bodies may involve the adjacent cranial nerves and the middle ear.

The Coccygeal Body

The coccygeal body (*glomus coccygeum*) is anterior or inferior to the apex of the coccyx, at the end of the median sacral vessels which supply it. It is close to the sympathetic ganglion impar, is about 2.5 mm in diameter and irregularly oval; smaller nodules of similar structure occur near the main mass of the body. The coccygeal glomus consists of irregular masses of spherical or polyhedral 'epithelioid' cells, grouped around sinusoidal capillaries. Each cell has a large, round or oval nucleus; its cytoplasm is clear and not stained by chromic salts, indicating no clear affiliation to the chromaffin system. The sinusoidal vessels are part of a complex of arteriovenous anastomoses; the epithelioid cells appear to be modified non-striated myocytes of the vessels' walls. Similar structures have long been identified in many mammals, ventral to the caudal vertebrae. Detailed analyses of innervation, ultrastructure and function are awaited with anticipation.
